This is referred to as ‘alcoholic cardiomyopathy’ and included by some workers as one of the subtypes of secondary cardiomyopathy. However, moderate consumption of alcohol provides some cardioprotection against IHD by raising HDL cholesterol. Another form of alcoholic cardiomyopathy is associated with consumption of large quantities of beer (beer drinkers’ myocardiosis). Cobalt added to the beer so as to improve the appearance of foam is thought to cause direct toxic injury to the heart in this condition.

v) *Peripartum association* has been observed in some cases. Poorly-nourished women may develop this form of cardiomyopathy within a month before or after delivery (peripartum cardiomyopathy).

MORPHOLOGIC FEATURES *Grossly*, the heart is enlarged and increased in weight (up to 1000 gm). The most characteristic feature is prominent dilatation of all the four chambers giving the heart typical globular appearance. Thickening of the ventricular walls even if present is masked by the ventricular dilatation (Fig. 14.35,B). The endocardium is thickened and mural thrombi are often found in the ventricles and atria. The cardiac valves are usually normal.

Microscopically, The endomyocardial biopsies or autopsy examination of the heart reveal non-specific and variable changes. There may be hypertrophy of some myocardial fibres and atrophy of others. Sometimes degenerative changes and small areas of interstitial fibrosis are found with focal mononuclear inflammatory cell infiltrate.

Idiopathic Hypertrophic Cardiomyopathy

This form of cardiomyopathy is known by various synonyms like asymmetrical hypertrophy, hypertrophic subaortic stenosis and Teare’s disease. The disease occurs more frequently between the age of 25 and 50 years. It is often asymptomatic but becomes symptomatic due to heavy physical activity causing dyspnoea, angina, congestive heart failure and even sudden death.

ETIOLOGY Though idiopathic, following factors have been implicated:

i) *Autosomal dominant inheritance* of the disease is available in about half the cases suggesting genetic factors in its causation.

ii) *Inherited mutations* in genes encoding for sarcomere proteins have been reported in much larger number of cases of hypertrophic cardiomyopathy than those of dilated cardiomyopathy. Particularly implicated are the mutations in heavy and light chains of cardiac β -myosin, troponin-I and troponin-T. The condition may result from *myocardial ischaemia* resulting in fibrosis of the intramyocardial arteries and compensatory hypertrophy.

iii) *Other contributory factors* are: increased circulating level of catecholamines, myocardial ischaemia as a result of thickened vasculature of the myocardium and abnormally increased fibrous tissue in the myocardium due to hypertrophy.

MORPHOLOGIC FEATURES *Grossly*, the characteristic features are cardiac enlargement, increase in weight, normal or small ventricular cavities and myocardial hypertrophy. The hypertrophy of the myocardium is typically asymmetrical and affects the interventricular septum more than the free walls of the ventricles (Fig. 14.35,C). This asymmetric septal hypertrophy may be confined to the apical region of the septum (*non-obstructive type*) or may extend up to the level of the mitral valve causing obstruction to left ventricular outflow in the form of subaortic stenosis (*obstructive type*). The designation of *rhabdomyoma of the septum* was applied to this form of cardiomyopathy in the old literature (page 859).

Microscopically, the classical feature is the myocardial cell disorganisation in the ventricular septum. The bundles of myocardial fibres are irregularly and haphazardly arranged rather than the usual parallel pattern and are separated by bands of interstitial fibrous tissue. The individual muscle cells show hypertrophy and large prominent nuclei.

Idiopathic Restrictive (Obliterative or Infiltrative) Cardiomyopathy

This form of cardiomyopathy is characterised by restriction in ventricular filling due to reduction in the volume of the ventricles (Fig. 14.35,D). The common feature in this heterogeneous group of conditions producing restrictive cardiomyopathy is abnormal diastolic function. Restrictive cardiomyopathy includes the following entities:

- i) Cardiac amyloidosis
- ii) Endocardial fibroelastosis
- iii) Endomyocardial fibrosis

- iv) Löeffler's endocarditis (Fibroplastic parietal endocarditis with peripheral blood eosinophilia)
- v) Other forms of restrictive cardiomyopathy.

I) CARDIAC AMYLOIDOSIS Amyloidosis of the heart may occur in any form of systemic amyloidosis or may occur as isolated organ amyloidosis in amyloid of ageing and result in subendocardial deposits (page 72).

II) ENDOCARDIAL FIBROELASTOSIS This is an unusual and uncommon form of heart disease occurring predominantly in infants and children under 2 years of age and less often in adults. The *infantile form* is clinically characterised by sudden breathlessness, cyanosis, cardiac failure and death whereas the symptoms in the *adult form* last for longer duration.

ETIOLOGY The etiology of the condition remains obscure. However, a number of theories have been proposed. These are as under:

- a) The infantile form is believed to be congenital in origin occurring due to the effect of intrauterine *endocardial anoxia*. The adult form may also be induced by anoxia-causing lesions such as anomalous coronary arteries, metabolic derangements influencing myocardial function etc.
- b) It may occur due to *haemodynamic pressure overload* such as in congenital septal defects and coarctation of the aorta.
- c) It may be an expression of *genetic disorder* as noticed in twins, triplets and siblings. Association of endocardial fibroelastosis with various congenital malformations in the heart or elsewhere further supports the genetic theory.
- d) Some workers consider this disease a form of *connective tissue disorder*.
- e) Certain factors causing *myocardial injury* may initiate the endocardial disease such as in thiamine deficiency (beri-beri heart disease) or from preceding idiopathic myocarditis.
- f) *Lymphatic obstruction* of the heart has been suggested by some as the causative mechanism.

MORPHOLOGIC FEATURES *Grossly*, the characteristic feature is the diffuse or patchy, rigid, pearly-white thickening of the mural endocardium (**Fig. 14.35,D**). Left ventricle is predominantly involved, followed in decreasing frequency by the left atrium, right ventricle and right atrium. Quite often, the valves, especially of the left heart, are affected. Some cases contain mural thrombi. Enlargement of the heart is present and is mainly due to left ventricular hypertrophy but the volume of the chamber is decreased.

Microscopically, typical finding is the proliferation of the collagen and elastic tissue (fibroelastosis) comprising the thickened endocardium. The fibroelastosis generally does not extend into the subjacent myocardium. The lesion is devoid of inflammatory cells.

III) ENDOMYOCARDIAL FIBROSIS This form of restrictive cardiomyopathy is a tropical condition prevalent in Africa, especially in Uganda and Nigeria, but some cases occur in South India, Sri Lanka, Malaysia and tropical South America. It is seen in children and young adults. The clinical manifestations consist of congestive heart failure of unknown cause just as in adult variety of endocardial fibroelastosis.

ETIOLOGY The etiology of the condition remains obscure but the geographic distribution suggests the role of certain factors like malnutrition, viral infections and heavy consumption of banana (rich in serotonin).

MORPHOLOGIC FEATURES *Grossly*, endomyocardial fibrosis is characterised by fibrous scarring of the ventricular endocardium that extends to involve the inner third of the myocardium. The atrioventricular valve leaflets are often affected but the semilunar valves are uninvolved. Mural thrombi may be present. The heart may be normal-sized or hypertrophied but the volume of the affected chambers is diminished due to fibrous scarring.

Microscopically, the endocardium and parts of inner third of the myocardium show destruction of normal tissue and replacement by fibrous tissue. The condition differs from endocardial fibroelastosis in having mononuclear inflammatory cell infiltrate and lacking in elastic tissue. The superficial layer may show dense hyalinised connective tissue and even calcification.

- IV) LÖEFFLER'S ENDOCARDITIS** Also known by the more descriptive term of 'fibroplastic parietal endocarditis with peripheral blood eosinophilia', the condition is considered by some as a variant of the entity described above, endomyocardial fibrosis. However, it differs from the latter in following respects:
- a) There is generally a peripheral blood eosinophilic leucocytosis.
 - b) The inflammatory infiltrate in the endocardium and in the part of affected myocardium chiefly consists of eosinophils.
 - c) The condition has a worse prognosis.

V) OTHER FORMS OF RESTRICTIVE CARDIOMYOPATHY Besides above, restrictive cardiomyopathy may result from various diverse causes as under:

- i) Haemochromatosis due to iron overload from multiple transfusions, haemoglobinopathies.
- ii) Myocardial sarcoidosis.
- iii) Carcinoid syndrome.
- iv) Scleroderma.
- v) Neoplastic infiltration in the heart.

B. SECONDARY CARDIOMYOPATHY

This is a group of myocardial diseases of known etiologies or having clinical associations. This, however, excludes well-defined entities such as ischaemic, hypertensive, valvular, pericardial, congenital and inflammatory involvements of the heart. The main entities included in this group are described elsewhere in the text and are listed below:

1. *Nutritional disorders* e.g. chronic alcoholism, thiamine deficiency causing beri-beri heart disease (page 247).
2. *Toxic chemicals* e.g. cobalt, arsenic, lithium and hydrocarbons.
3. *Drugs* e.g. cyclophosphamide, adriamycin, catecholamines.
4. *Metabolic diseases* e.g. amyloidosis, haemochromatosis, glycogen storage diseases, hypo- and hyperthyroidism, hypo- and hyperkalaemia.
5. *Neuromuscular diseases* e.g. Friedreich's ataxia, muscular dystrophies.
6. *Infiltrations* e.g. from leukaemia and carcinoma.
7. *Connective tissue diseases* e.g. rheumatoid arthritis, systemic sclerosis, dermatomyositis, lupus erythematosus.

GIST BOX 14.10 Myocardial Diseases

- ☐ Myocardial diseases are *myocarditis* (i.e. inflammatory involvement of the myocardium) and *cardiomyopathy* (i.e. a non-inflammatory myocardial involvement).
- ☐ Based on etiologic classification, myocarditis is divided into: infective (viral, suppurative, toxic, granulomatous, syphilitic, rickettsial, protozoal and helminthic), idiopathic (Fiedler's), in connective tissue disorders and caused by miscellaneous agents.
- ☐ Cardiomyopathies are *primary* (i.e. heart muscle disease with unknown underlying cause) and *secondary* having known underlying cause.
- ☐ Primary cardiomyopathies are subdivided into 3 pathophysiological types: idiopathic dilated (congestive), idiopathic hypertrophic and idiopathic restrictive or obliterative or infiltrative cardiomyopathy.

PERICARDIAL DISEASES

Diseases of the pericardium are usually secondary to, or associated with, other cardiac and systemic diseases. These are discussed under 2 headings:

- I. Pericardial fluid accumulations
- II. Pericarditis

PERICARDIAL FLUID ACCUMULATIONS

Accumulation of fluid in the pericardial sac may be watery or pure blood. Accordingly, it is of 2 types: hydropericardium (pericardial effusion) and haemopericardium.

A. HYDROPERICARDIUM (PERICARDIAL EFFUSION)

Accumulation of fluid in the pericardial cavity due to non-inflammatory causes is called hydropericardium or pericardial effusion. Normally, the pericardial cavity contains 30 to 50 ml of clear watery fluid. Considerable quantities of fluid (up to 1000 ml) can be accommodated in the pericardial cavity without seriously affecting the cardiac function if the accumulation is slow. But sudden accumulation of a smaller volume (up to 250 ml) may produce deficient diastolic filling of the cardiac chambers (cardiac tamponade). Pericardial effusion is detected by cardiac enlargement in the X-rays and by faint apex beat.

The various types of effusions and their causes are as follows:

- 1. Serous effusions** This is the most common type occurring in conditions in which there is generalised oedema e.g. in cardiac (in CHF), renal, nutritional and hepatic causes. The serous effusion is clear, watery, straw-coloured with specific gravity less than 1.015 (transudate). The serosal surface is smooth and glistening.
- 2. Serosanguineous effusion** This type is found following blunt trauma to chest and cardiopulmonary resuscitation.
- 3. Chylous effusion** Milky or chylous fluid accumulates in conditions causing lymphatic obstruction.
- 4. Cholesterol effusion** This is a rare type of fluid accumulation characterised by the presence of cholesterol crystals such as in myxoedema.

B. HAEMOPERICARDIUM Accumulation of pure blood in the pericardial sac is termed haemopericardium. The condition must be distinguished from haemorrhagic pericarditis in which there is escape of small quantities of blood into the pericardial cavity. Massive and sudden bleeding into the sac causes compression of the heart leading to cardiac tamponade. The causes of haemopericardium are as under:

- i) Rupture of the heart through a myocardial infarct.
- ii) Rupture of dissecting aneurysm.
- iii) Bleeding diathesis such as in scurvy, acute leukaemias, thrombocytopenia.
- iv) Trauma following cardiopulmonary resuscitation or by laceration of a coronary artery.

PERICARDITIS

Pericarditis is the inflammation of the pericardial layers and is generally secondary to diseases in the heart or caused by systemic diseases. Primary or idiopathic pericarditis is quite rare. Based on the morphologic appearance, pericarditis is classified into acute and chronic types, each of which may have several etiologies. Acute and chronic pericarditis has further subtypes based on the character of the exudate (**Table 14.11**).

A. ACUTE PERICARDITIS

Acute bacterial and non-bacterial pericarditis are the most frequently encountered forms of pericarditis. These may have the following subtypes:

1. SEROUS PERICARDITIS Acute pericarditis may be accompanied by accumulation of serous effusion which differs from transudate of hydropericardium in having increased protein content and higher specific gravity. Its various causes are as under:

- i) Viral infection e.g. coxsackie A or B viruses, influenza virus, mumps virus, adenovirus and infectious mononucleosis.
- ii) Rheumatic fever.
- iii) Rheumatoid arthritis.
- iv) Systemic lupus erythematosus.
- v) Involvement of the pericardium by malignant tumour in the vicinity e.g. carcinoma lung, mesothelioma and mediastinal tumours.
- vi) Tuberculous pericarditis in the early stage.

Table 14.11 Classification of pericarditis.

| | |
|----|--|
| A. | ACUTE PERICARDITIS |
| | 1. Serous pericarditis |
| | 2. Fibrinous or serofibrinous pericarditis |
| | 3. Purulent or fibrinopurulent pericarditis |
| | 4. Haemorrhagic pericarditis |
| B. | CHRONIC PERICARDITIS |
| | 1. Tuberculous pericarditis |
| | 2. Chronic adhesive pericarditis |
| | 3. Chronic constrictive pericarditis |
| | 4. Pericardial plaques (milk spots, soldiers' spots) |

The fluid accumulation is generally not much and ranges from 50 to 200 ml but may rarely be large enough to cause cardiac tamponade.

Microscopically, the epicardial and pericardial surfaces show infiltration by some neutrophils, lymphocytes and histiocytes. The fluid usually resorbs with the resolution of underlying disease.

2. FIBRINOUS AND SEROFIBRINOUS PERICARDITIS

The response of the pericardium by fibrinous exudate is the most common type of pericarditis. Quite often, there is admixture of fibrinous exudate with serous fluid. The various causes of this type of pericarditis are as follows:

- i) Uraemia
- ii) Myocardial infarction
- iii) Rheumatic fever
- iv) Trauma such as in cardiac surgery
- v) Acute bacterial infections.

The amount of fluid accumulation is variable. The cardiac surface is characteristically covered by dry or moist, shaggy, fibrinous exudate which gives 'bread and butter' appearance. Clinically, these cases manifest by friction rub. In less extensive cases of fibrinous or serofibrinous pericarditis, there is complete resorption of the exudate. In cases with advanced fibrinous exudate, pericarditis heals by organisation and develops fibrous adhesions resulting in adhesive pericarditis.

3. PURULENT OR FIBRINOPURULENT PERICARDITIS

Purulent or fibrinopurulent pericarditis is mainly caused by pyogenic bacteria (e.g. staphylococci, streptococci and pneumococci) and less frequently by fungi and parasites. The infection may spread to the pericardium by the following routes:

- i) By direct extension from neighbouring inflammation e.g. in empyema of the pleural cavity, lobar pneumonia, infective endocarditis and mediastinal infections.
- ii) By haematogenous spread.
- iii) By lymphatic permeation.
- iv) Direct implantation during cardiac surgery.

Generally, fibrinous or serofibrinous pericarditis precedes the development of purulent pericarditis. The amount of exudate is variable and is generally thick, creamy pus, coating the pericardial surfaces.

Microscopically, besides the purulent exudate on the pericardial surfaces, the serosal layers show dense infiltration by neutrophils (Fig. 14.36). Purulent exudate generally does not resolve completely but instead heals by organisation resulting in adhesive or chronic constrictive pericarditis.

4. HAEMORRHAGIC PERICARDITIS Haemorrhagic pericarditis is the one in which the exudate consists of admixture of an inflammatory effusion of one of the foregoing types along with blood. The causes are as under:

- i) Neoplastic involvement of the pericardium
- ii) Haemorrhagic diathesis with effusion
- iii) Tuberculosis
- iv) Severe acute infections

The outcome of haemorrhagic pericarditis is generally similar to that of purulent pericarditis.

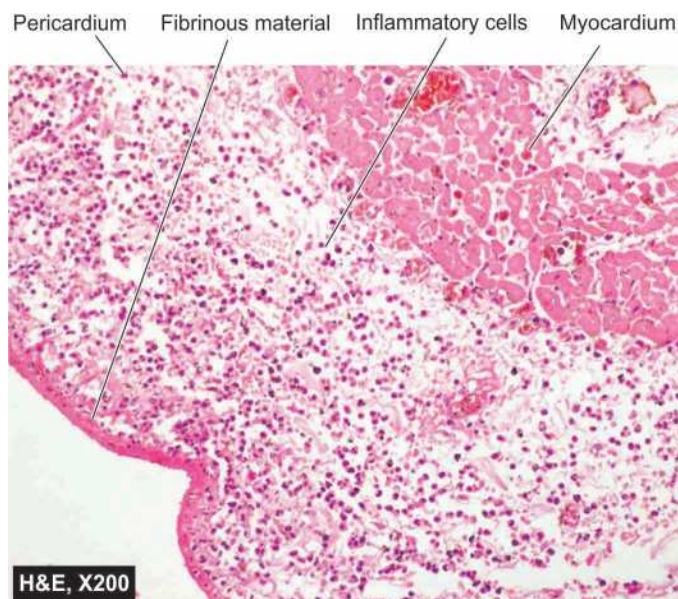

Figure 14.36 Fibrinopurulent pericarditis. The pericardium is covered with pink serofibrinous exudates. The space between the layers of the pericardium contains numerous inflammatory cells, chiefly PMNs.

B. CHRONIC PERICARDITIS

Chronic pericarditis is the term used for tuberculous pericarditis and the healed stage of one of the various forms of acute pericarditis already described. Included under this are: tuberculous pericarditis, chronic adhesive pericarditis, chronic constrictive pericarditis, and the pericardial plaques.

1. TUBERCULOUS PERICARDITIS Tuberculous pericarditis is the most frequent form of granulomatous inflammation of the pericardium. The lesions may occur by one of the following mechanisms:

- i) Direct extension from an adjacent focus of tuberculosis.
- ii) By lymphatic spread e.g. from tracheobronchial lymph nodes, chronic pulmonary tuberculosis or infected pleura.

The exudate is slightly turbid, caseous or blood-stained with sufficient fibrin. Tubercles are generally visible on the pericardial surfaces and sometimes caseous areas are also visible to the naked eye.

Microscopically, typical tuberculous granulomas with caseation necrosis are seen in the pericardial wall. The lesions generally do not resolve but heal by fibrosis and calcification resulting in chronic constrictive pericarditis.

2. CHRONIC ADHESIVE PERICARDITIS Chronic adhesive pericarditis is the stage of organisation and healing by formation of fibrous adhesions in the pericardium following preceding fibrinous, suppurative or haemorrhagic pericarditis. The process begins by formation of granulation tissue and neovascularisation. Subsequently, fibrous adhesions develop between the parietal and the visceral layers of the pericardium and obliterate the pericardial space (Fig. 14.37,A). Sometimes, fibrous adhesions develop between the parietal pericardium and the adjacent mediastinum and are termed *adhesive mediastinopericarditis*. Chronic adhesive pericarditis differs from chronic constrictive pericarditis in not embarrassing the function of the heart. However, cardiac

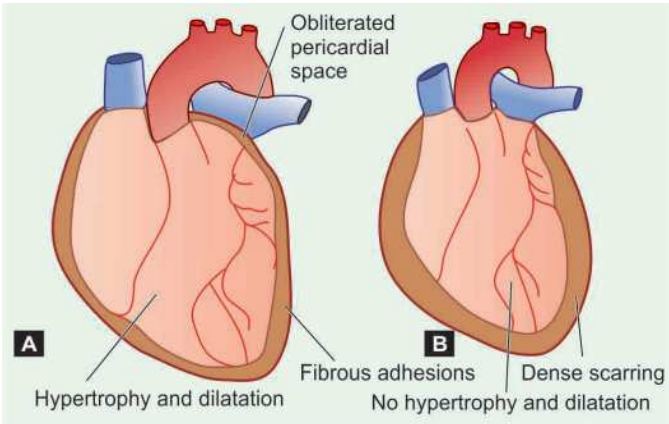

Figure 14.37 Appearance of the heart and the pericardium in chronic adhesive (A) and chronic constrictive pericarditis (B).

hypertrophy and dilatation may occur in severe cases due to increased workload.

3. CHRONIC CONSTRICTIVE PERICARDITIS This is a rare condition characterised by dense fibrous or fibro-calcific thickening of the pericardium resulting in mechanical interference with the function of the heart and reduced cardiac output. The condition usually results from long-standing preceding causes, e.g.

- i) Tuberculous pericarditis
- ii) Purulent pericarditis
- iii) Haemopericardium
- iv) Concato's disease (polyserositis)
- v) Rarely, acute non-specific and viral pericarditis.

The heart is encased in 0.5 to 1 cm thick and dense collagenous scar which may be calcified. As a result, the heart fails to dilate during diastole. The dense fibrocollagenous tissue may cause narrowing of the openings of the vena cavae, resulting in obstruction to the venous return to the right heart and consequent right heart failure. In contrast to chronic adhesive pericarditis, hypertrophy and dilatation do not occur due to dense fibrous scarring. Instead, the heart size is normal or smaller (**Fig. 14.37,B**).

4. PERICARDIAL PLAQUES (MILK SPOTS, SOLDIERS' SPOTS) These are opaque, white, shining and well-circumscribed areas of organisation with fibrosis in the pericardium measuring 1 to 3 cm in diameter. They are seen most frequently on the anterior surface of the right ventricle. The exact cause is not known but they are generally believed to arise from healing of preceding pericarditis. The plaque-like lesions of pericardial thickenings are also termed *milk spots* or *soldiers' spots* as they were often found at autopsy in the soldiers in World War I who carried their shoulder bags causing pressure against the chest wall by the straps which produced chronic irritation of the pericardium.

GIST BOX 14.11 Pericardial Diseases

- ▣ Pericardial effusion is accumulation of fluid in the pericardial sac.
- ▣ Hydropericardium is watery collection (serous, serosanguineous, chylous) while haemopericardium is collection of pure blood.

- ▣ Pericarditis is the inflammation of the pericardial layers and may be acute and chronic types.
- ▣ Depending upon character of accumulated fluid, acute pericarditis may be serous, fibrinous, purulent, and haemorrhagic.
- ▣ Chronic pericarditis is due to fibrous healing by organisation and may be chronic adhesive, chronic constrictive and plaque formation.

TUMOURS OF THE HEART

Tumours of the heart are classified into primary and secondary, the latter being more common than the former.

PRIMARY TUMOURS

Primary tumours of the heart are quite rare, found in 0.04% of autopsies. In decreasing order of frequency, the benign tumours encountered in the heart are: myxoma, lipoma, fibroelastoma, rhabdomyoma, haemangioma and lymph-angioma. The malignant tumours are still rarer, the important ones are: rhabdomyosarcoma, angiosarcoma and malignant mesothelioma. Out of all these, only myxoma of the heart requires elaboration.

MYXOMA This is the most common primary tumour of the heart comprising about 50% of all primary cardiac tumours. Majority of them occur in the age range of 30 to 60 years. Myxomas may be located in any cardiac chamber or the valves, but 90% of them are situated in the left atrium.

Grossly, they are often single but may be multiple. They range in size from less than 1 to 10 cm, polypoid, pedunculated, spherical, soft and haemorrhagic masses resembling an organising mural thrombus. Some investigators actually consider them to be organising mural thrombi rather than true neoplasms.

Microscopically, the tumour shows the following features:

- i) There is abundant myxoid or mucoid intercellular stroma positive for mucin.
- ii) The cellularity is sparse. The tumour cells are generally stellate-shaped, spindle and polyhedral, scattered in the stroma. Occasional multinucleate tumour giant cells are present.
- iii) Numerous capillary-sized blood vessels are found and the tumour cells may be aggregated around them.
- iv) A few lymphocytes, plasma cells and macrophages are seen.
- v) Foci of haemorrhage and deposits of haemosiderin granules are often present.

SECONDARY TUMOURS

Metastatic tumours of the heart are more common than the primary tumours. About 10% cases with disseminated cancer have metastases in the heart. Most of these result from haematogenous or lymphatic spread. In descending order of frequency, primary sites of origin are: carcinoma of the lung, breast, malignant lymphoma, leukaemia and malignant melanoma. Occasionally, there may be direct extension of a primary intrathoracic tumour such as carcinoma of the lung into the pericardium and into the cardiac chambers.

GIST BOX 14.12 Tumours of the Heart

- ▣ Tumours of the heart are classified into primary and secondary.
- ▣ Myxoma of the heart is the most common benign primary tumour occurring most often in the left atrium.
- ▣ Secondary tumours are more common than primary tumours and are metastases from disseminated cancers.

PATHOLOGY OF CARDIOVASCULAR INTERVENTIONS

Nowadays, with the development of surgical and non-surgical coronary revascularisation procedures in coronary artery disease in conjunction with lifestyle changes for modifying the risk factors, it has become possible to study the pathology of native as well as grafted vessel. Besides, the myocardial tissue by endomyocardial biopsy is also accessible for histopathologic study.

ENDOMYOCARDIAL BIOPSY

Endomyocardial biopsy (EMB) is done for making a final histopathologic diagnosis in certain cardiac diseases. The main *indications* for EMB are: myocarditis, cardiac transplant cases, restrictive heart disease, infiltrative heart diseases such as in amyloidosis, storage disorders etc.

EMB is done by biopsy forceps introduced via cardiac catheter into either of the ventricles but preferably right ventricle is biopsied for its relative ease and safety. The route for the catheter may be through internal jugular vein or femoral vein for accessing the right ventricle.

BALLOON ANGIOPLASTY

Balloon angioplasty or percutaneous coronary intervention (PCI) is a non-surgical procedure that employs percutaneous insertion and manipulation of a balloon catheter into the occluded coronary artery. The balloon is inflated to dilate the stenotic artery which causes endothelial damage, plaque fracture, medial dissection and haemorrhage in the affected arterial wall. PCI is accompanied with insertion of coronary stents in the blocked coronaries with a success rate of symptoms in over 95% cases. However, case selection for PCI is important and major indications are 2 or 3 vessel block but blockage of left main coronary is a contraindication for PCI. Unstable angioplasty may be associated with acute coronary syndromes. PCI is followed by administration of anti-platelet (oral aspirin) and antithrombin therapy to avoid occurrence of coronary thrombosis.

Recurrent stenosis after metal stenting in PCI may occur within 6 months in about 20% patients, more often in patients of diabetes mellitus. Restenosis is multifactorial in etiology that includes smooth muscle cell proliferation, extracellular matrix and local thrombosis. However, widespread use of drug-delivering stents has made it possible to overcome several long-term complications of coronary stenting. Currently, stents with anti-proliferative, anti-inflammatory, cytotoxic and cytostatic agents are commercially available.

CORONARY ARTERY BYPASS GRAFTING

Coronary artery bypass grafting (CABG) employs the use of autologous grafts to replace or bypass the blocked coronary arteries. Most frequently used is autologous graft of saphenous vein which is reversed (due to valves in the vein) and transplanted, or left internal mammary artery may be used being in the operative area of the heart. Long-term follow-up of CABG surgery has yielded following observations on pathology of grafted vessel:

1. In a reversed saphenous vein graft, long-term luminal patency is 50% after 10 years. Pathologic changes which develop in grafted vein include thrombosis in early stage, intimal thickening and graft atherosclerosis with or without complicated lesions.
2. Internal mammary artery graft, however, has a patency of more than 90% after 10 years.
3. Atherosclerosis with superimposed complications may develop in native coronary artery distal to the grafted vessel as well as in the grafted vessel.

CARDIAC TRANSPLANTATION

Since the first human-to-human cardiac transplant was carried out successfully by South African surgeon Dr Christian Barnard in 1967, cardiac transplantation and prolonged assisted circulation is being done in many countries in end-stage cardiac diseases, most often in idiopathic dilated cardiomyopathy, heart failure and IHD. Worldwide, about 3,000 cardiac transplants are performed annually. The survival following heart transplants is reported as: 1 year in 85%, 5 years in 65% and 10 years in 45% cases. Major complications are: transplant rejection reaction, infections (particularly with *Toxoplasma gondii* and cytomegaloviruses), graft coronary atherosclerosis and higher incidence of malignancy due to long-term administration of immunosuppressive therapy. One of the main problems in cardiac transplant centres is the availability of donors.

The concept of cardiac stem cells resident in the heart and possibly of bone marrow stem cells transdifferentiating into cardiac myocyte has generated interest in treatment of patients of IHD with transplantation of these stem cells. Preliminary studies in IHD cases have yielded encouraging results in clinical improvement and reduction in infarct size and holds promise for future.

GIST BOX 14.13 Pathology of Cardiovascular Interventions

- ▣ Endomyocardial biopsy (EMB) from right ventricle is done for making a final histopathologic diagnosis in certain cardiac diseases.
- ▣ Balloon angioplasty is percutaneous insertion and manipulation of a balloon catheter into the occluded coronary artery.
- ▣ Coronary artery bypass grafting (CABG) employs the use of autologous grafts to replace or bypass the blocked coronary arteries. Most frequently used is autologous graft of saphenous vein.
- ▣ Following CABG, atherosclerosis with superimposed complications may develop in native coronary artery distal to the grafted vessel as well as in the grafted vessel.

CLINICAL CASE 10

An 18 years old male reports to medical outpatient department with complaints of palpitation and joint pains for one year. The palpitation does not show any improvement on rest. Joint pain is fleeting type involving multiple major joints, associated with redness and swelling. Lately, for one month he has been having low-grade fever, sometimes with chills, and dyspnoea on outdoor activity. There is no history of IV drug abuse.

On examination, his blood pressure is 100/70 mmHg, pulse rate 88/min, respiration rate 16/min. Pedal oedema: +, no pallor, jaundice, cyanosis, lymphadenopathy, or clubbing of fingers. On CVS examination, pansystolic murmur is heard.

1. **Discuss the clinical correlation with pathogenesis of the features.**
2. **What is the probable diagnosis?**
3. **How will you investigate and confirm the diagnosis?**

Answers on page 909 (Appendix II)

15

The Respiratory System

NORMAL STRUCTURE OF LUNGS

ANATOMY The normal *adult right lung* weighs 375 to 550 gm (average 450 gm) and is divided by two fissures into three lobes—the upper, middle and lower lobes. The weight of the normal *adult left lung* is 325 to 450 gm (average 400 gm) and has one fissure dividing it into two lobes—the upper and lower lobes, while the middle lobe is represented by the lingula. The airways of the lungs arise from the trachea by its division into right and left main bronchi which continue to divide and subdivide further, eventually terminating into the alveolar sacs (**Fig. 15.1**).

The right main bronchus is more vertical so that aspirated foreign material tends to pass down to the right lung rather than to the left. The trachea, major bronchi and their branchings possess cartilage, smooth muscle and mucous glands in their walls, while the bronchioles have smooth muscle but lack cartilage as well as the mucous glands. Between the tracheal bifurcation and the smallest bronchi, about 8 divisions take place. The *bronchioles* so formed further undergo 3 to 4 divisions leading to the *terminal bronchioles* which are less than 2 mm in diameter. The part of the lung tissue distal to a

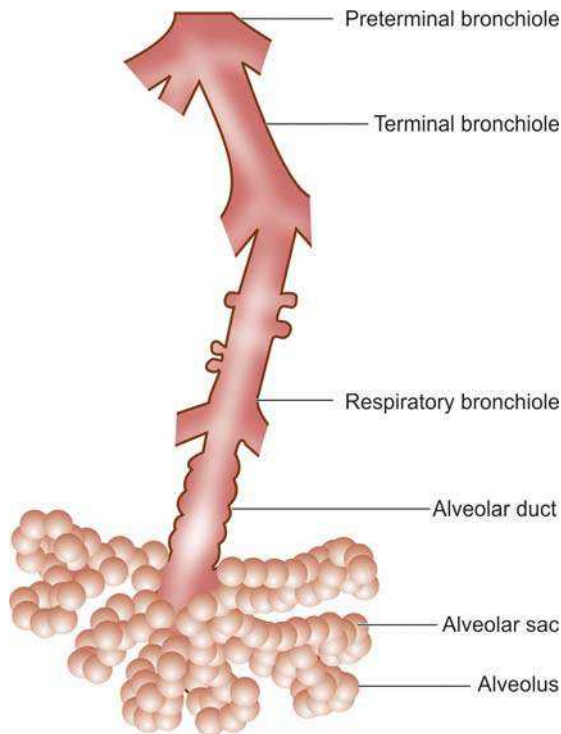

Figure 15.1 The structure of an acinus which is part of the lung distal to terminal bronchiole. It shows respiratory bronchiole, alveolar ducts and alveolar sacs.

terminal bronchiole is called an *acinus*. A cluster of about 5 acini supplied by terminal bronchioles and enclosed by visible fibrous septa is termed as the *pulmonary lobule*. An **acinus** consists of 3 parts:

1. Several (usually 3 to 5 generations) *respiratory bronchioles* originate from a terminal bronchiole.
2. Each respiratory bronchiole divides into several *alveolar ducts*.
3. Each alveolar duct opens into many *alveolar sacs (alveoli)* which are blind ends of the respiratory passages.

The lungs have double blood supply—oxygenated blood from the bronchial arteries and venous blood from the pulmonary arteries, and there is mixing of the blood to some extent. In case of blockage of one side of circulation, the supply from the other can maintain the vitality of pulmonary parenchyma. The bronchial veins drain the blood supplied by the bronchial arteries. The lungs have abundant intercommunicating lymphatics on the surface which drain into the subpleural plexus. Hilar and tracheobronchial lymph nodes receive the lymph and drain into the thoracic duct.

HISTOLOGY The bronchi and their subdivisions up to bronchioles are lined by pseudostratified columnar ciliated epithelial cells, also called *respiratory epithelium*. These cells are admixed with mucus-secreting goblet cells which decrease in number as the bronchioles are approached. The mucosa of bronchi contains numerous submucosal mucous glands and neuroendocrine cells which are bronchial counterparts of the argentaffin cells of the alimentary tract (page 544). The structure of bronchioles differs from that of bronchi and its subdivisions as well as from alveoli. They are lined by a single layer of pseudostratified columnar ciliated epithelium but no mucus cells and hence, unlike the bronchi, contain no mucus secretion on the surface. They contain some nonciliated Clara cells which secrete protein rich in lysozyme and immunoglobulins but unlike the alveoli contain no surfactant.

The **alveolar walls or alveolar septa** are the sites of exchange between the blood and air and have the following microscopic features (**Fig. 15.2**):

1. The *capillary endothelium* lines the anastomotic capillaries in the alveolar walls.
2. The capillary endothelium and the, alveolar lining epithelial cells are separated by the *capillary basement membrane and some interstitial tissue*. The interstitial tissue consists of scanty amount of collagen, fibroblasts, fine elastic fibres, smooth muscle cells, a few mast cells and mononuclear cells.
3. The *alveolar epithelium* consists of 2 types of cells: *type I* or *membranous pneumocytes* are the most numerous covering about 95% of alveolar surface, while *type II* or *granular pneumocytes* project into the alveoli and are covered by microvilli. Type II pneumocytes are essentially reserve

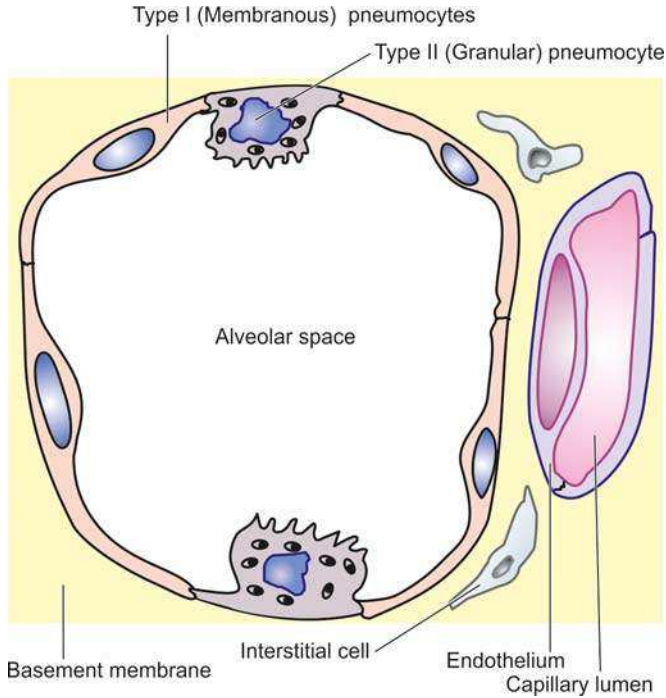

Figure 15.2 Histologic structure of alveolar wall (alveolar septa). It shows capillary endothelium, capillary basement membrane and scanty interstitial tissue and the alveolar lining cells (type I or membranous pneumocytes and type II or granular pneumocytes).

cells which undergo compensatory hyperplasia when type I pneumocytes are injured and are also the source of pulmonary surfactant rich in lecithin. The main functions of coating of surfactant are to lower the surface tension of the alveolar lining cells and in maintaining the stability of the alveoli.

4. The *alveolar macrophages* belonging to mononuclear-phagocyte system are present either free in the alveolar spaces or are attached to the alveolar cells.

5. The *pores of Kohn* are the sites of alveolar connections between the adjacent alveoli and allow the passage of bacteria and exudate.

FUNCTIONS The primary functions of lungs are oxygenation of the blood and removal of carbon dioxide. The respiratory tract is particularly exposed to infection as well as to the hazards of inhalation of pollutants from the inhaled air and cigarette smoke. There exists a natural mechanism of filtering and clearing of such pollutants through respiratory epithelium, tracheobronchial lymphatics and alveolar macrophages. Besides, the lungs are the only other organ after heart through which all the blood of the body passes during circulation. Therefore, cardiovascular diseases have serious effects on the lungs, and conversely, diseases of the lungs which interfere with pulmonary blood flow have significant effects on the heart and systemic circulation.

For the purpose of discussion, diseases of respiratory system are discussed as under:

1. Paediatric lung disease
2. Pulmonary vascular disease
3. Pulmonary infections
4. Chronic obstructive pulmonary disease
5. Chronic restrictive pulmonary disease
6. Tumours of lungs
7. Pleura and diseases

GIST BOX 15.1

Normal Structure of Lungs

- Average weight of normal adult right lung is 450 gm and has three lobes, while the average weight of the normal adult left lung is 400 gm and has two lobes.
- The right main bronchus is more vertical.
- Between the tracheal bifurcation and the smallest bronchi, about 8 divisions take place and bronchioles are formed, which further undergo 3 to 4 divisions leading to the terminal bronchioles.
- The bronchioles are lined by a single layer of pseudo-stratified columnar ciliated epithelium.
- The alveolar walls or alveolar septa are the sites of exchange between the blood and air.
- Alveolar wall has the capillary endothelium, capillary basement membrane and some interstitial tissue, and the alveolar epithelium which consists of 2 types of cells: type I or membranous pneumocytes and type II or granular pneumocytes.

PAEDIATRIC LUNG DISEASE

A number of congenital anomalies (e.g. agenesis, hypoplasia, heterotopic tissue, vascular anomalies, tracheal and bronchial anomalies, congenital pulmonary overinflation or lobar emphysema, congenital cysts and bronchopulmonary sequestration) and certain neonatal acquired lung diseases (respiratory distress syndrome or hyaline membrane disease, bronchopulmonary dysplasia, meconium aspiration syndrome, persistent foetal circulation, atelectasis, collapse and bronchiolitis) have been described. Some of the important conditions from point of view of pathology are discussed below.

CONGENITAL CYSTS

Developmental defects involving deficiency of bronchial or bronchiolar cartilage, elastic tissue and muscle result in congenital cystic disease of lungs. A single large cyst of this type occupying almost a lobe is called *pneumatocele*. Multiple small cysts are more common and give sponge-like appearance to the lung. The cysts are thin-walled and dilated and generally lined by flattened ciliated epithelium overlying a thin layer of supportive connective tissue. These cysts may contain air or may get infected and become abscesses. Cysts may rupture into bronchi producing haemoptysis, or into the pleural cavity producing pneumothorax.

BRONCHOPULMONARY SEQUESTRATION

Sequestration is the presence of lobes or segments of lung tissue which are not connected to the airway system. The blood supply of the sequestered area is not from the pulmonary arteries but from the aorta or its branches. Sequestration may be intralobar or extralobar.

◆ **Intralobar sequestration** is the sequestered bronchopulmonary mass within the pleural covering of the affected lung.

◆ **Extralobar sequestration** is the sequestered mass of lung tissue lying outside the pleural investing layer such as in the base of left lung or below the diaphragm. The extralobar sequestration is predominantly seen in infants and children and is often associated with other congenital malformations.

ACUTE RESPIRATORY DISTRESS SYNDROME (HYALINE MEMBRANE DISEASE)

Acute respiratory distress syndrome (ARDS) is a severe, at times life-threatening, form of progressive respiratory insufficiency which involves pulmonary tissues diffusely i.e. involvement of the alveolar epithelium, alveolar lumina and interstitial tissue. ARDS exists in 2 forms: neonatal and adult type. Both have the common morphological feature of formation of hyaline membrane in the alveoli and hence is also termed as hyaline membrane disease (HMD). The two forms of ARDS have different clinical settings, response to treatment and consequences, etiology, pathogenesis but have similar morphology, and hence are discussed together below.

CLINICAL FEATURES AND CONSEQUENCES These are as under:

◆ **Neonatal ARDS** occurring in newborn infants begins with dyspnoea within a few hours after birth with tachypnoea, hypoxia and cyanosis; in severe cases death may occur within a few hours.

◆ **Adult ARDS** is known by various synonyms such as shock-lung syndrome, diffuse alveolar damage (DAD), acute alveolar injury, traumatic wet lungs and post-traumatic respiratory insufficiency. The condition was first recognised in adults during World War II in survivors of non-thoracic injuries with shock. Adult ARDS also presents clinically by sudden and severe respiratory distress, tachypnoea, tachycardia, cyanosis and severe hypoxaemia.

ETIOLOGY The two forms of ARDS have distinct etiology:

◆ **Neonatal ARDS** is primarily initiated by hypoxia, either shortly before birth or immediately afterward. It occurs in following clinical settings:

1. Preterm infants
2. Infants born to diabetic mothers
3. Delivery by caesarean section
4. Infants born to mothers with previous premature infants
5. Excessive sedation of the mother causing depression in respiration of the infant
6. Birth asphyxia from various causes such as coils of umbilical cord around the neck
7. Male preponderance (1.5 to 2 times) over female babies due to early maturation of female lungs
8. Finally, many cases of neonatal ARDS remain idiopathic.

◆ **Adult ARDS** may occur from the following causes:

a) *Direct lung injury:*

1. Diffuse pulmonary infections, chiefly viral pneumonia
2. Oxygen toxicity
3. Inhalation of toxins and irritants e.g. smoke, war gases, nitrogen dioxide, metal fumes etc.
4. Aspiration of gastric contents
5. Near drowning

b) *Indirect lung injury:*

1. Shock due to sepsis, trauma, burns
2. Narcotic overdose
3. Pancreatitis
4. Drugs e.g. salicylates, colchicines
5. Fat embolism
6. Radiation
7. Multiple transfusions

PATHOGENESIS In both neonatal and adult type ARDS, there is damage to alveolocapillary wall triggered by etiologic

factors listed above, and the final pathologic consequence of formation of hyaline membrane is also similar. However, how it occurs is different in the neonates than in adults. The sequence of events in the pathogenesis of both neonatal and adult ARDS is schematically illustrated in **Fig. 15.3** and is outlined below:

◆ **Neonatal ARDS** *Entry of air into alveoli is essential for formation of hyaline membrane i.e. still born infants do not develop HMD.*

i) The basic defect in neonatal ARDS is a *deficiency of pulmonary surfactant*, normally synthesised by type II alveolar cells. The production of surfactant is normally increased shortly before birth but in prematurity and in neonatal hypoxia from any of the foregoing causes, its synthesis is decreased. The main function of alveolar surfactant being lowering of alveolar surface tension, its deficiency leads to increased alveolar surface tension which in turn causes *atelectasis*.

ii) Atelectasis of the lungs results in hypoventilation, pulmonary hypoperfusion and ischaemic damage to capillary endothelium.

iii) This results in *ischaemic necrosis* of the alveolocapillary wall, exudation of plasma proteins including fibrinogen into the alveoli and eventually formation of hyaline membrane on the alveolar surface containing largely fibrin.

◆ **Adult ARDS** The mechanism of acute injury by etiologic agents listed earlier depends upon the *imbalance between pro-inflammatory and anti-inflammatory cytokines*:

i) Activated pulmonary macrophages release *proinflammatory cytokines* such as IL8, IL1, and tumour necrosis factor (TNF), while macrophage inhibitory factor (MIF) helps to sustain inflammation in the alveoli. Number of neutrophils in the alveoli is increased in acute injury. Neutrophils on activation release products which cause active tissue injury e.g. proteases, platelet activating factor, oxidants and leukotrienes.

ii) Besides the role of cytokines in acute injury, a few *fibrogenic cytokines* such as transforming growth factor- α (TGF- α) and platelet-derived growth factor (PDGF) play a role in repair process by stimulation of proliferation of fibroblasts and collagen.

In either case, injury to the capillary endothelium leads to increased vascular permeability while injured pneumocytes, especially type I, undergo necrosis. The net effect of injury to both capillary endothelium and alveolar epithelium is interstitial and intra-alveolar oedema, congestion, fibrin deposition and formation of hyaline membranes. As a result of coating of the alveoli with hyaline membranes, there is loss of surfactant causing collapse resulting in 'stiff lung'. There is an attempt at regeneration of alveolar cells by proliferation of type II alveolar cells so as to increase the secretion of surfactant.

MORPHOLOGIC FEATURES *Grossly*, the lungs are normal in size. They are characteristically stiff, congested, heavy and airless so that they sink in water.

Microscopically, the important features are as follows (**Fig. 15.4**):

1. There is presence of collapsed alveoli (atelectasis) alternating with dilated alveoli.
2. Necrosis of alveolar epithelial cells and formation of characteristic eosinophilic hyaline membranes lining the respiratory bronchioles, alveolar ducts and the proximal alveoli. The membrane is largely composed of fibrin admixed with cell debris derived from necrotic alveolar cells.
3. Interstitial and intra-alveolar oedema, congestion and intra-alveolar haemorrhages.

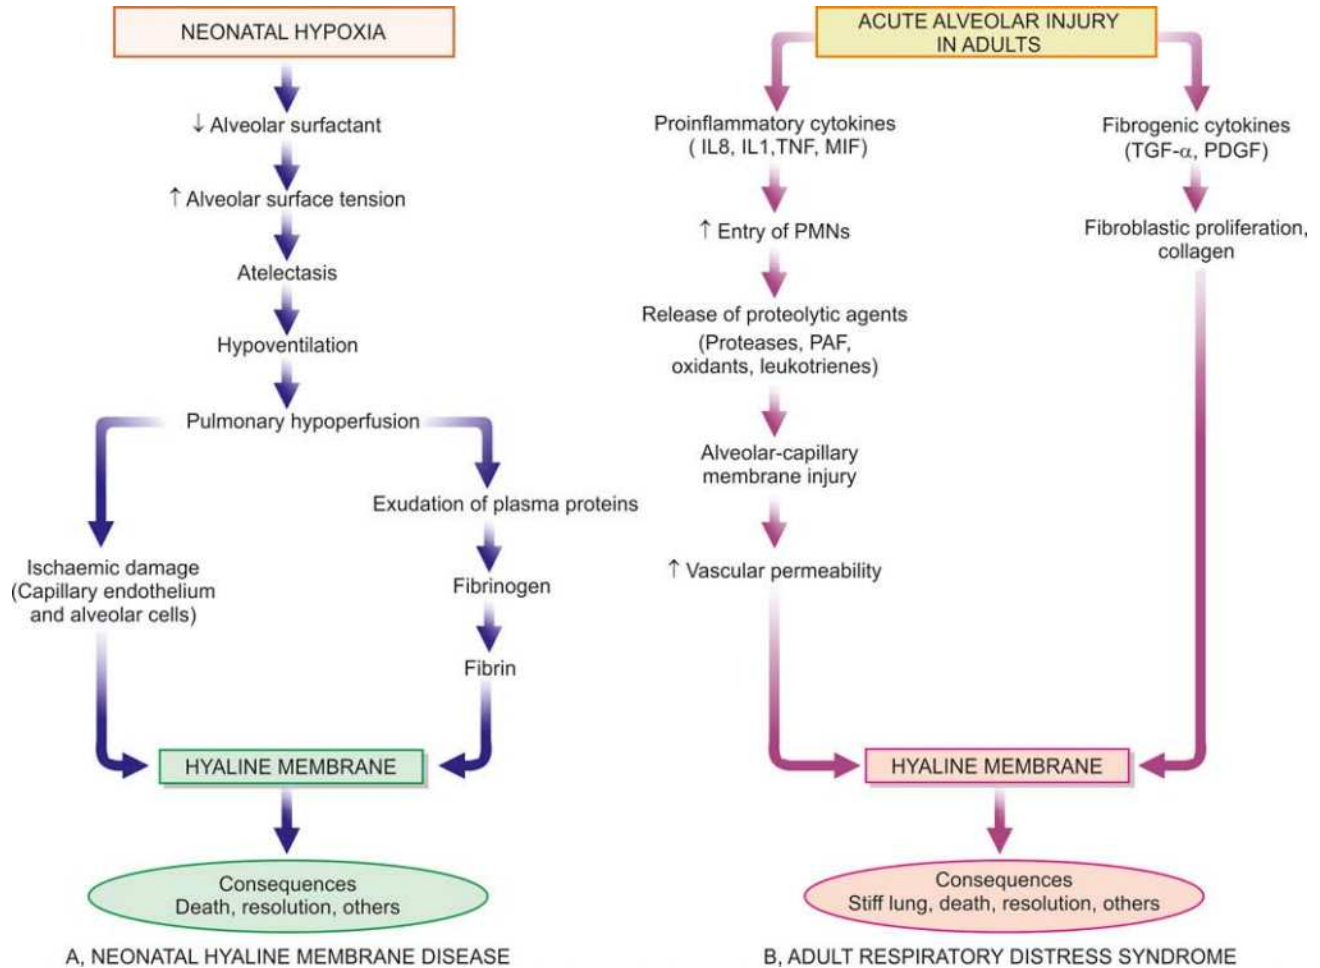

Figure 15.3 Schematic representation of sequence of events leading to the formation of hyaline membrane in neonatal and adult acute respiratory distress syndrome (ARDS).

4. Changes of bronchopneumonia may supervene.
5. With time, compensatory proliferation of pneumocytes into alveolar lumen may be seen as tufts of alveolar epithelium.
6. In organising stage, there is interstitial fibrosis obliterating alveolar spaces.

CONSEQUENCES ARDS in both neonates and adults can have following consequences:

1. Death The mortality rate in neonatal ARDS is high (20 to 30%) and is still higher in babies under 1 kg of body weight. The stiff lung in adult ARDS fails to respond to oxygen therapy and is acutely serious and severe respiratory problem which may be fatal.

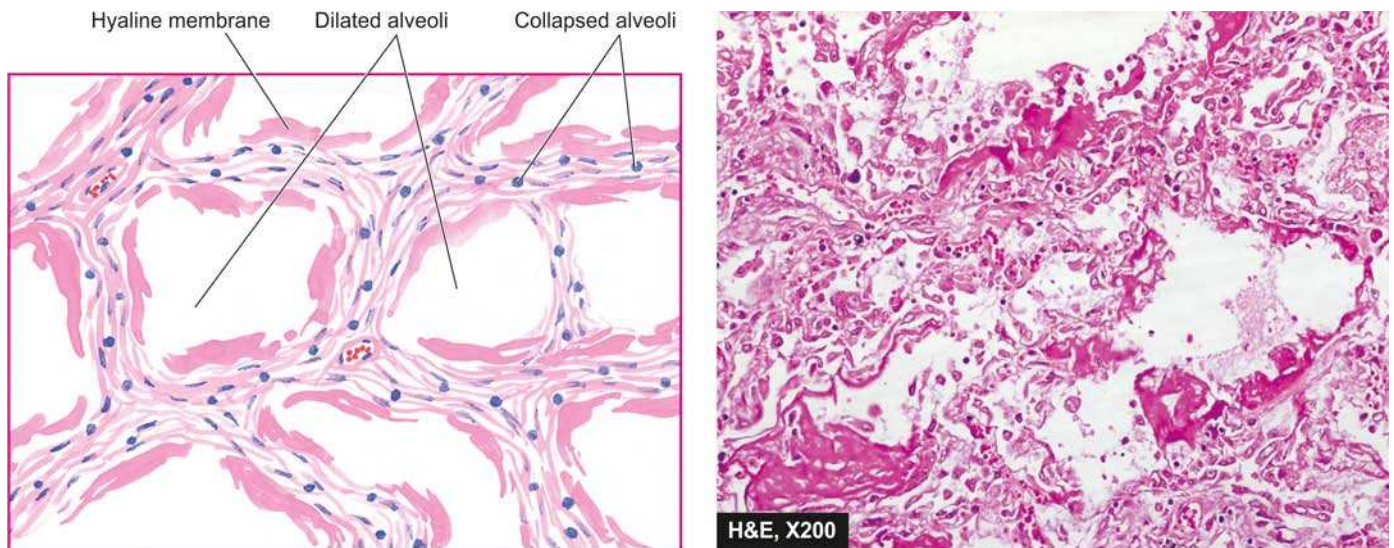

Figure 15.4 Histological appearance of hyaline membrane disease. There are alternate areas of collapsed and dilated alveolar spaces, many of which are lined by eosinophilic hyaline membranes.

2. Resolution Milder cases of neonatal ARDS recover with adequate oxygen therapy by ventilator-assist methods in a few days, while in adult ARDS control of the trigger which initiated it may result in resolution. The hyaline membrane is liquefied by the neutrophils and macrophages and thus absorbed. The cell debris in alveolar lumina are cleared by the macrophages and restore the normal aeration of the alveoli.

3. Other sequelae Besides the two extremes—death and recovery, other long-term sequelae of ARDS are as under:

- i) Some cases of neonatal ARDS who recover may develop *bronchopulmonary dysplasia* later on.
- ii) In both neonatal and adult ARDS, there may be development of *desquamative interstitial pneumonia (DIP)* due to pneumocytes proliferation supervened with inflammation.
- iii) Patients of adult ARDS who survive acute episodes may develop widespread interstitial fibrosis later and progress to *diffuse fibrosing alveolitis (Hamman-Rich syndrome)*.

BRONCHOPULMONARY DYSPLASIA

Bronchopulmonary dysplasia occurs as a complication in infants treated for neonatal ARDS with oxygen and assisted ventilation. The toxicity of oxygen and barotrauma from high pressure of oxygen give rise to subacute or chronic fibrosing condition of the lungs termed bronchopulmonary dysplasia. The condition is clinically characterised by persistence of respiratory distress for upto 3 to 6 months.

Microscopically, there is organisation of hyaline membranes resulting in fibrous thickening of the alveolar walls, bronchiolitis, peribronchial fibrosis, and development of emphysema due to alveolar dilatation. Many bronchioles show squamous metaplasia.

ATELECTASIS AND COLLAPSE

Atelectasis in the newborn or *primary atelectasis* is defined as incomplete expansion of a lung or part of a lung, while pulmonary collapse or *secondary atelectasis* is the term used for reduction in lung size of a previously expanded and well-aerated lung. Obviously, the former occurs in newborn whereas the latter may occur at any age.

ATELECTASIS Stillborn infants have total atelectasis, while the newborn infants with weak respiratory action develop incomplete expansion of the lungs and clinical atelectasis. The common causes are prematurity, cerebral birth injury, CNS malformations and intrauterine hypoxia.

Grossly, the lungs are small, dark blue, fleshy and non-crepitant

Microscopically, the alveolar spaces in the affected area are small with thick interalveolar septa. The alveolar spaces contain proteinaceous fluid with a few epithelial squames and meconium. Scattered aerated areas of the lung are hyperinflated causing interstitial emphysema and pneumothorax.

COLLAPSE Pulmonary collapse or secondary atelectasis in children and adults may occur from various causes such as compression, obstruction, contraction and lack of pulmonary surfactant. Accordingly, collapse may be of the following types:

1. Compressive collapse Pressure from outside causes compressive collapse e.g. by massive pleural effusion, haemothorax, pneumothorax, intrathoracic tumour, high diaphragm and spinal deformities. Compressive collapse involves subpleural regions and affects lower lobes more than the central areas.

2. Obstructive/absorptive collapse Obstruction of a bronchus or many bronchioles causes absorption of oxygen in the affected alveoli followed by collapse e.g. by viscid mucus secretions in bronchial asthma, chronic bronchitis, bronchiectasis, bronchial tumours and aspiration of foreign bodies. Obstructive collapse is generally less severe than the compressive collapse and is patchy.

3. Contraction collapse This type occurs due to localised fibrosis in lung causing contraction followed by collapse.

SUDDEN INFANT DEATH SYNDROME

Sudden infant death syndrome (SIDS) or crib death is an uncommon condition seen more often in the developed countries. It affects infants in the age group of 2 to 6 months. The condition is seen in premature babies born to mothers who have been smokers and indulged in drug abuse.

Microscopically, at autopsy the upper respiratory airways and lungs invariably show petechial haemorrhages.

GIST BOX 15.2

Paediatric Lung Disease

- ▣ Developmental deficiency of bronchial or bronchiolar cartilage, elastic tissue and muscle results in congenital cystic disease of lungs.
- ▣ Sequestration is the presence of lobes or segments of lung tissue which are not connected to the airway system.
- ▣ Acute respiratory distress syndrome (ARDS) is a severe form of progressive respiratory insufficiency which involves pulmonary tissues diffusely and exists as neonatal and adult type.
- ▣ Neonatal ARDS is primarily initiated by hypoxia, while adult ARDS is caused by either direct or indirect lung injury.
- ▣ ARDS is characterised by formation of hyaline membrane in the alveolar wall.
- ▣ Atelectasis or primary atelectasis is defined as incomplete expansion of a lung or part of a lung, while pulmonary collapse or secondary atelectasis is the reduction in lung size of a previously expanded and well-aerated lung.

PULMONARY VASCULAR DISEASE

As stated before, diseases of the heart affect the lungs and diseases of the lungs affect the heart. This is because of the peculiar characteristics of pulmonary vasculature. The pressure in the pulmonary arteries is much lower than in the systemic arteries. The pulmonary arterial system is thinner than the systemic arterial system. They are thin elastic vessels which can be easily distinguished from thick-walled bronchial arteries supplying the large airways and the pleura.

General diseases of vascular origin occurring in the lungs such as pulmonary oedema, pulmonary congestion,

pulmonary embolism and pulmonary infarction, have all been already discussed in Chapter 4. The other important disease of pulmonary alveocapillary wall, ARDS, has already been discussed above. Here, an account of pulmonary hypertension is given.

PULMONARY HYPERTENSION

Normally, the pulmonary arterial circulation is high-flow and low-pressure system with much lower blood pressure than the systemic blood pressure; it does not exceed 30/15 mmHg even during exercise (normally, blood pressure in the pulmonary veins is between 3 and 8 mmHg). Pulmonary hypertension is defined as a systolic blood pressure in the pulmonary arterial circulation above 30 mmHg. Pulmonary hypertension is broadly classified into 2 groups: primary (idiopathic) and secondary; the latter being more common.

Primary (Idiopathic) Pulmonary Hypertension

Primary or idiopathic pulmonary hypertension is an uncommon condition of unknown cause. The diagnosis can be established only after a thorough search for the usual causes of secondary pulmonary hypertension (discussed below). The patients are usually young females between the age of 20 and 40 years, or children around 5 years of age.

ETIOPATHOGENESIS Though the etiology of primary pulmonary hypertension is unknown, a number of etiologic factors have been suggested to explain its pathogenesis:

1. A *neurohumoral vasoconstrictor mechanism* may be involved leading to chronic vasoconstriction that induces pulmonary hypertension.
2. The occurrence of disease in young females has prompted a suggestion that *unrecognised thromboemboli* or *amniotic fluid emboli* during pregnancy may play a role.
3. There is a suggestion that primary pulmonary hypertension may be a form of *collagen vascular disease*. This is supported by occurrence of Raynaud's phenomenon preceding the onset of this disease by a number of years in many patients, and disease association with SLE, scleroderma and rheumatoid arthritis.
4. *Pulmonary veno-occlusive disease* characterised by fibrous obliteration of small pulmonary veins is believed to be responsible for some cases of primary pulmonary hypertension, especially in children. This is generally considered a consequence of thrombosis or vasculitis.
5. *Ingestion of substances* like 'bush tea', oral contraceptives and appetite depressant agents like aminorex are believed to be related to primary pulmonary hypertension.
6. *Familial occurrence* has been reported in a number of cases.

Secondary Pulmonary Hypertension

When pulmonary hypertension occurs secondary to a recognised lesion in the heart or lungs, it is termed as secondary pulmonary hypertension. It is the more common type and may be encountered at any age, but is seen more frequently over the age of 50 years.

ETIOPATHOGENESIS Based on the underlying mechanism, causes of secondary pulmonary hypertension are divided into the following 3 groups:

A. Passive pulmonary hypertension This is the commonest and is produced by diseases raising pressure in the pulmonary veins e.g.

1. Mitral stenosis.
2. Chronic left ventricular failure (e.g. in severe systemic hypertension, aortic stenosis, myocardial fibrosis).

B. Hyperkinetic (Reactive) pulmonary hypertension In this group are included causes in which the blood enters the pulmonary arteries in greater volume or at a higher pressure. For example:

1. Patent ductus arteriosus.
2. Atrial or ventricular septal defects.

C. Vaso-occlusive pulmonary hypertension All such conditions which produce progressive diminution of the vascular bed in the lungs are included in this group. Vaso-occlusive causes may be further sub-divided into 3 types:

1. *Obstructive type*, in which there is block in the pulmonary circulation e.g.
 - i) Multiple emboli or thrombi
 - ii) Sickle cell disease
 - iii) Schistosomiasis
2. *Obliterative type*, in which there is reduction of pulmonary vascular bed by chronic parenchymal lung diseases e.g.
 - i) Chronic emphysema
 - ii) Chronic bronchitis
 - iii) Bronchiectasis
 - iv) Pulmonary tuberculosis
 - v) Pneumoconiosis
3. *Vasoconstrictive type*, in which there is widespread and sustained hypoxic vasoconstriction and alveolar hypoventilation leading to pulmonary hypertension e.g.
 - i) In those residing at high altitude
 - ii) Pathologic obesity (Pickwickian disease)
 - iii) Upper airway disease such as tonsillar hypertrophy
 - iv) Neuromuscular diseases such as poliomyelitis
 - v) Severe kyphoscoliosis.

MORPHOLOGIC FEATURES Irrespective of the type of pulmonary hypertension (primary or secondary), chronic cases invariably lead to cor pulmonale (page 418). The pathologic changes are confined to the right side of the heart and pulmonary arterial tree in the lungs. There is hypertrophy of the right ventricle and dilatation of the right atrium. The vascular changes are similar in primary and secondary types and involve the entire arterial tree from the main pulmonary arteries down to the arterioles. These changes are as under (**Fig. 15.5**):

1. Arterioles and small pulmonary arteries These branches show most conspicuous changes. These are as follows:

- i) Medial hypertrophy.
- ii) Thickening and reduplication of elastic laminae.
- iii) Plexiform pulmonary arteriopathy in which there is intraluminal tuft of capillary formation in dilated thin-walled arterial branches. These lesions are not so marked in secondary pulmonary hypertension.

2. Medium-sized pulmonary arteries

- i) Medial hypertrophy, which is not so marked in secondary pulmonary hypertension.
- ii) Concentric intimal thickening.
- iii) Adventitial fibrosis.
- iv) Thickening and reduplication of elastic laminae.

3. Large pulmonary arteries

- i) Atheromatous deposits.

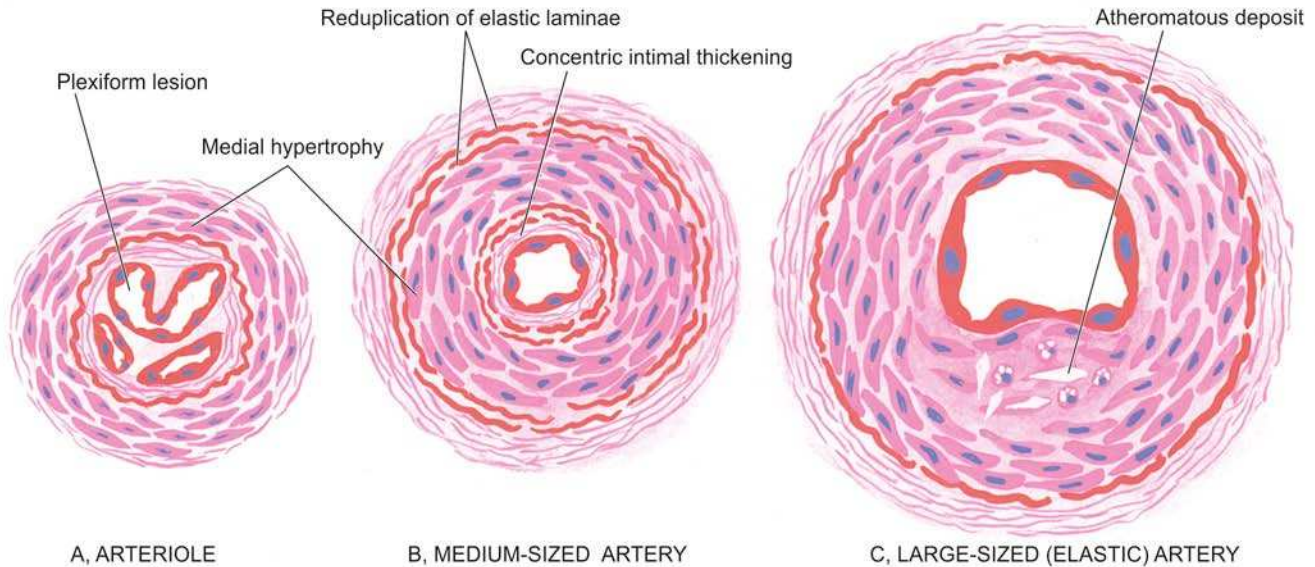

Figure 15.5 Histologic changes in the pulmonary arterial branches of different sizes in pulmonary hypertension.

GIST BOX 15.3

Pulmonary Hypertension

- ▣ Pulmonary hypertension is elevated systolic blood pressure in the pulmonary arterial circulation above 30 mmHg.
- ▣ It may be primary (idiopathic) or secondary; the latter is common.
- ▣ Primary type is idiopathic but there is role of neurohumoral vasoconstrictor mechanism.
- ▣ Secondary type may be due to diseases that passively raise pressure in the pulmonary veins, hyperkinetic circulation, or vasoocclusive causes.
- ▣ Characteristically, the changes in the pulmonary arterial branches are intimal thickening and medial hypertrophy.

PULMONARY INFECTIONS

Acute and chronic pulmonary infections are common at all ages and are a frequent cause of death. They are generally caused by a wide variety of microorganisms such as bacteria, viruses, fungi and mycoplasma. Important and common examples of acute pulmonary infectious diseases discussed here are *pneumonias*, *fungal infections* and *lung abscess*, while *pulmonary tuberculosis*, generally regarded as an example of chronic lung infections, is discussed in Chapter 5.

PNEUMONIAS

Pneumonia is defined as acute inflammation of the lung parenchyma distal to the terminal bronchioles (consisting of the respiratory bronchiole, alveolar ducts, alveolar sacs and alveoli). The terms 'pneumonia' and 'pneumonitis' are often used synonymously for inflammation of the lungs, while 'consolidation' (meaning solidification) is the term used for gross and radiologic appearance of the lungs in pneumonia.

PATHOGENESIS The microorganisms gain entry into the lungs by one of the following four routes:

1. *Inhalation* of the microbes present in the air.

2. *Aspiration* of organisms from the nasopharynx or oropharynx.
3. *Haematogenous spread* from a distant focus of infection.
4. *Direct spread* from an adjoining site of infection.

The normal lung is free of bacteria because of the presence of a number of lung defense mechanisms at different levels such as nasopharyngeal filtering action, mucociliary action of the lower respiratory airways, the presence of phagocytosing alveolar macrophages and immunoglobulins. Failure of these defense mechanisms and presence of certain predisposing factors result in pneumonias. These conditions are as under:

1. Altered consciousness The oropharyngeal contents may be aspirated in states causing unconsciousness e.g. in coma, cranial trauma, seizures, cerebrovascular accidents, drug overdose, alcoholism etc.

2. Depressed cough and glottic reflexes Depression of effective cough may allow aspiration of gastric contents e.g. in old age, pain from trauma or thoracoabdominal surgery, neuromuscular disease, weakness due to malnutrition, kyphoscoliosis, severe obstructive pulmonary diseases, endotracheal intubation and tracheostomy.

3. Impaired mucociliary transport The normal protection offered by mucus-covered ciliated epithelium in the airways from the larynx to the terminal bronchioles is impaired or destroyed in many conditions favouring passage of bacteria into the lung parenchyma. These conditions are cigarette smoking, viral respiratory infections, immotile cilia syndrome, inhalation of hot or corrosive gases and old age.

4. Impaired alveolar macrophage function Pneumonias may occur when alveolar macrophage function is impaired e.g. by cigarette smoke, hypoxia, starvation, anaemia, pulmonary oedema and viral respiratory infections.

5. Endobronchial obstruction The effective clearance mechanism is interfered in endobronchial obstruction from tumour, foreign body, cystic fibrosis and chronic bronchitis.

6. Immunocompromised states Disorders of lymphocytes including congenital and acquired immunodeficiencies (e.g.

AIDS, debility, senility, immunosuppressive therapy) and granulocyte abnormalities may predispose to pneumonia.

CLASSIFICATION There are several classification schemes for pneumonias:

I. On the basis of the *anatomic region* of the lung parenchyma involved, pneumonias are traditionally classified into 3 main types:

1. Lobar pneumonia
2. Bronchopneumonia (or Lobular pneumonia)
3. Interstitial pneumonia.

II. Based on the *clinical settings* in which infection occurred, pneumonias are classified as under:

1. Community-acquire pneumonia
2. Health care-associated pneumonia (including hospital-acquired pneumonia)
3. Ventilator-associated pneumonia

III. Based on *etiology and pathogenesis*, pneumonias are classified as under (**Table 15.1**):

- A. Bacterial pneumonia
- B. Viral pneumonia
- C. Pneumonias from other etiologies.

In the present discussion, a combined approach of etiologic and morphologic classification will be followed.

A. BACTERIAL PNEUMONIA

Bacterial infection of the lung parenchyma is the most common cause of pneumonia or consolidation of one or both the lungs. Two types of acute bacterial pneumonias are distinguished—lobar pneumonia and broncho-(lobular-) pneumonia, each with distinct etiologic agent and morphologic changes. Another type distinguished by some workers separately is *confluent pneumonia* which combines the features of both lobar and bronchopneumonia and involves larger (confluent) areas in both the lungs irregularly, while others consider this as a variant of bronchopneumonia.

Lobar Pneumonia

Lobar pneumonia is an acute bacterial infection of a part of a lobe, the entire lobe, or even two lobes of one or both the lungs.

ETIOLOGY Based on the etiologic microbial agent causing lobar pneumonia, following types of lobar pneumonia are described:

1. Pneumococcal pneumonia More than 90% of all lobar pneumonias are caused by *Streptococcus pneumoniae*, a lancet-shaped diplococcus. Out of various types, type 3

S. pneumoniae causes particularly virulent form of lobar pneumonia. Pneumococcal pneumonia in majority of cases is community-acquired infection.

2. Staphylococcal pneumonia *Staphylococcus aureus* causes pneumonia by haematogenous spread of infection from another focus or after viral infections.

3. Streptococcal pneumonia β -haemolytic streptococci may rarely cause pneumonia such as in children after measles or influenza, in severely debilitated elderly patients and in diabetics.

4. Pneumonia by gram-negative aerobic bacteria Less common causes of lobar pneumonia are gram-negative bacteria like *Haemophilus influenzae*, *Klebsiella pneumoniae* (*Friedlander's bacillus*), *Pseudomonas*, *Proteus* and *Escherichia coli*. *H. influenzae* commonly causes pneumonia in children below 3 years of age after a preceding viral infection.

MORPHOLOGIC FEATURES Laennec's original description divides lobar pneumonia into 4 sequential pathologic phases: *stage of congestion* (initial phase), *red hepatisation* (early consolidation), *grey hepatisation* (late consolidation) and *resolution*. However, these classic stages seen in untreated cases are found much less often nowadays due to early institution of antibiotic therapy and improved medical care.

In lobar pneumonia, as the name suggests, part of a lobe, a whole lobe, or two lobes are involved, sometimes bilaterally. The lower lobes are affected most commonly. The sequence of pathologic changes described below represents the inflammatory response of lungs in bacterial infection.

1 STAGE OF CONGESTION: INITIAL PHASE (Fig. 15.6,A)

The initial phase represents the early acute inflammatory response to bacterial infection that lasts for 1 to 2 days.

Grossly, the affected lobe is enlarged, heavy, dark red and congested. Cut surface exudes blood-stained frothy fluid.

Histologically, typical features of acute inflammatory response to the organisms are seen. These are as under (**Fig. 15.7**):

- i) Dilatation and congestion of the capillaries in the alveolar walls.
- ii) Pale eosinophilic oedema fluid in the air spaces.
- iii) A few red cells and neutrophils in the intra-alveolar fluid.
- iv) Numerous bacteria demonstrated in the alveolar fluid by Gram's staining.

2. RED HEPATISATION: EARLY CONSOLIDATION (Fig. 15.6,B)

This phase lasts for 2 to 4 days. The term hepatisation in pneumonia refers to liver-like consistency of the affected lobe on cut section.

Grossly, the affected lobe is red, firm and consolidated. The cut surface of the involved lobe is airless, red-pink, dry, granular and has liver-like consistency. The stage of red hepatisation is accompanied by serofibrinous pleurisy.

Histologically, the following features are observed (**Fig. 15.8**):

- i) The oedema fluid of the preceding stage is replaced by strands of fibrin.
- ii) There is marked cellular exudate of neutrophils and extravasation of red cells.
- iii) Many neutrophils show ingested bacteria.

Table 15.1 Etiologic classification of pneumonias.

| | |
|------|--|
| A. | BACTERIAL PNEUMONIA |
| I. | Lobar pneumonia |
| II. | Bronchopneumonia (Lobular pneumonia) |
| III. | <i>Legionella</i> pneumonia (Legionnaire's disease) |
| B. | VIRAL AND MYCOPLASMAL PNEUMONIA (PRIMARY ATYPICAL PNEUMONIA) |
| C. | FUNGAL PNEUMONIAS |
| I. | <i>Pneumocystis</i> pneumonia |
| II. | Others |
| D. | NON INFECTIVE PNEUMONIAS |
| I. | Aspiration (inhalation) pneumonia |
| II. | Hypostatic pneumonia |
| III. | Lipid pneumonia |

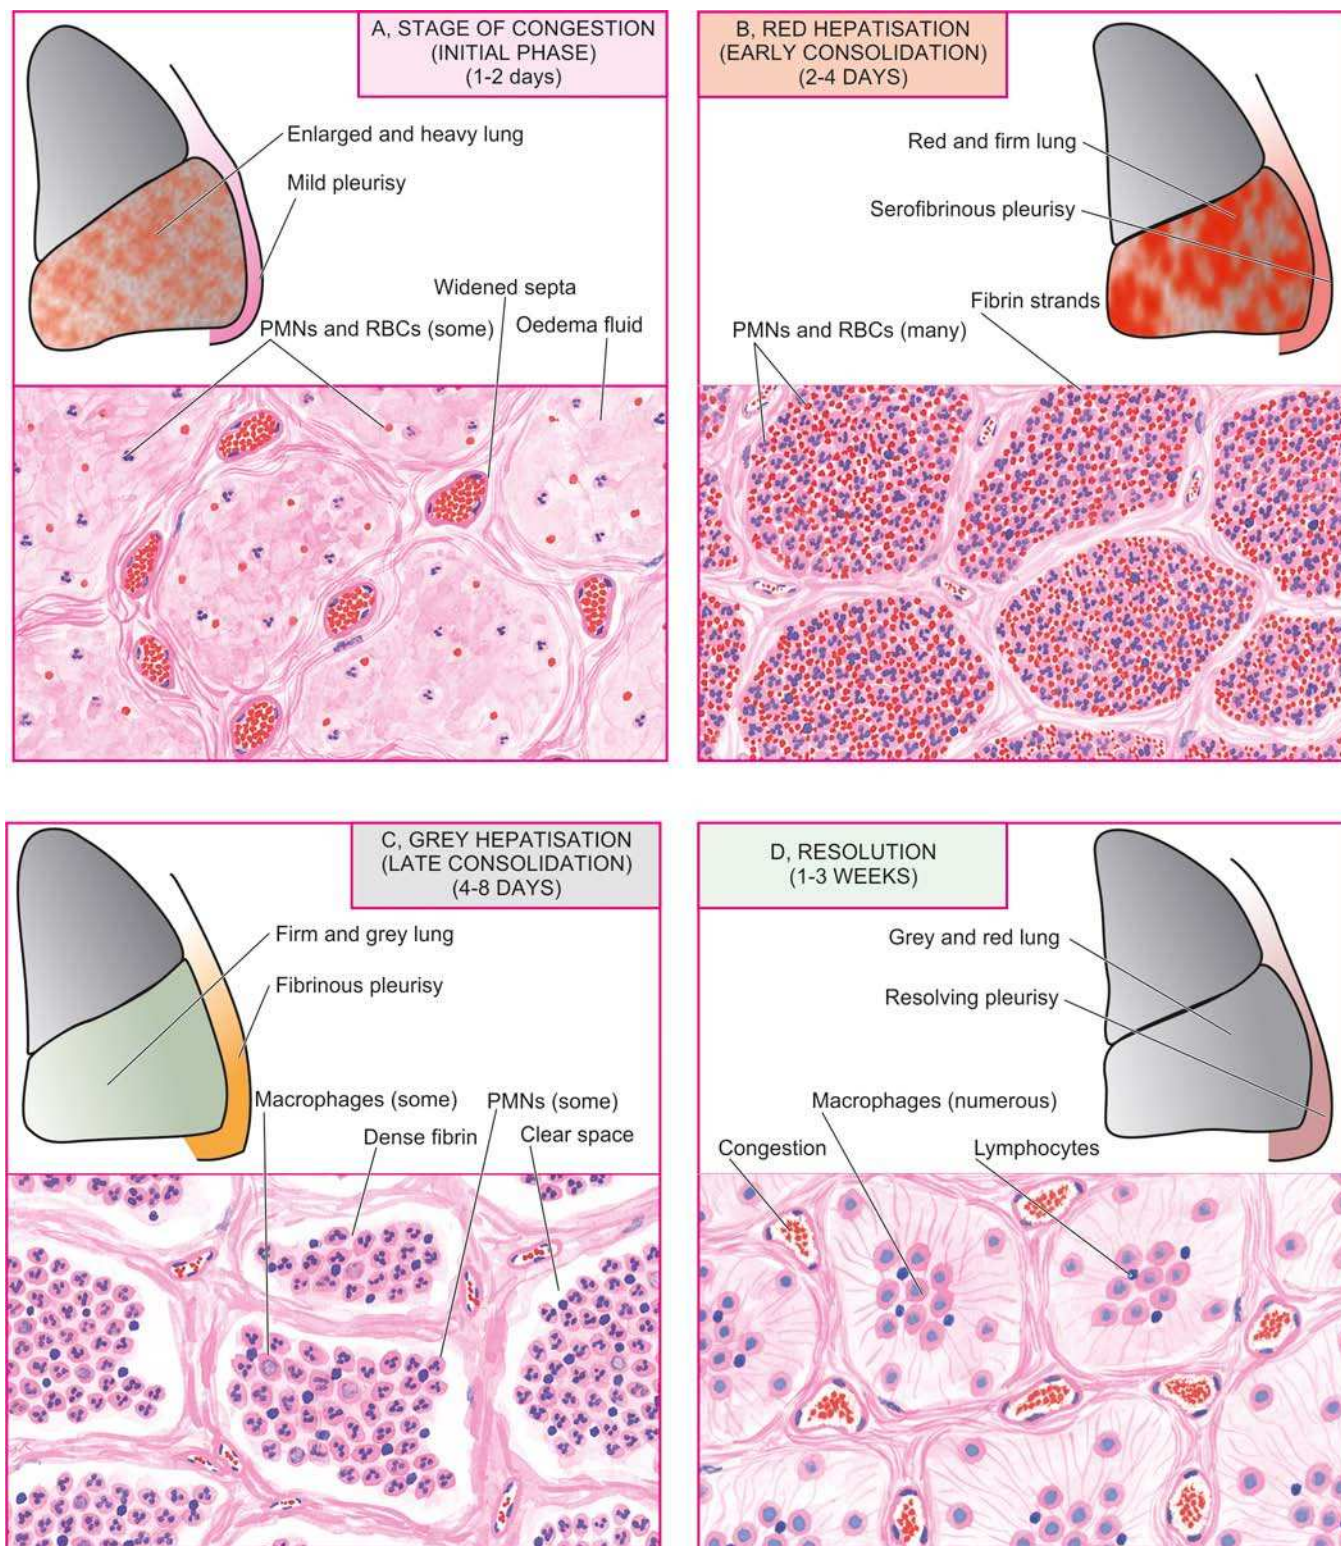

Figure 15.6 The four stages of lobar pneumonia, showing correlation of gross appearance of the lung with microscopic features in each stage. For details consult the text.

iv) The alveolar septa are less prominent than in the first stage due to cellular exudation.

3. GREY HEPATISATION: LATE CONSOLIDATION (Fig. 15.6,C) This phase lasts for 4 to 8 days.

Grossly, the affected lobe is firm and heavy. The cut surface is dry, granular and grey in appearance with liver-like consistency (Fig. 15.9, A). The change in colour from red to

grey begins at the hilum and spreads towards the periphery. Fibrinous pleurisy is prominent.

Histologically, the following changes are present (Fig. 15.9,B):

- i) The fibrin strands are dense and more numerous.
- ii) The cellular exudate of neutrophils is reduced due to disintegration of many inflammatory cells as evidenced

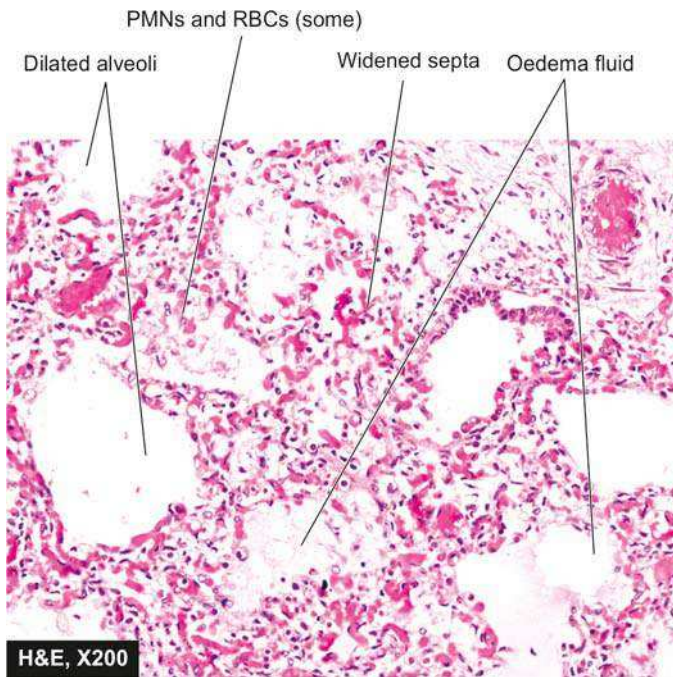

Figure 15.7 Lobar pneumonia, acute congestion stage. There is congestion of septal walls while the air spaces contain pale oedema fluid and a few red cells.

by their pyknotic nuclei. The red cells are also fewer. The macrophages begin to appear in the exudate.

iii) The cellular exudate is often separated from the septal walls by a thin clear space.

iv) The organisms are less numerous and appear as degenerated forms.

4. RESOLUTION (Fig. 15.6,D) This stage begins by 8th to 9th day if no chemotherapy is administered and is completed in 1 to 3 weeks. However, antibiotic therapy induces resolution on about 3rd day. Resolution proceeds in a progressive manner.

Grossly, the previously solid fibrinous constituent is liquefied by enzymatic action, eventually restoring the

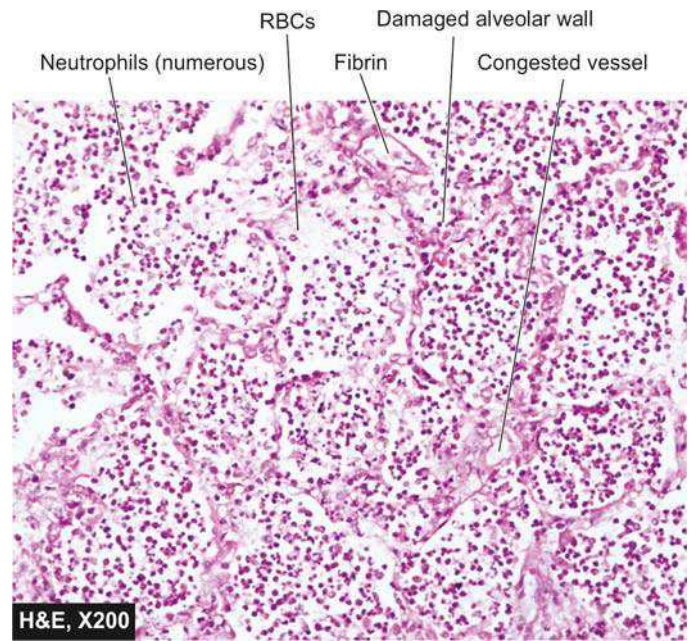

Figure 15.8 Lobar pneumonia, red hepatisation stage. The alveoli are filled with cellular exudates composed of neutrophils admixed with some red cells.

normal aeration in the affected lobe. The process of softening begins centrally and spreads to the periphery. The cut surface is grey-red or dirty brown and frothy, yellow, creamy fluid can be expressed on pressing. The pleural reaction may also show resolution but may undergo organisation leading to fibrous obliteration of pleural cavity.

Histologically, the following features are noted:

i) Macrophages are the predominant cells in the alveolar spaces, while neutrophils diminish in number. Many of the macrophages contain engulfed neutrophils and debris.

ii) Granular and fragmented strands of fibrin in the alveolar spaces are seen due to progressive enzymatic digestion.

iii) Alveolar capillaries are engorged.

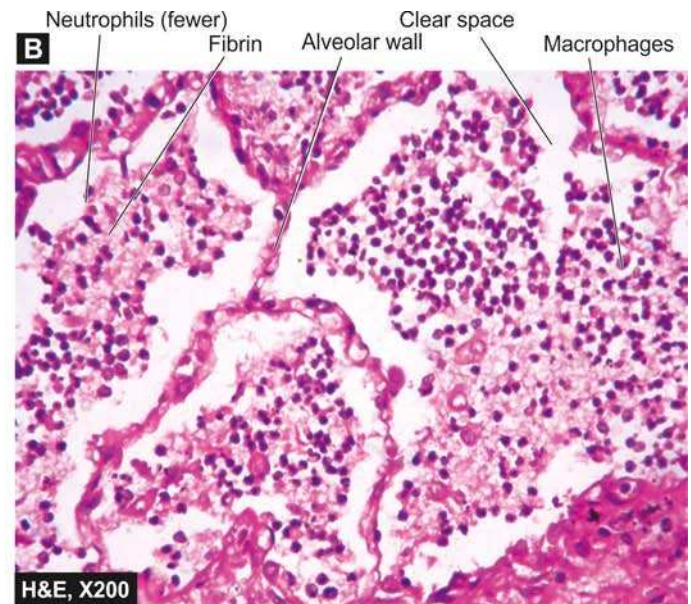

Figure 15.9 Lobar pneumonia, grey hepatisation stage. A, The sectioned surface of the lung shows grey-brown, firm area of consolidation (liver-like) affecting a lobe (arrow). B, The cellular exudate in the alveolar lumina is lying separated from the septal walls by a clear space. The infiltrate in the lumina is composed of neutrophils and macrophages.

iv) There is progressive removal of fluid content as well as cellular exudate from the air spaces, partly by expectoration but mainly by lymphatics, resulting in restoration of normal lung parenchyma with aeration.

COMPLICATIONS Since the advent of antibiotics, serious complications of lobar pneumonia are uncommon. However, they may develop in neglected cases and in patients with impaired immunologic defenses. These are as under:

1. Organisation In about 3% of cases, resolution of the exudate does not occur but instead it undergoes organisation. There is ingrowth of fibroblasts from the alveolar septa resulting in fibrosed, tough, airless leathery lung tissue. This type of post-pneumonic fibrosis is called *carnification*.

2. Pleural effusion About 5% of treated cases of lobar pneumonia develop inflammation of the pleura with effusion. The pleural effusion usually resolves but sometimes may undergo organisation with fibrous adhesions between visceral and parietal pleura.

3. Empyema Less than 1% of treated cases of lobar pneumonia develop encysted pus in the pleural cavity termed empyema.

4. Lung abscess A rare complication of lobar pneumonia is formation of lung abscess, especially when there is secondary infection by other organisms.

5. Metastatic infection Occasionally, infection in the lungs and pleural cavity in lobar pneumonia may extend into the pericardium and the heart causing purulent pericarditis, bacterial endocarditis and myocarditis. Other forms of metastatic infection encountered rarely in lobar pneumonias are otitis media, mastoiditis, meningitis, brain abscess and purulent arthritis.

CLINICAL FEATURES Classically, the onset of lobar pneumonia is sudden. The major symptoms are: shaking chills, fever, malaise with pleuritic chest pain, dyspnoea and cough with expectoration which may be mucoid, purulent or even bloody. The common physical findings are fever, tachycardia, and tachypnoea, and sometimes cyanosis if the patient is severely hypoxaemic. There is generally a marked neutrophilic leucocytosis. Blood cultures are positive in about 30% of cases. Chest radiograph may reveal consolidation. Culture of the organisms in the sputum and antibiotic sensitivity are most significant investigations for institution of specific antibiotics. The response to antibiotics is usually rapid with clinical improvement in 48 to 72 hours after the initiation of antibiotics.

Bronchopneumonia (Lobular Pneumonia)

Bronchopneumonia or lobular pneumonia is infection of the terminal bronchioles that extends into the surrounding alveoli resulting in patchy consolidation of the lung. The condition is particularly frequent at the extremes of life (i.e. in infancy and old age), as a terminal event in chronic debilitating diseases and as a secondary infection following viral respiratory infections such as influenza, measles etc.

ETIOLOGY The common organisms responsible for bronchopneumonia are staphylococci, streptococci, pneumococci, *Klebsiella pneumoniae*, *Haemophilus influenzae*, and gram-negative bacilli like *Pseudomonas* and coliform bacteria.

MORPHOLOGIC FEATURES *Grossly*, bronchopneumonia is identified by patchy areas of red or grey consolidation affecting one or more lobes, frequently found bilaterally and more often involving the lower zones of the lungs due to gravitation of the secretions. On cut surface, these patchy consolidated lesions are dry, granular, firm, red or grey in colour, 3 to 4 cm in diameter, slightly elevated over the surface and are often centred around a bronchiole (**Fig. 15.10**). These patchy areas are best picked up by passing the fingertips on the cut surface.

Histologically, the following features are observed (**Fig. 15.11**):

- i) Acute bronchiolitis.
- ii) Suppurative exudate, consisting chiefly of neutrophils, in the peribronchiolar alveoli.
- iii) Thickening of the alveolar septa by congested capillaries and leucocytic infiltration.
- iv) Less involved alveoli contain oedema fluid.

COMPLICATIONS The complications of lobar pneumonia may occur in bronchopneumonia as well. However, complete resolution of bronchopneumonia is uncommon. There is generally some degree of destruction of the bronchioles resulting in foci of bronchiolar fibrosis that may eventually cause bronchiectasis.

CLINICAL FEATURES The patients of bronchopneumonia are generally infants or elderly individuals. There may be history of preceding bed-ridden illness, chronic debility, aspiration of gastric contents or upper respiratory infection. For initial 2 to 3 days, there are features of acute bronchitis but subsequently signs and symptoms similar to those of lobar pneumonia appear. Blood examination usually shows a neutrophilic leucocytosis. Chest radiograph shows mottled, focal opacities in both the lungs, chiefly in the lower zones.

The salient features of the two main types of bacterial pneumonias are contrasted in **Table 15.2**.

Legionella Pneumonia

Legionella pneumonia or Legionnaire's disease is an epidemic illness caused by gram-negative bacilli, *Legionella pneumophila* that thrives in aquatic environment. It was first recognised following investigation into high mortality among those attending American Legion Convention in Philadelphia in July 1976 and hence the name. The epidemic occurs in summer months by spread of organisms through contaminated drinking water or in air-conditioning cooling towers. Impaired host defenses in the form of immunodeficiency, corticosteroid therapy, old age and cigarette smoking play important roles.

MORPHOLOGIC FEATURES *Grossly*, there are changes of widespread bronchopneumonia involving many lobes and there may be consolidation of the entire lung. Pleural effusion is frequently present.

Histologically, the changes are not distinctive. Common features are as under:

- i) Intra-alveolar exudate, initially of neutrophils but later composed mainly of macrophages.
- ii) Alveolar septa show foci of hyperplasia of the lining epithelium and thrombosis of vessels in the septa.

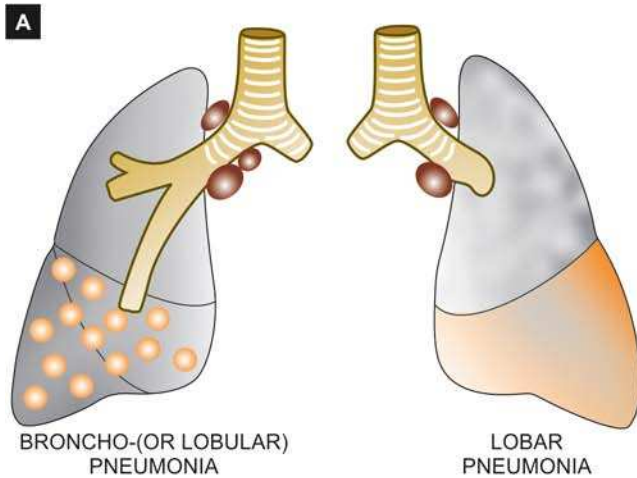

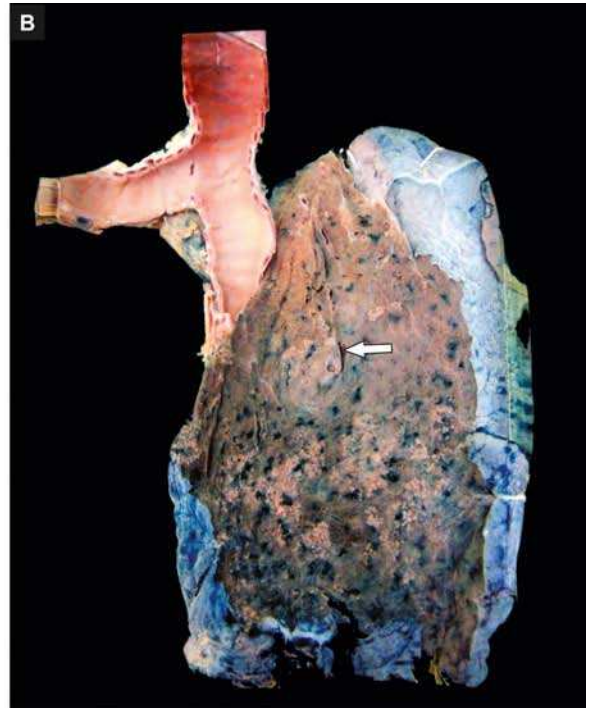

Figure 15.10 A, Gross appearance of bronchopneumonia contrasted with that of lobar pneumonia. B, The pleural surface of the specimen of the lung shows serofibrinous exudate. The sectioned surface shows multiple, small, grey-brown, firm, patchy areas of consolidation around bronchioles (arrow), while the intervening lung is spongy.

- iii) The organisms may be demonstrated in the macrophages by special stains or by immunofluorescent techniques.

CLINICAL FEATURES The disease begins with malaise, headache and muscle-aches followed by high fever, chills, cough and tachypnoea. Systemic manifestations unrelated to pathologic changes in the lungs are seen due to bacteraemia and include abdominal pain, watery diarrhoea, proteinuria and mild hepatic dysfunction.

B. VIRAL AND MYCOPLASMAL PNEUMONIA (PRIMARY ATYPICAL PNEUMONIA)

Viral and mycoplasmal pneumonia is characterised by patchy inflammatory changes, largely confined to interstitial tissue of

the lungs, without any alveolar exudate. Other terms used for these respiratory tract infections are *interstitial pneumonitis*, reflecting the interstitial location of the inflammation, and *primary atypical pneumonia*, atypicality being the absence of alveolar exudate commonly present in other pneumonias. Interstitial pneumonitis may occur in all ages. Most of the cases are mild and transient; exceptionally it may be severe and fulminant.

ETIOLOGY Interstitial pneumonitis is caused by a wide variety of agents, the most common being *respiratory syncytial virus* (RSV). Others are *Mycoplasma pneumoniae* and many viruses such as influenza and parainfluenza viruses, adenoviruses, rhinoviruses, coxsackieviruses and cytomegaloviruses (CMV). Occasionally, psittacosis (*Chlamydia*) and Q fever (*Coxiella*) are associated with interstitial pneumonitis.

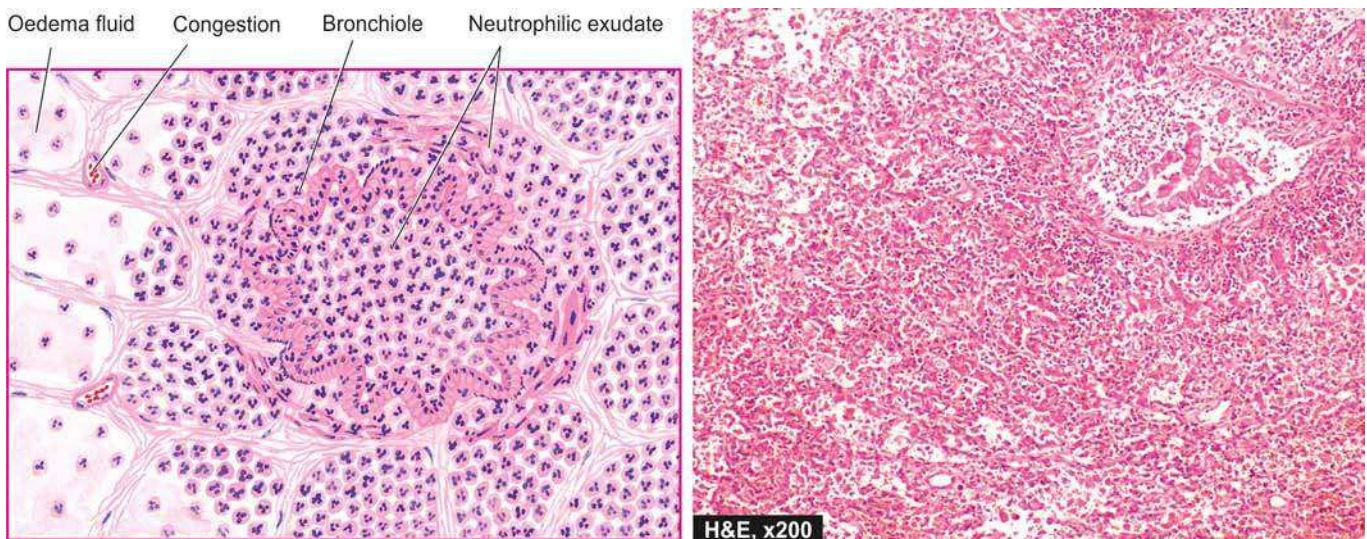

Figure 15.11 Microscopic appearance of bronchopneumonia. The bronchioles as well as the adjacent alveoli are filled with exudate consisting chiefly of neutrophils. The alveolar septa are thickened due to congested capillaries and neutrophilic infiltrate.

Table 15.2 Contrasting features of lobar pneumonia and bronchopneumonia.

| FEATURE | LOBAR PNEUMONIA | BRONCHOPNEUMONIA |
|----------------------------|---|--|
| 1. Definition | Acute bacterial infection of a part of a lobe of one or both lungs, or the entire lobe/s | Acute bacterial infection of the terminal bronchioles extending into adjoining alveoli |
| 2. Age group | More common in adults | Commoner at extremes of age—infants and old age |
| 3. Predisposing factors | More often affects healthy individuals | Pre-existing diseases e.g. chronic debility, terminal illness, flu, measles |
| 4. Common etiologic agents | Pneumococci, <i>Klebsiella pneumoniae</i> , staphylococci, streptococci | Staphylococci, streptococci, <i>Pseudomonas</i> , <i>Haemophilus influenzae</i> |
| 5. Pathologic features | Typical case passes through stages of congestion (1-2 days), early (2-4 days) and late consolidation (4-8 days), followed by resolution (1-3 weeks) | Patchy consolidation with central granularity, alveolar exudation, thickened septa |
| 6. Investigations | Neutrophilic leucocytosis, positive blood culture, X-ray shows consolidation | Neutrophilic leucocytosis, positive blood culture, X-ray shows mottled focal opacities |
| 7. Prognosis | Better response to treatment, resolution common, prognosis good | Response to treatment variable, organisation may occur, prognosis poor |
| 8. Complications | Less common; pleural effusion, empyema, lung abscess, organisation | Bronchiectasis may occur; other complications same as for lobar pneumonia |

Infections of the respiratory tract with these organisms are quite common. In most cases, the infection remains confined to the upper respiratory tract presenting as common cold. Occasionally, it may extend lower down to involve the interstitium of the lungs. The circumstances favouring such extension of infection are malnutrition, chronic debilitating diseases and alcoholism.

MORPHOLOGIC FEATURES Irrespective of the etiologic agent, the pathologic changes are similar in all cases.

Grossly, depending upon the severity of infection, the involvement may be patchy to massive and widespread consolidation of one or both the lungs. The lungs are heavy, congested and subcrepitant. Sectioned surface of the lung exudes small amount of frothy or bloody fluid. The pleural reaction is usually infrequent and mild.

Histologically, hallmark of viral pneumonias is the interstitial nature of the inflammatory reaction. The microscopic features are as under (Fig. 15.12):

i) Interstitial inflammation There is thickening of alveolar walls due to congestion, oedema and mononuclear inflammatory infiltrate comprised by lymphocytes, macrophages and some plasma cells.

ii) Necrotising bronchiolitis This is characterised by foci of necrosis of the bronchiolar epithelium, inspissated secretions in the lumina and mononuclear infiltrate in the walls and lumina.

iii) Reactive changes The lining epithelial cells of the bronchioles and alveoli proliferate in the presence of virus and may form multinucleate giant cells and syncytia in the bronchiolar and alveolar walls. Occasionally, viral inclusions (intranuclear and/or intracytoplasmic) are found, especially in pneumonitis caused by CMV.

iv) Alveolar changes In severe cases, the alveolar lumina may contain oedema fluid, fibrin, scanty inflammatory exudate and coating of alveolar walls by pink, hyaline membrane similar to the one seen in respiratory distress syndrome (page 444). Alveolar changes are prominent if bacterial infection supervenes.

COMPLICATIONS The major complication of interstitial pneumonitis is superimposed bacterial infection and its complications. Most cases of interstitial pneumonitis recover completely. In more severe cases, there may be interstitial fibrosis and permanent damage.

CLINICAL FEATURES Majority of cases of interstitial pneumonitis initially have upper respiratory symptoms with fever, headache and muscle-aches. A few days later, dry, hacking, non-productive cough with retrosternal burning appears due to tracheitis and bronchitis. Blood film shows characteristic neutrophilic leucocytosis. Chest radiograph may show patchy or diffuse consolidation. Cold agglutinin titres in the serum are elevated in almost half the cases of mycoplasmal

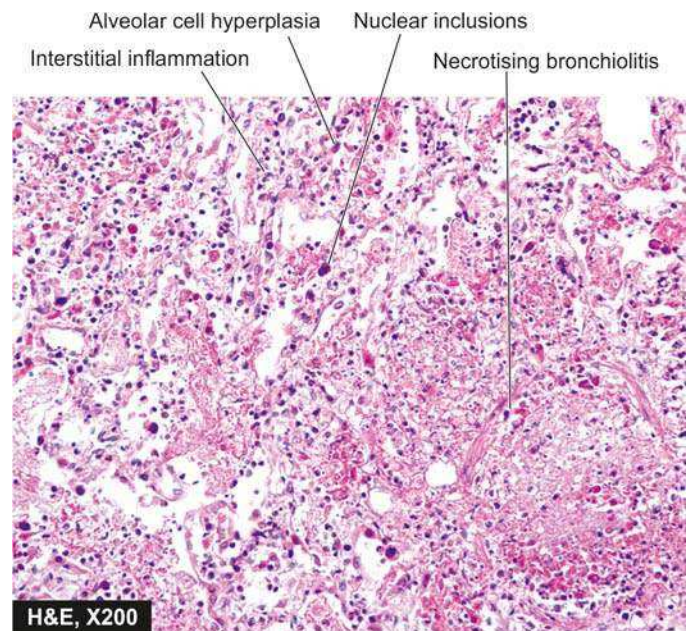

Figure 15.12 Microscopic appearance of interstitial pneumonitis (viral pneumonia). There is necrotising bronchiolitis, reactive hyperplasia of alveolar epithelial cells, some having nuclear inclusions, and there is interstitial inflammation.

pneumonia, 20% cases of adenovirus infection but absent in other forms of viral pneumonia. Isolation of the etiologic agent, otherwise, is difficult.

C. FUNGAL INFECTIONS OF LUNG (FUNGAL PNEUMONIAS)

Fungal infections of the lung are more common than tuberculosis in the US. These infections in healthy individuals are rarely serious but in immunosuppressed individuals may prove fatal. General aspects of mycotic infections are covered in Chapter 6. Here, some common examples of fungal infections of the lung are briefly given:

Pneumocystis Pneumonia

Pneumocystis is an opportunistic fungal infection of the lungs. The original species *P. carinii* infects rats while *P. jirovecii* causes pneumonia by inhalation of the organisms in neonates and immunosuppressed people. Almost 100% cases of HIV/AIDS develop opportunistic infection during the course of disease, most commonly *Pneumocystis* pneumonia. **Table 15.3** lists the various etiologic types of pneumonias associated with HIV infection due to profound immunosuppression. Other immunosuppressed groups are patients on chemotherapy for organ transplant and tumours, malnutrition, agammaglobulinaemia etc.

MORPHOLOGIC FEATURES *Grossly*, the affected parts of the lung are consolidated, dry and grey.

Microscopically, the features are as under:

- i) Interstitial pneumonitis with thickening and mononuclear infiltration of the alveolar walls.
- ii) Alveolar lumina contain pink frothy fluid having the organisms (**Fig. 15.13**).
- iii) By Grocott's methenamine-silver (GMS) stain, the characteristic oval or crescentic cysts, about 5 µm in diameter and surrounded by numerous tiny black dot-like organism *P. jirovecii* are demonstrable in the frothy fluid.
- iv) No significant inflammatory exudate is seen in the air spaces.

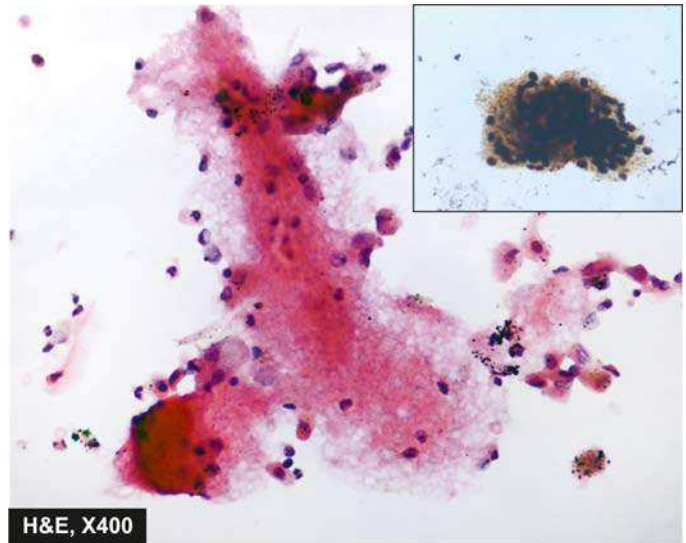

CLINICAL FEATURES There is rapid onset of dyspnoea, tachycardia, cyanosis and non-productive cough. If untreated, it causes death in one or two weeks. Chest radiograph shows diffuse alveolar and interstitial infiltrate.

Other Fungal Infections of Lung

1. Aspergillosis Aspergillosis is the most common fungal infection of the lung caused by *Aspergillus fumigatus* that grows

Table 15.3 Etiologic types of HIV-infection associated pneumonias.

1. *Pneumocystis jirovecii*
2. Cytomegalovirus
3. *Mycobacterium avium-intracellulare*
4. *Mycobacterium tuberculosis*
5. *Streptococcus pneumoniae*
6. *Haemophilus influenzae*
7. Invasive aspergillosis
8. Invasive candidiasis

H&E, X400

Figure 15.13 *Pneumocystis* pneumonia. Smears from the sputum show frothy vacuolated exudate containing the organisms. Inbox shows Grocott's silver methenamine stain positivity for the organisms.

best in cool, wet climate. The infection may result in *allergic bronchopulmonary aspergillosis*, *aspergilloma* and *necrotising bronchitis*. Immunocompromised persons develop more serious manifestations of aspergillus infection, especially in leukaemic patients on cytotoxic drug therapy and HIV/AIDS. Extensive haematogenous spread of aspergillus infection may result in widespread changes in lung tissue due to arterial occlusion, thrombosis and infarction.

Grossly, pulmonary aspergillosis may occur within pre-existing pulmonary cavities or in bronchiectasis as fungal ball.

Microscopically, the fungus may appear as a tangled mass within the cavity. The organisms are identified by their characteristic morphology—thin septate hyphae with dichotomous branching at acute angles which stain positive for fungal stains such as PAS and silver impregnation technique (**Fig. 15.14**). The wall of the cavity shows chronic inflammatory cells.

2. Mucormycosis Mucormycosis or phycomycosis is caused by *Mucor* and *Rhizopus*. The infection in the lung occurs in a similar way as in aspergillosis. The pulmonary lesions are especially common in patients of *diabetic ketoacidosis*. *Mucor* is distinguished by its broad, non-parallel, nonseptate hyphae which branch at an obtuse angle. Mucormycosis is more often angioinvasive, and disseminates; hence it is more destructive than aspergillosis.

3. Candidiasis Candidiasis or moniliasis caused by *Candida albicans* is a normal commensal in oral cavity, gut and vagina but attains pathologic form in immunocompromised host. Angioinvasive growth of the organism may occur in the airways.

4. Histoplasmosis It is caused by oval organism, *Histoplasma capsulatum*, by inhalation of infected dust or bird droppings. The condition may remain asymptomatic or may produce lesions similar to the Ghon's complex.

5. Cryptococcosis It is caused by *Cryptococcus neoformans* which is round yeast having a halo around it due to shrinkage

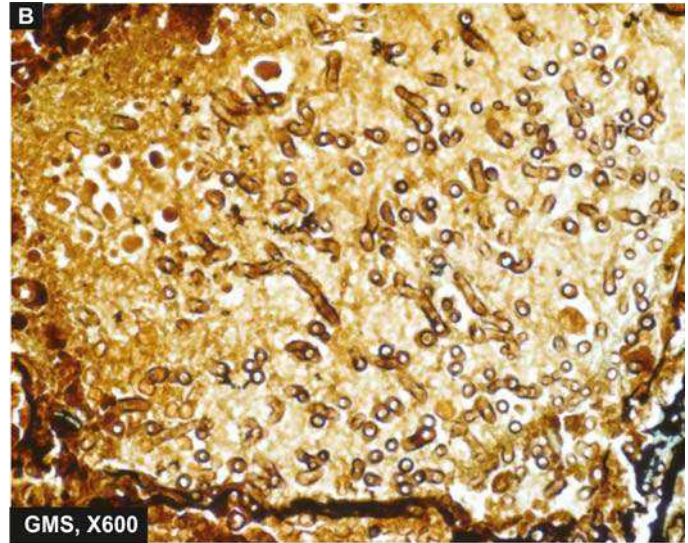

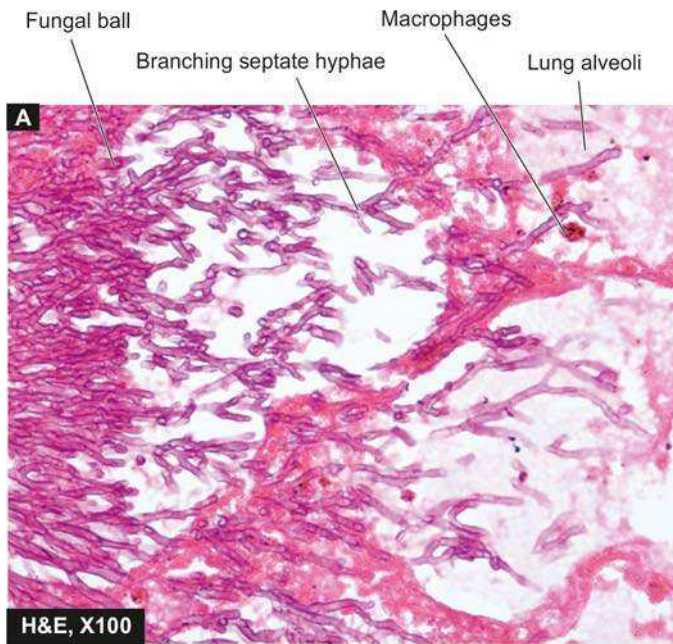

Figure 15.14 Aspergillosis lung. A, Acute angled septate hyphae lying in necrotic debris and acute inflammatory exudates in lung abscess. B, Organisms, *Aspergillus flavus*, are best identified with a special stain for fungi, Gomory's methenamine silver (GMS).

in tissue sections. The infection occurs from infection by inhalation of pigeon droppings. The lesions in the body may range from a small parenchymal granuloma in the lung to cryptococcal meningitis.

6. Coccidioidomycosis Coccidioidomycosis is caused by *Coccidioides immitis* which are spherical spores. The infection in human beings is acquired by close contact with infected dogs. The lesions consist of peripheral parenchymal granuloma in the lung.

7. Blastomycosis It is an uncommon condition caused by *Blastomyces dermatitidis*. The lesions result from inhalation of spores in the ground. Pathological features may present as Ghon's complex-like lesion, as a pneumonic consolidation, and as multiple skin nodules.

D. NON INFECTIVE PNEUMONIAS

Some other types of pneumonias caused by certain *non-infective varieties* (e.g. aspiration pneumonia, hypostatic pneumonia and lipid pneumonia) are described here.

Aspiration (Inhalation) Pneumonia

Aspiration or inhalation pneumonia results from inhalation of different agents into the lungs. These substances include food, gastric contents, foreign body and infected material from oral cavity. A number of factors predispose to inhalation pneumonia which include: unconsciousness, drunkenness, neurological disorders affecting swallowing, drowning, necrotic oropharyngeal tumours, in premature infants and congenital tracheo-oesophageal fistula. Some patients die immediately from asphyxiation or laryngospasm without developing pneumonia.

MORPHOLOGIC FEATURES Pathologic changes vary depending upon the aspirated particulate matter but in general right lung is affected more often due to direct path from the main bronchus:

1. Aspiration of small amount of **sterile foreign matter** such as acidic gastric contents produces *chemical pneumonitis*. It is characterised by haemorrhagic pulmonary oedema with presence of particles in the bronchioles. Patients rapidly develop cyanosis, dyspnoea, shock and bloody sputum and are often likely to die of cardiac failure. If the patient survives the acute episode, secondary bacterial infection is likely to occur.
2. **Non-sterile aspirate** causes widespread *broncho-pneumonia* with multiple areas of necrosis and suppuration. A granulomatous reaction with foreign body giant cells may surround the aspirated vegetable matter.

Hypostatic Pneumonia

Hypostatic pneumonia is the term used for collection of oedema fluid and secretions in the dependent parts of the lungs in severely debilitated, bed-ridden patients. The accumulated fluid in the basal zone and posterior part of lungs gets infected by bacteria from the upper respiratory tract and sets in bacterial pneumonia. Hypostatic pneumonia is a common terminal event in the old, feeble, comatose patients.

Lipid Pneumonia

Another variety of non-infective pneumonia is lipid pneumonia which is of 2 types: exogenous and endogenous.

1. Exogenous lipid pneumonia This is caused by aspiration of a variety of oily materials. These are: inhalation of oily nasal drops, regurgitation of oily medicines from stomach (e.g. liquid paraffin), administration of oily vitamin preparation to reluctant children or to debilitated old patients.

2. Endogenous lipid pneumonia Endogenous origin of lipids causing pneumonic consolidation is more common. The sources of origin are tissue breakdown following obstruction to airways e.g. obstruction by bronchogenic cancer, tuberculosis and bronchiectasis.

MORPHOLOGIC FEATURES *Grossly*, the exogenous lipid pneumonia affects the right lung more frequently due to direct path from the main bronchus. Quite often, the lesions are bilateral. The affected part of the lungs is consolidated. Cut surface is characteristically 'golden yellow'.

Microscopically, the features are as under:

- i) Lipid is finely dispersed in the cytoplasm of macrophages forming foamy macrophages within the alveolar spaces.
- ii) There may be formation of cholesterol clefts due to liberation of cholesterol and other lipids.
- iii) Formation of granulomas with foreign body giant cells may be seen around the large lipid droplets.

LUNG ABSCESS

Lung abscess is a localised area of necrosis of lung tissue with suppuration. It is of 2 types (Fig. 15.15):

- ◆ *Primary lung abscess* that develops in an otherwise normal lung. The commonest cause is aspiration of infected material.
- ◆ *Secondary lung abscess* that develops as a complication of some other disease of the lung or from another site.

ETIOPATHOGENESIS The microorganisms commonly isolated from the lungs in lung abscess are streptococci, staphylococci and various gram-negative organisms. These are introduced into the lungs from one of the following mechanisms:

1. Aspiration of infected foreign material A number of foreign materials such as food, decaying teeth, gastric contents, severely infected gingivae and teeth, and necrotic tissue from lesions in the mouth, upper respiratory tract or nasopharynx may be aspirated. This occurs particularly in favourable circumstances such as during sleep, unconsciousness, anaesthesia, general debility and acute alcoholism.

2. Preceding bacterial infection Preceding bronchopneumonia in a debilitated patient may develop into lung abscess. Other infective conditions like tuberculosis, bronchiectasis and mycotic infections may occasionally result in formation of lung abscess.

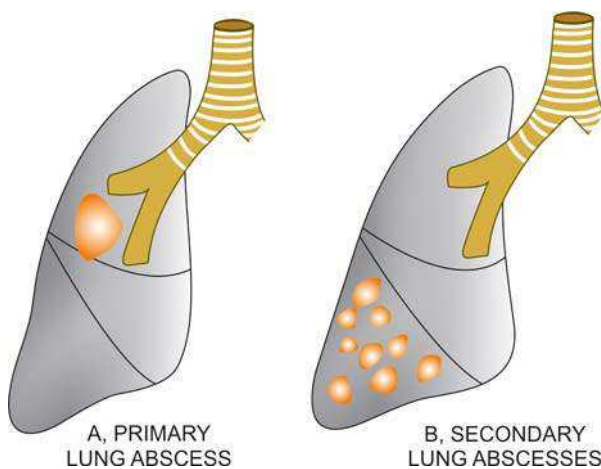

Figure 15.15 Common locations of lung abscess. A, *Primary lung abscess*—mostly single, large, commonly due to aspiration, located most frequently in the lower part of right upper lobe or apex of right lower lobe. B, *Secondary lung abscesses*—mostly multiple, small, most commonly post-pneumonic or following septic embolism.

3. Bronchial obstruction An abscess may form distal to an obstructed bronchus such as from bronchial tumour or from impacted foreign body.

4. Septic embolism Infected emboli originating from pyaemia, thrombophlebitis or from vegetative bacterial endocarditis may be disseminated in the venous circulation and reach the right side of the heart from where they are lodged in the lung and result in multiple abscesses.

5. Miscellaneous Rarely lung abscesses may occur from following causes:

- i) Infection in pulmonary infarcts.
- ii) Amoebic abscesses due to infection with *Entamoeba histolytica*.
- iii) Trauma to the lungs.
- iv) Direct extension from a suppurative focus in the mediastinum, oesophagus, subphrenic area or spine.

MORPHOLOGIC FEATURES Abscesses due to aspiration are more likely to be in right lung due to more vertical main bronchus and are frequently single. They are commonly located in the lower part of the right upper lobe or apex of right lower lobe. Abscesses developing from preceding pneumonia and septic or pyaemic abscesses are often multiple and scattered throughout the lung.

Grossly, abscesses may be of variable size from a few millimeters to large cavities, 5 to 6 cm in diameter. The cavity often contains exudate. An acute lung abscess is initially surrounded by acute pneumonia and has poorly-defined ragged wall. With passage of time, the abscess becomes chronic and develops fibrous wall (Fig. 15.16,A).

Histologically, characteristic feature is the destruction of lung parenchyma with suppurative exudate in the lung cavity. The cavity is initially surrounded by acute inflammation in the wall but later there is replacement by chronic inflammatory cell infiltrate composed of lymphocytes, plasma cells and macrophages. In more chronic cases, there is considerable fibroblastic proliferation forming a fibrocollagenic wall (Fig. 15.16,B).

CLINICAL FEATURES The clinical manifestations are fever, malaise, loss of weight, cough, purulent expectoration and haemoptysis in half the cases. Clubbing of the fingers and toes appears in about 20% of patients. Secondary amyloidosis may occur in chronic long-standing cases.

PULMONARY TUBERCULOSIS

The classical and most common example of chronic infection of the lungs is pulmonary tuberculosis. Pulmonary lesions caused by *Mycobacterium tuberculosis* and other mycobacteria have already been discussed along with general aspects of tuberculosis and other granulomatous inflammations in Chapter 5.

GIST BOX 15.4 Pulmonary Infections

- ☐ Pulmonary tuberculosis is most common and has been covered in detail in Chapter 5.
- ☐ Pneumonia or consolidation is acute inflammation of the lung parenchyma distal to the terminal bronchioles.
- ☐ Pneumonias occur in settings of altered consciousness, impaired immunity, endobronchial obstruction etc.

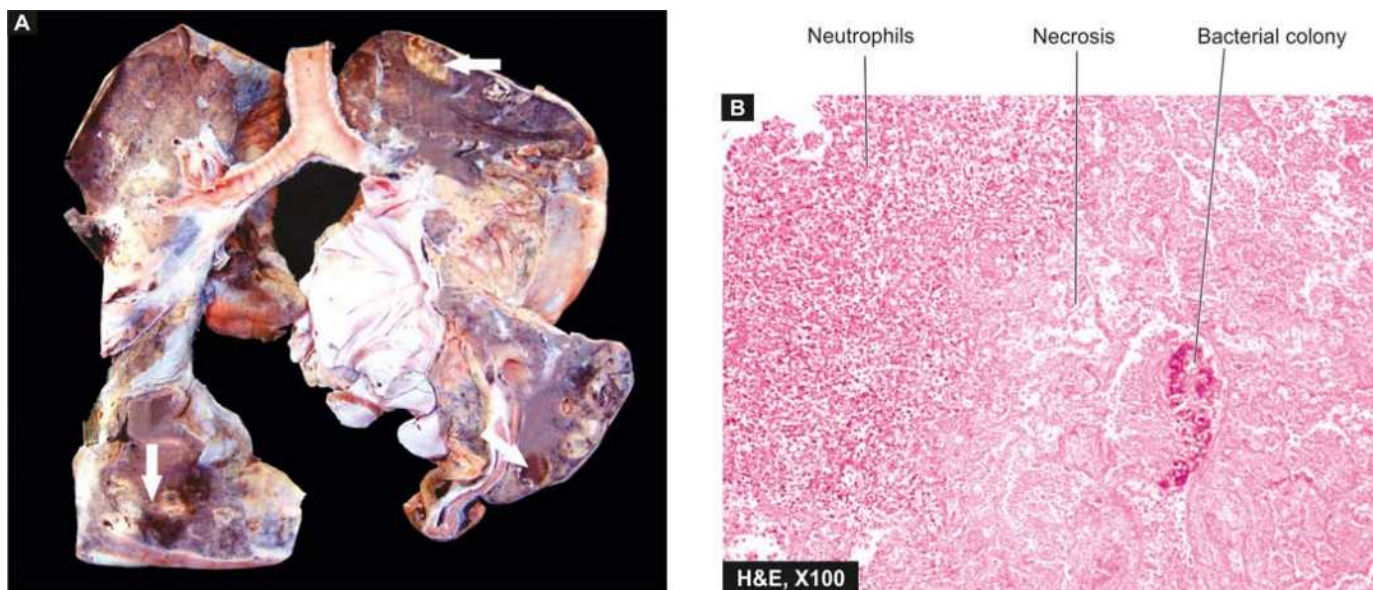

Figure 15.16 Lung abscess. A, The pleura is thickened. Cut surface of the lung shows multiple cavities 1-4 cm in diameter, having irregular and ragged inner walls (arrow). The lumina contain necrotic debris. The surrounding lung parenchyma is consolidated. B, The photomicrograph shows abscess formed by necrosed alveoli and dense acute and chronic inflammatory cells.

- ▣ Pneumonias are classified on location in the part of lung, clinical settings and etiology.
- ▣ Bacterial pneumonias may be located in a lobe (lobar) or terminal bronchiole (bronchopneumonia).
- ▣ Lobar pneumonia is caused by pneumococci, staphylococci, streptococci and gram-negative organisms.
- ▣ Lobar pneumonia passes through stages of congestion, red and grey hepatisation, and resolution.
- ▣ Bronchopneumonia is patchy areas of consolidation around terminal bronchioles.
- ▣ Viral pneumonia is characterised by interstitial inflammation, necrotising bronchiolitis and multinucleate giant cells.
- ▣ Common fungal infections of lung are pneumocystis, aspergillosis, mucormycosis, candidiasis etc.
- ▣ Lung abscesses are variable in size and may form cavities.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic obstructive pulmonary disease (COPD) or chronic obstructive airway disease (COAD) are commonly used clinical terms for a group of pathological conditions in which there is chronic, partial or complete, obstruction to the airflow at any level from trachea to the smallest airways resulting in functional disability of the lungs i.e. these are diffuse lung diseases. One etiologic factor which is a common denominator in all forms of COPD is smoking. The following entities are included in COPD:

- I. Chronic bronchitis
- II. Emphysema
- III. Bronchial asthma
- IV. Bronchiectasis
- V. Small airways disease (bronchiolitis)

Chronic bronchitis and emphysema are quite common and often occur together. Contrasting features of all five conditions included in COPD are given in **Table 15.4**.

CHRONIC BRONCHITIS

Chronic bronchitis is a common condition defined *clinically* as persistent cough with expectoration on most days for at least three months of the year for two or more consecutive years. The cough is caused by oversecretion of mucus. In spite of its name, chronic inflammation of the bronchi is not a prominent feature. The condition is more common in middle-aged males than females; approximately 20% of adult men and 5% of adult women have chronic bronchitis, but only a minority of them develop serious disabling COPD or cor pulmonale. Quite frequently, chronic bronchitis is associated with emphysema.

ETIOPATHOGENESIS The two most important etiologic factors responsible for majority of cases of chronic bronchitis are: cigarette smoking and atmospheric pollution. Other contributory factors are occupation, infection, familial and genetic factors.

1. Smoking The most commonly identified factor implicated in causation of chronic bronchitis and in emphysema is heavy smoking. Heavy cigarette smokers have 4 to 10 times higher proneness to develop chronic bronchitis. Prolonged cigarette smoking appears to act on the lungs in a number of ways:

- i) It impairs ciliary movement.
- ii) It inhibits the function of alveolar macrophages.
- iii) It leads to hypertrophy and hyperplasia of mucus-secreting glands.
- iv) It causes considerable obstruction of small airways.
- v) It stimulates the vagus and causes bronchoconstriction.

2. Atmospheric pollution The incidence of chronic bronchitis is higher in industrialised urban areas where air is polluted. Some of the atmospheric pollutants which increase the risk of developing chronic bronchitis are sulfur dioxide, nitrogen dioxide, particulate dust and toxic fumes.

3. Occupation Workers engaged in certain occupations such as in cotton mills (byssinosis), plastic factories etc. are exposed to various organic or inorganic dusts which contribute to disabling chronic bronchitis in such individuals.

4. Infection Bacterial, viral and mycoplasmal infections do not initiate chronic bronchitis but usually occur secondary to

Table 15.4 Contrasting features of major forms of COPD.

| FEATURE | CHRONIC BRONCHITIS | EMPHYSEMA | ASTHMA | BRONCHIECTASIS | SMALL AIRWAYS DISEASE |
|------------------------------|--|--|---|--|---------------------------------|
| 1. Location | Bronchus | Acinus | Bronchus | Bronchus | Bronchiole |
| 2. Age at diagnosis | Adults | Adults | Extrinsic: children Intrinsic: adults | Adults | Children |
| 3. Etiology | Smoking, air pollution | Smoking, air pollution | Extrinsic: allergy Intrinsic: viral infection | Infection, obstruction | Viral infection, smoke |
| 4. Pathogenesis | Impaired ciliary movement | Deficiency of α -1 antitrypsin | IgE-sensitised mast cells | Damaged airways | Damage to surfactant |
| 5. Major gross feature | Thickened bronchial wall | Distended air sacs | Overdistended lungs | Dilated bronchi and bronchioles | Occluded bronchioles |
| 6. Main histology | Hyperplasia of mucous glands | Broken alveolar septa | Mucus plugs in bronchioles | Inflamed bronchi | Fibrous plugs in bronchioles |
| 7. Major clinical feature | Persistent cough with expectoration | Exertional dyspnoea | Bronchospasm | Copious foul-smelling expectoration | Cough, dyspnoea |

bronchitis. Cigarette smoke, however, predisposes to infection responsible for acute exacerbation in chronic bronchitis.

5. Familial and genetic factors There appears to be a poorly-defined familial tendency and genetic predisposition to develop disabling chronic bronchitis. However, it is more likely that nonsmoker family members who remain in the air-pollution of home are significantly exposed to smoke (passive smoking) and hence have increased blood levels of carbon monoxide.

MORPHOLOGIC FEATURES *Grossly*, the bronchial wall is thickened, hyperaemic and oedematous. Lumina of the bronchi and bronchioles may contain mucus plugs and purulent exudate.

Microscopically, just as there is clinical definition, there is histologic definition of chronic bronchitis by increased Reid index. *Reid index* is the ratio between thickness of the submucosal mucous glands (i.e. hypertrophy and hyperplasia) in the cartilage-containing large airways to that of the total bronchial wall (Fig. 15.17). The increase in thickness can be quantitatively assessed by micrometer lens or by morphometry. The bronchial epithelium may show squamous metaplasia and dysplasia. There is little chronic inflammatory cell infiltrate. The non-cartilage containing small airways show goblet cell hyperplasia and intraluminal and peribronchial fibrosis.

CLINICAL FEATURES There is considerable overlap of clinical features of chronic bronchitis and pulmonary emphysema (discussed below) as quite often the two coexist. Some important features of 'predominant bronchitis' are as under:

1. Persistent cough with copious expectoration of long duration; initially beginning in a heavy smoker with 'morning catarrh' or 'throat clearing' which worsens in winter.
2. Recurrent respiratory infections are common.
3. Dyspnoea is generally not prominent at rest but is more on exertion.
4. Patients are called 'blue bloaters' due to cyanosis and oedema.
5. Features of right heart failure (cor pulmonale) are common.
6. Chest X-ray shows enlarged heart with prominent vessels.

EMPHYSEMA

The WHO has defined pulmonary emphysema as combination of permanent dilatation of air spaces distal to the terminal bronchioles and the destruction of the walls of dilated air spaces. *Thus, emphysema is defined morphologically, while chronic bronchitis is defined clinically.* Since the two conditions coexist frequently and show considerable overlap in their clinical features, it is usual to label patients as 'predominant emphysema' and 'predominant bronchitis'.

CLASSIFICATION As mentioned in the beginning of this chapter, a lobule is composed of about 5 acini distal to a terminal bronchiole and that an acinus consists of 3 to 5 generations of respiratory bronchioles and a variable number of alveolar ducts and alveolar sacs (page 442). As per WHO definition of pulmonary emphysema, it is classified according to the portion of the acinus involved, into 5 types: centriacinar, panacinar (panlobular), para-septal (distal acinar), irregular (paracatricial) and mixed (unclassified) emphysema. A number

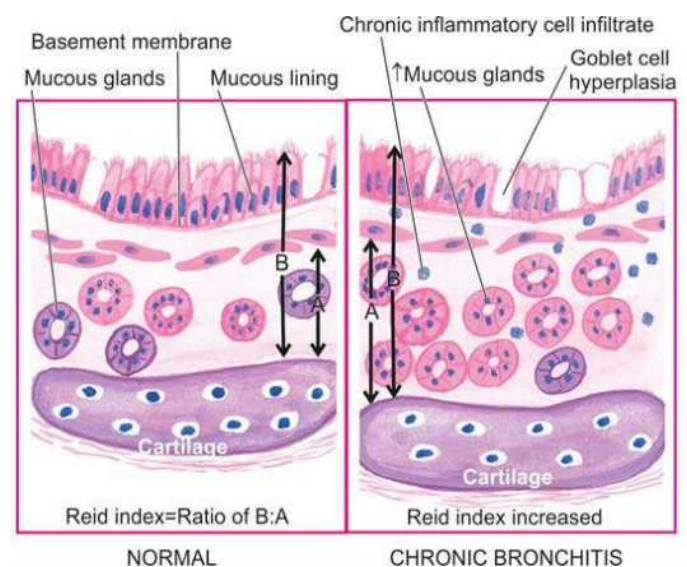

Figure 15.17 Diagrammatic representation of increased Reid's index in chronic bronchitis.

Table 15.5 Classification of 'true emphysema' and 'overinflation'.

| | |
|-------------------|---|
| A. TRUE EMPHYSEMA | |
| 1. | Centriacinar (centrilobular) emphysema |
| 2. | Panacinar (panlobular) emphysema |
| 3. | Paraseptal (distal acinar) emphysema |
| 4. | Irregular (para-cicatricial) emphysema |
| 5. | Mixed (unclassified) emphysema |
| B. OVERINFLATION | |
| 1. | Compensatory overinflation (compensatory emphysema) |
| 2. | Senile hyperinflation (ageing lung, senile emphysema) |
| 3. | Obstructive overinflation (infantile lobar emphysema) |
| 4. | Unilateral translucent lung (unilateral emphysema) |
| 5. | Interstitial emphysema (surgical emphysema) |

of other conditions to which the term 'emphysema' is loosely applied are, in fact, examples of 'overinflation'. A classification based on these principles is outlined in **Table 15.5**.

ETIOPATHOGENESIS The commonest form of COPD is the combination of chronic bronchitis and pulmonary emphysema. Chronic bronchitis, however, does not always lead to emphysema, nor all cases of emphysema have changes of chronic bronchitis. The association of the two conditions is principally linked to the common etiologic factors—most importantly *tobacco smoke* and *air pollutants*. Other less significant contributory factors are occupational exposure, infection and somewhat poorly-understood familial and genetic influences. All these factors have already been discussed above.

However, pathogenesis of the most significant event in emphysema, the *destruction of the alveolar walls*, is not linked to bronchial changes but is closely related to deficiency of serum α -1-antitrypsin (α -1-protease inhibitor) commonly termed *protease-antiprotease hypothesis* detailed below.

Protease-antiprotease hypothesis α -1-antitrypsin (α -1-AT), also called α -1-protease inhibitor (α -1-Pi), is a glycoprotein that forms the normal constituent of the α 1-globulin fraction of the plasma proteins on serum electrophoresis. The single gene locus that codes for α -1-AT is located on the long arm of chromosome 15. It is normally synthesised in the liver and is distributed in the circulating blood, tissue fluids and macrophages. The normal function of α -1-AT is to inhibit proteases and hence its name α -1-protease inhibitor. The proteases (mainly elastases) are derived from neutrophils. Neutrophil elastase has the capability of digesting lung parenchyma but is inhibited from doing so by anti-elastase effect of α -1-AT.

There are several known alleles of α -1-AT which have an autosomal codominant inheritance pattern and are classified as normal (*PiMM*), deficient (*PiZZ*), null type (*Pi null null*) having no detectable level, and dysfunctional (*PiSS*) type having about half the normal level.

◆ The most common abnormal phenotype in classic α -1-AT deficiency is *homozygous state PiZZ* resulting from a single amino acid substitution Glu→Lys which causes spontaneous polymerisation of α -1-AT and inhibits its release from the liver. The remaining material of α -1-AT in the liver causes hepatic cirrhosis (Chapter 20).

◆ Clinically significant deficiency is also associated with *homozygous Pi null null* and *heterozygous Pi nullZ*.

◆ The *heterozygote pattern* of *PiMZ* has intermediate levels which is not sufficient to produce clinical deficiency, but heterozygote individuals who smoke heavily have higher risk of developing emphysema.

The α -1-AT deficiency develops in adults and causes pulmonary emphysema in smokers as well as in non-smokers, though smokers become symptomatic about 15 years earlier than non-smokers. The other organ showing effects of α -1-AT deficiency is the liver which may develop obstructive jaundice early in infancy, and cirrhosis and hepatoma late in adulthood (Chapter 20).

The mechanism of alveolar wall destruction in emphysema by elastolytic action is based on the imbalance between proteases (chiefly *elastase*) and anti-proteases (chiefly *anti-elastase*):

- By decreased anti-elastase activity i.e. deficiency of α -1 antitrypsin.
- By increased activity of elastase i.e. increased neutrophilic infiltration in the lungs causing excessive elaboration of neutrophil elastase.

There are enough evidences to suggest that smoking promotes emphysema by both decreasing the amount of anti-elastase as well as by increasing the elastolytic protease in the lungs. These are as under:

- Oxidant in cigarette smoke has inhibitory influence on α -1-antitrypsin, thus lowering the level of anti-elastase activity.
- Smokers have up to ten times more phagocytes and neutrophils in their lungs than nonsmokers; thus they have very high elastase activity.

Pathogenesis of emphysema by protease-antiprotease mechanism is diagrammatically illustrated in **Fig. 15.18**.

PATHOLOGIC FEATURES Emphysema can be diagnosed with certainty only by gross and histologic examination of sections of whole lung. The lungs should be perfused

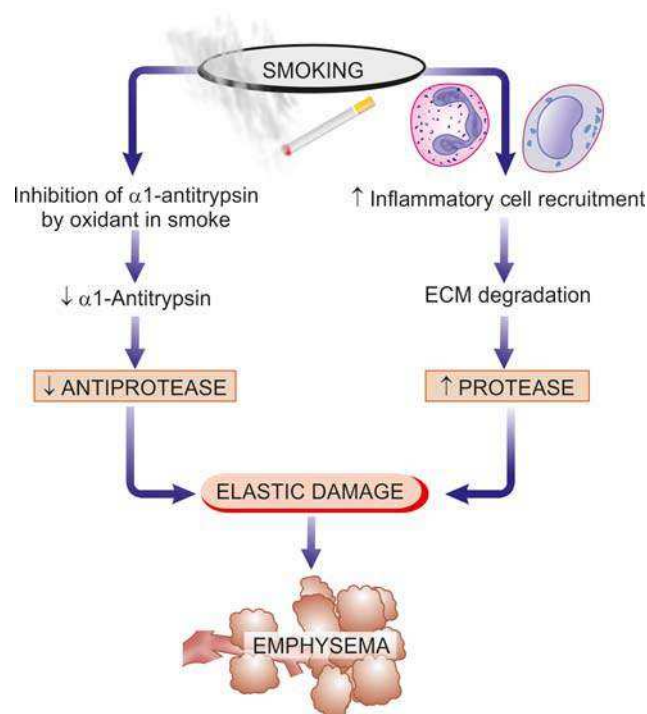

Figure 15.18 Pathogenesis of alveolar wall destruction in emphysema by protease-antiprotease mechanism.

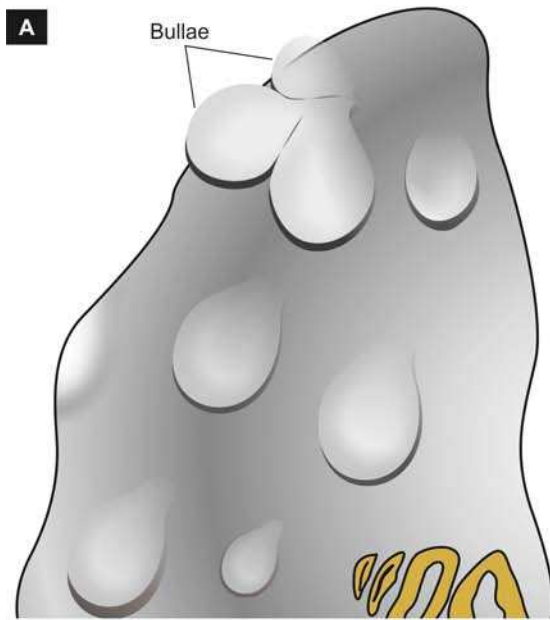

Figure 15.19 Bullous emphysema. A, Diagrammatic view as seen on the external surface of the lung. B, Sectioned lung showing air-filled sacs.

with formalin under pressure in inflated state to grade the severity of emphysema with naked eye.

Grossly, the lungs are voluminous, pale with little blood. The edges of the lungs are rounded. Mild cases show dilatation of air spaces visible with hand lens. Advanced cases show subpleural bullae and blebs bulging outwards from the surface of the lungs with rib markings between them. The *bullae* are air-filled cyst-like or bubble-like structures, larger than 1 cm in diameter (Fig. 15.19). They are formed by the rupture of adjacent air spaces while *blebs* are the result of rupture of alveoli directly into the subpleural interstitial tissue and are the common cause of spontaneous pneumothorax.

Microscopically, depending upon the type of emphysema, there is dilatation of air spaces and destruction of septal walls of part of acinus involved i.e. respiratory bronchioles, alveolar ducts and alveolar sacs. Changes of bronchitis may be present. Bullae and blebs when present show fibrosis and chronic inflammation of the walls.

CLINICAL FEATURES Cases of 'predominant emphysema' develop clinical features after about one-third of the pulmonary parenchyma is damaged which occurs most severely in panacinar emphysema. The age at the time of diagnosis is often a decade later (about 60 years) than the age for predominant bronchitis (about 50 years). Though there is considerable overlap between the clinical features of chronic bronchitis and emphysema, the following features generally characterise 'predominant emphysema':

1. There is long history of slowly increasing severe exertional dyspnoea.
2. Patient is quite distressed with obvious use of accessory muscles of respiration.
3. Chest is barrel-shaped and hyperresonant.

4. Cough occurs late after dyspnoea starts and is associated with scanty mucoid sputum.
5. Recurrent respiratory infections are not frequent.
6. Patients are called 'pink puffers' as they remain well oxygenated and have tachypnoea.
7. Weight loss is common.
8. Features of right heart failure (cor pulmonale) and hypercapnic respiratory failure are the usual terminal events.
9. Chest X-ray shows small heart with hyperinflated lungs.

After these general comments about morphologic and clinical features of emphysema, the specific pathologic changes in individual types of 'emphysema' and 'overinflation' as classified in Table 15.5 are described below.

Morphology of Individual Types of Emphysema

1. CENTRIACINAR (CENTRILOBULAR) EMPHYSEMA

Centriacinar or centrilobular emphysema is one of the common types. It is characterised by initial involvement of respiratory bronchioles i.e. the central or proximal part of the acinus (Fig. 15.20,B). This is the type of emphysema that usually coexists with chronic bronchitis and occurs predominantly in smokers and in coal miners' pneumoconiosis (page 468).

Grossly, the lesions are more common and more severe in the upper lobes of the lungs. The characteristic appearance is obvious in cut surface of the lung. It shows distended air spaces in the centre of the lobules surrounded by a rim of normal lung parenchyma in the same lobule. The lobules are separated from each other by fine fibrous tissue septa. Large amount of black pigment is often present in the walls of emphysematous spaces. In more severe cases, distal parts of acini are also involved and the appearance may closely resemble panacinar emphysema.

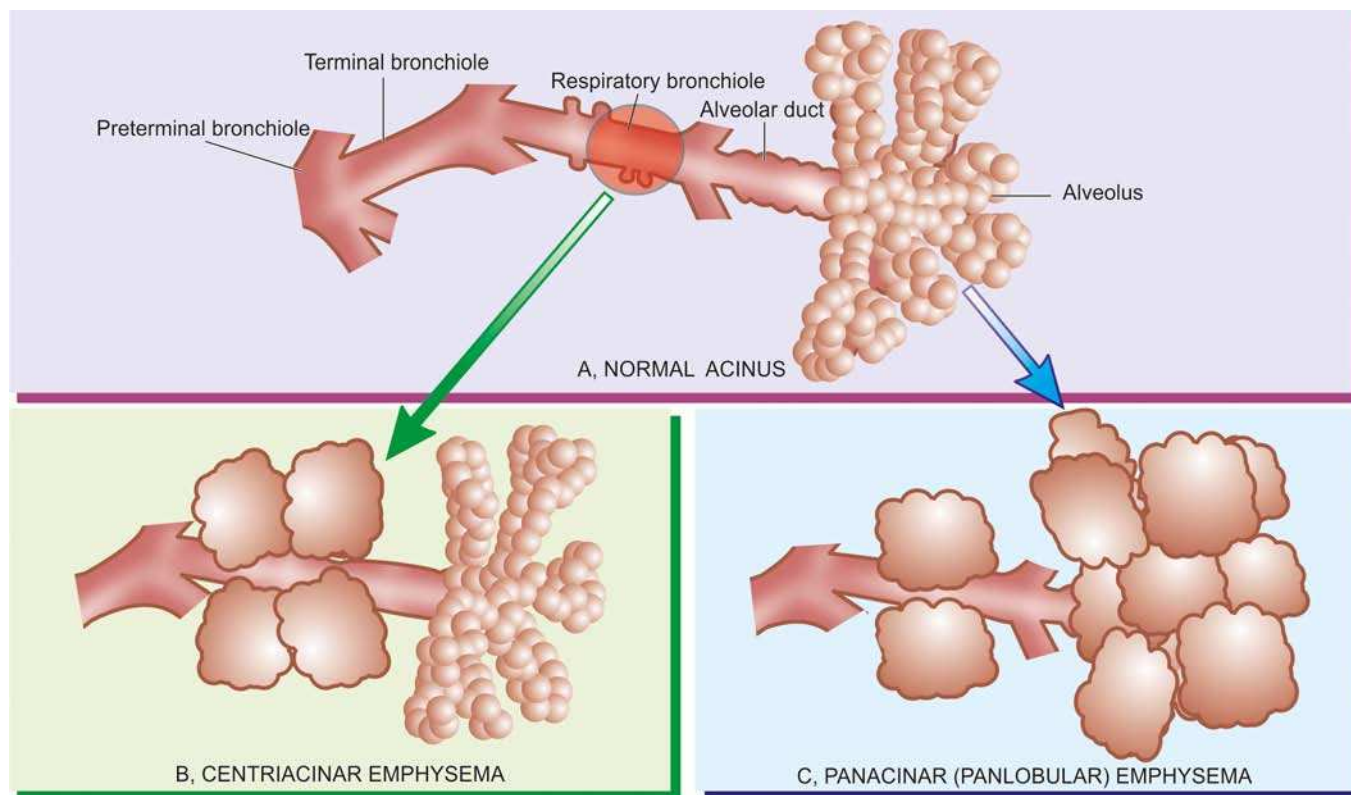

Figure 15.20 The anatomic regions of involvement in an acinus in major forms of emphysema.

Microscopically, there is distension and destruction of the respiratory bronchiole in the centre of lobules, surrounded peripherally by normal uninvolved alveoli. The terminal bronchioles supplying the acini show chronic inflammation and are narrowed.

2. PANACINAR (PANLOBULAR) EMPHYSEMA Panacinar or panlobular emphysema is the other common type. In this type, all portions of the acinus are affected but not of the entire lung (**Fig. 15.20,C**). Panacinar emphysema is most often associated with $\alpha 1$ -antitrypsin deficiency in middle-aged smokers and is the one that produces the most characteristic anatomical changes in the lung in emphysema.

Grossly, in contrast to centriacinar emphysema, the panacinar emphysema involves lower zone of lungs more frequently and more severely than the upper zone. The involvement may be confined to a few lobules, or may be more widespread affecting a lobe or part of a lobe of the lung. The lungs are enlarged and overinflated.

Microscopically, usually all the alveoli within a lobule are affected to the same degree. All portions of acini are distended—respiratory bronchioles, alveolar ducts and alveoli, are all dilated and their walls stretched and thin. Ruptured alveolar walls and spurs of broken septa are seen between the adjacent alveoli. The capillaries are stretched and thinned. Special stains show loss of elastic tissue. Inflammatory changes are usually absent (**Fig. 15.21**).

3. PARASEPTAL (DISTAL ACINAR) EMPHYSEMA This type of emphysema involves distal part of acinus while the proximal part is normal. Paraseptal or distal acinar emphysema

is localised along the pleura and along the perilobular septa. The involvement is seen adjacent to the areas of fibrosis and atelectasis and involves upper part of lungs more severely than the lower. This form of emphysema is seldom associated with COPD but is the common cause of spontaneous pneumothorax in young adults. Grossly, the subpleural portion of the lung shows air-filled cysts, 0.5 to 2 cm in diameter.

4. IRREGULAR (PARA-CICATRICIAL) EMPHYSEMA This is the most common form of emphysema, seen surrounding scars from any cause. The involvement is irregular as regards the portion of acinus involved as well as within the lung as a whole. During life, irregular emphysema is often asymptomatic and may be only an incidental autopsy finding.

5. MIXED (UNCLASSIFIED) EMPHYSEMA Quite often, the same lung may show more than one type of emphysema. It is usually due to more severe involvement resulting in loss of clearcut distinction between one type of emphysema and the other. Thus, the lungs of an elderly smoker at autopsy may show continuation of centriacinar emphysema in the upper lobes, panacinar in the lower lobes, and paraseptal emphysema in the subpleural region.

Morphology of Types of Overinflation

Under this heading are covered a group of lung conditions of heterogeneous etiology characterised by overinflation of the parts of acini but without significant destruction of the walls and are sometimes loosely termed emphysema.

1. COMPENSATORY OVERINFLATION (COMPENSATORY EMPHYSEMA) When part of a lung or a lobe of lung is

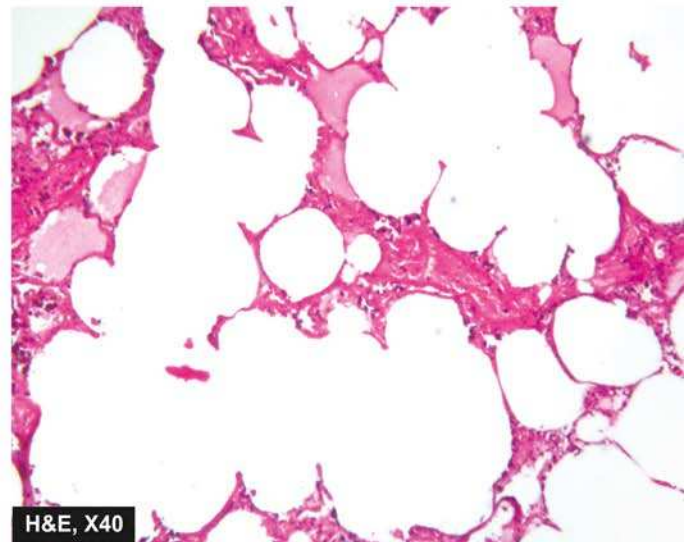

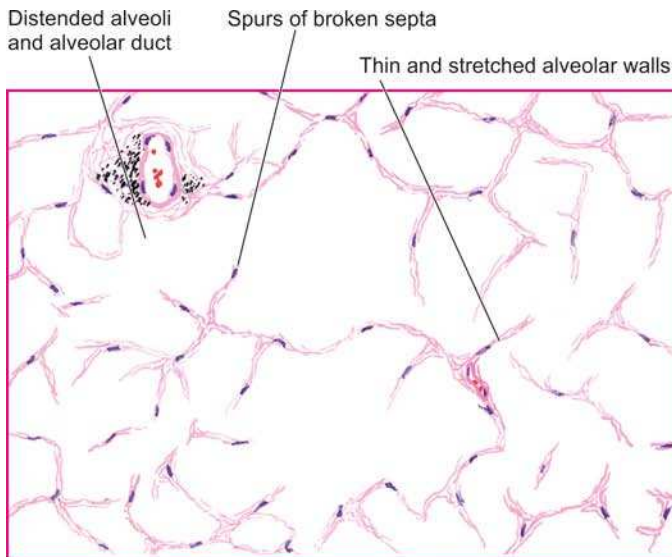

Figure 15.21 Panacinar (Panlobular) emphysema showing involvement of the entire lobules and whole of acinus.

surgically removed, the residual lung parenchyma undergoes compensatory hyperinflation so as to fill the pleural cavity. Histologic examination shows dilatation of alveoli but no destruction of septal walls and hence the term compensatory overinflation is preferable over 'compensatory emphysema.'

2. SENILE HYPERINFLATION (AGEING LUNG, SENILE EMPHYSEMA) In old people, the lungs become voluminous due to loss of elastic tissue, thinning and atrophy of the alveolar ducts and alveoli. The alveoli are thin-walled and distended throughout the lungs but there is no significant destruction of the septal walls and, therefore, preferable designation is 'senile hyperinflation' over 'senile emphysema.'

3. OBSTRUCTIVE OVERINFLATION (INFANTILE LOBAR EMPHYSEMA) Partial obstruction to the bronchial tree such as by a tumour or a foreign body causes overinflation of the region supplied by obstructed bronchus. Infantile lobar emphysema is a variant of obstructive overinflation occurring in infants in the first few days of life who develop respiratory distress or who have congenital hypoplasia of bronchial cartilage. In all such cases, air enters the lungs during inspiration but cannot leave on expiration resulting in ballooning up of the affected part of the lung.

4. UNILATERAL TRANSLUCENT LUNG (UNILATERAL EMPHYSEMA) This is a form of overinflation in which one lung or one of its lobes or segments of a lobe are radiolucent. The condition occurs in adults and there is generally a history of serious pulmonary infection in childhood, probably bronchiolitis obliterans. The affected lung is grossly overinflated. Microscopy shows overinflated alveoli and there is histologic evidence of preceding widespread bronchiolitis obliterans.

5. INTERSTITIAL EMPHYSEMA (SURGICAL EMPHYSEMA) The entry of air into the connective tissue framework of the lung is called interstitial or surgical emphysema. The usual sources of entry of air into stroma of the lung are rupture of alveoli or of larger airways. The causes are as under:

i) Violent coughing with bronchiolar obstruction e.g. in children with whooping cough, bronchitis, in patients with obstruction to the airways by foreign bodies, blood clots and exposure to irritant gases.

- ii) Rupture of the oesophagus, trauma to the lung, or major bronchus and trachea.
- iii) Entry of air through surgical incision.
- iv) Fractured rib puncturing the lung parenchyma.
- v) Sudden change in atmospheric pressure e.g. in decompression sickness.

The condition may affect patients of all ages. On rupture of alveoli, the leaked air enters the fibrous connective tissue of the alveolar walls from where it extends into the fibrous septa of the lung, into the mediastinum, the pleura, and even the subcutaneous tissues. Escape of air into the pleural cavity may cause pneumothorax. Collection of small quantities of air is generally harmless and is resorbed. However, extensive accumulation of air in surgical emphysema may produce impaired blood flow in the lungs. *Pneumo-mediastinum* may produce symptoms resembling myocardial infarction.

Histologically, the alveoli are distended but septal walls are not damaged; therefore it is not true emphysema. There are clear spaces of leaked out air in connective tissue septa.

BRONCHIAL ASTHMA

Asthma is a disease of airways that is characterised by increased responsiveness of the tracheobronchial tree to a variety of stimuli resulting in widespread spasmodic narrowing of the air passages which may be relieved spontaneously or by therapy. Asthma is an episodic disease manifested clinically by paroxysms of dyspnoea, cough and wheezing. However, a severe and unremitting form of the disease termed *status asthmaticus* may prove fatal.

Bronchial asthma is common and prevalent worldwide; in the United States about 4% of population is reported to suffer from this disease. It occurs at all ages but nearly 50% of cases develop it before the age of 10 years. In adults, both sexes are affected equally but in children there is 2:1 male-female ratio.

ETIOPATHOGENESIS AND TYPES Based on the stimuli initiating bronchial asthma, two broad etiologic types are traditionally described: *extrinsic (allergic, atopic)* and *intrinsic (idiosyncratic, non-atopic) asthma*. A third type is a *mixed*

Table 15.6 Contrasting features of the two major types of asthma.

| FEATURE | EXTRINSIC ASTHMA | INTRINSIC ASTHMA |
|--|--|------------------------------|
| 1. Age at onset | In childhood | In adult |
| 2. Personal/family history | Commonly present | Absent |
| 3. Preceding allergic illness (atopy) | Present (e.g. rhinitis, urticaria, eczema) | Absent |
| 4. Allergens | Present (dust, pollens, danders etc) | None |
| 5. Drug hypersensitivity | None | Present (usually to aspirin) |
| 6. Serum IgE level | Elevated | Normal |
| 7. Associated chronic bronchitis, nasal polyps | Absent | Present |
| 8. Emphysema | Unusual | Common |

pattern in which the features do not fit clearly into either of the two main types. The contrasting features of the two main types are summed up in Table 15.6.

1. Extrinsic (atopic, allergic) asthma This is the most common type of asthma. It usually begins in childhood or in early adult life. Most patients of this type of asthma have personal and/or family history of preceding allergic diseases such as rhinitis, urticaria or infantile eczema. Hypersensitivity to various extrinsic antigenic substances or 'allergens' is usually present in these cases. Most of these allergens cause ill-effects by inhalation e.g. house dust, pollens, animal danders, moulds etc. Occupational asthma stimulated by fumes, gases and organic and chemical dusts is a variant of extrinsic asthma. There is increased level of IgE in the serum and positive skin test with the specific offending inhaled antigen representing an IgE-mediated type I hypersensitivity reaction which includes an 'acute immediate response' and a 'late phase reaction':

◆ *Acute immediate response* is initiated by IgE-sensitised mast cells (tissue counterparts of circulating basophils) on the mucosal surface. Mast cells on degranulation release mediators like histamine, leukotrienes, prostaglandins, platelet activating factor and chemotactic factors for eosinophils and neutrophils. The net effects of these mediators are bronchoconstriction, oedema, mucus hypersecretion and accumulation of eosinophils and neutrophils.

◆ *Late phase reaction* follows the acute immediate response and is responsible for the prolonged manifestations of asthma. It is caused by excessive mobilisation of blood leucocytes that include basophils besides eosinophils and neutrophils. These result in further release of mediators which accentuate the above-mentioned effects. In addition, inflammatory injury is caused by neutrophils and by major basic protein (MBP) of eosinophils.

2. Intrinsic (idiosyncratic, non-atopic) asthma This type of asthma develops later in adult life with negative personal or family history of allergy, negative skin test and normal serum levels of IgE. Most of these patients develop typical symptom-complex after an upper respiratory tract infection by viruses. Associated nasal polypi and chronic bronchitis are commonly present. There are no recognisable allergens but about 10% of patients become hypersensitive to drugs, most notably to small doses of aspirin (aspirin-sensitive asthma).

3. Mixed type Many patients do not clearly fit into either of the above two categories and have mixed features of both. Those patients who develop asthma in early life have strong allergic component, while those who develop the disease late tend to

be non-allergic. Either type of asthma can be precipitated by cold, exercise and emotional stress.

MORPHOLOGIC FEATURES The pathologic changes are similar in both major types of asthma. The pathologic material examined is generally autopsy of lungs in patients dying of status asthmaticus but the changes are expected to be similar in non-fatal cases.

Grossly, the lungs are overdistended due to over-inflation. The cut surface shows characteristic occlusion of the bronchi and bronchioles by viscid mucus plugs.

Microscopically, the following changes are observed (Fig. 15.22):

1. The mucus plugs contain normal or degenerated respiratory epithelium forming twisted strips called *Curschmann's spirals*.
2. The sputum usually contains numerous eosinophils and diamond-shaped crystals derived from eosinophils called *Charcot-Leyden crystals*.
3. The bronchial wall shows thickened basement membrane of the bronchial epithelium, submucosal oedema and inflammatory infiltrate consisting of lymphocytes and plasma cells with prominence of eosinophils. There is hypertrophy of submucosal glands as well as of the bronchial smooth muscle.
4. Changes of bronchitis and emphysema may supervene, especially in intrinsic asthma.

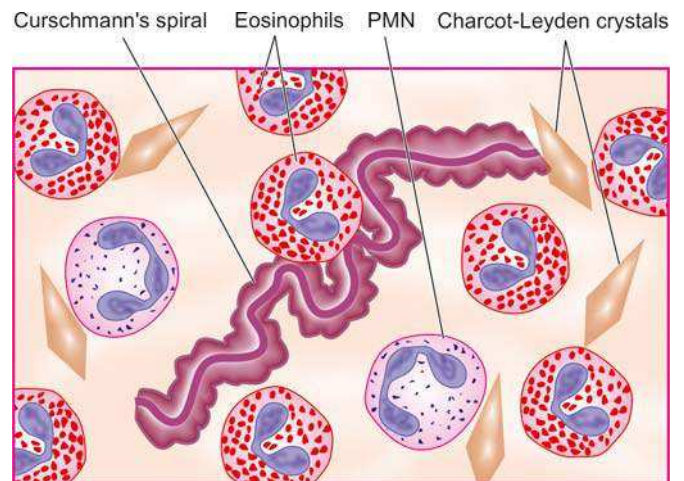

Figure 15.22 Diagrammatic appearance of Curschmann's spiral and Charcot-Leyden crystals found in mucus plugs in patients with bronchial asthma.

CLINICAL FEATURES Asthmatic patients suffer from episodes of acute exacerbations interspersed with symptom-free periods. Characteristic clinical features are paroxysms of dyspnoea, cough and wheezing. Most attacks typically last for a few minutes to hours. When attacks occur continuously, it may result in more serious condition called *status asthmaticus*. The clinical diagnosis is supported by demonstration of circulation eosinophilia and sputum demonstration of Curschmann's spirals and Charcot-Leyden crystals. More chronic cases may develop cor pulmonale.

BRONCHIECTASIS

Bronchiectasis is defined as abnormal and irreversible dilatation of the bronchi and bronchioles (greater than 2 mm in diameter) developing secondary to inflammatory weakening of the bronchial walls. The most characteristic clinical manifestation of bronchiectasis is persistent cough with expectoration of copious amounts of foul-smelling, purulent sputum. Post-infectious cases commonly develop in childhood and in early adult life.

ETIOPATHOGENESIS The origin of inflammatory destructive process of bronchial walls is nearly always a result of two basic mechanisms: endobronchial obstruction and infection.

◆ *Endobronchial obstruction* by foreign body, neoplastic growth or enlarged lymph nodes causes resorption of air distal to the obstruction with consequent atelectasis and retention of secretions.

◆ *Infection* may be secondary to local obstruction and impaired systemic defense mechanism promoting bacterial growth, or infection may be a primary event i.e. bronchiectasis developing in suppurative necrotising pneumonia.

These 2 mechanisms—endobronchial obstruction and infection, are seen in a number of clinical settings as under:

1. Hereditary and congenital factors Several hereditary and congenital factors may result secondarily in diffuse bronchiectasis:

- i) *Congenital bronchiectasis* caused by developmental defect of the bronchial system.
- ii) *Cystic fibrosis*, a generalised defect of exocrine gland secretions, results in obstruction, infection and bronchiectasis (page 631).
- iii) *Hereditary immune deficiency diseases* are often associated with high incidence of bronchiectasis.
- iv) *Immotile cilia syndrome* that includes Kartagener's syndrome (bronchiectasis, situs inversus and sinusitis) is characterised by ultrastructural changes in the microtubules causing immotility of cilia of the respiratory tract epithelium, sperms and other cells. Males in this syndrome are often infertile (page 692).
- v) *Atopic bronchial asthma* patients have often positive family history of allergic diseases and may rarely develop diffuse bronchiectasis.

2. Obstruction Post-obstructive bronchiectasis, unlike the congenital-hereditary forms, is of the localised variety, usually confined to one part of the bronchial system. The causes of endobronchial obstruction include foreign bodies, endobronchial tumours, compression by enlarged hilar lymph nodes and post-inflammatory scarring (e.g. in healed tuberculosis) all of which favour the development of post-obstructive bronchiectasis.

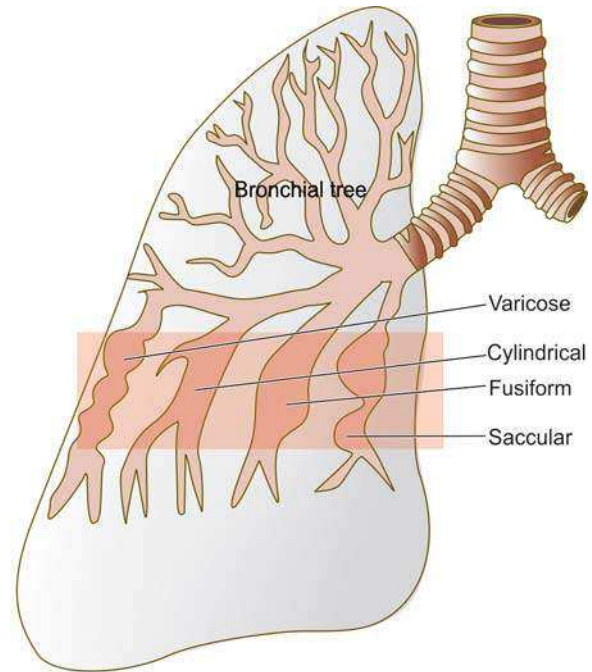

Figure 15.23 Types of bronchial dilatations in bronchiectasis.

3. As secondary complication *Necrotising pneumonias* such as in staphylococcal suppurative pneumonia and *tuberculosis* may develop bronchiectasis as a complication.

MORPHOLOGIC FEATURES The disease characteristically affects distal bronchi and bronchioles beyond the segmental bronchi.

Grossly, the lungs may be involved diffusely or segmentally. Bilateral involvement of lower lobes occurs most frequently. More vertical air passages of left lower lobe are more often involved than the right. The pleura is usually fibrotic and thickened with adhesions to the chest wall. The dilated airways, depending upon their gross or bronchographic appearance, have been subclassified into the following different types (**Fig. 15.23**):

- i) *Cylindrical*: the most common type characterised by tube-like bronchial dilatation.
- ii) *Fusiform*: having spindle-shaped bronchial dilatation.
- iii) *Saccular*: having rounded sac-like bronchial distension.
- iv) *Varicose*: having irregular bronchial enlargements.

Cut surface of the affected lobes, generally the lower zones, shows characteristic honey-combed appearance. The bronchi are extensively dilated nearly to the pleura, their walls are thickened and the lumina are filled with mucus or mucopus. The intervening lung parenchyma is reduced and fibrotic (**Fig. 15.24**).

Microscopically, fully-developed cases show the following histologic features (**Fig. 15.25**):

- i) The bronchial epithelium may be normal, ulcerated or may show squamous metaplasia.
- ii) The bronchial wall shows infiltration by acute and chronic inflammatory cells and destruction of normal muscle and elastic tissue with replacement by fibrosis.
- iii) The intervening lung parenchyma shows fibrosis, while the surrounding lung tissue shows changes of interstitial pneumonia.

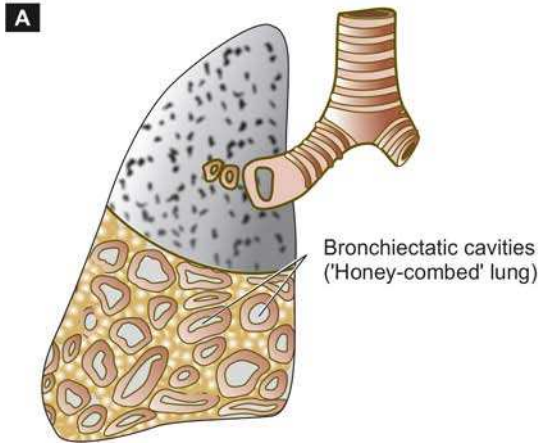

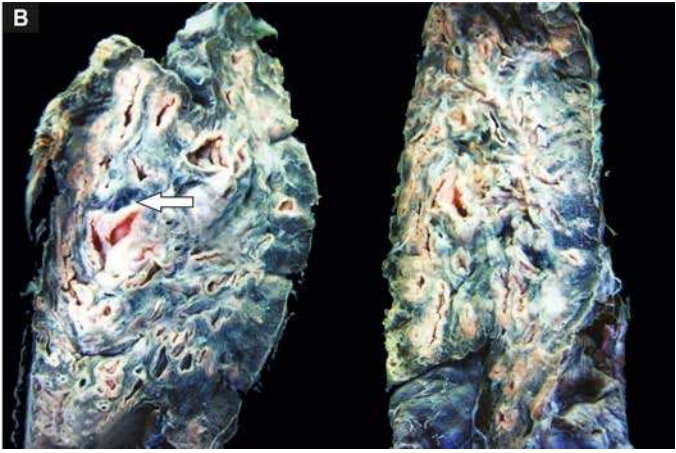

Figure 15.24 Bronchiectasis of the lung. Sectioned surface shows honey-combed appearance of the lung in the lower lobe where many thick-walled dilated cavities with cartilaginous wall are seen (arrow).

iv) The pleura in the affected area is adherent and shows bands of fibrous tissue between the bronchus and the pleura.

CLINICAL FEATURES The clinical manifestations of bronchiectasis typically consist of chronic cough with foul-smelling sputum production, haemoptysis and recurrent pneumonia. Sinusitis is a common accompaniment of diffuse bronchiectasis. Late complications occurring in cases uncontrolled for years include development of clubbing of the fingers, metastatic abscesses (often to the brain), amyloidosis and cor pulmonale.

SMALL AIRWAYS DISEASE

Bronchiolitis and bronchiolitis obliterans are the inflammatory conditions affecting the small airways occurring predominantly in older paediatric age group and in quite elderly persons. A number of etiologic factors have been stated to cause this condition. These include viral infection (frequently adenovirus and respiratory syncytial virus),

bacterial infection, fungal infection, inhalation of toxic gases (e.g. in silo-fillers' disease) and aspiration of gastric contents.

Microscopically, the lumina of affected bronchioles are narrow and occluded by fibrous plugs. The bronchiolar walls are inflamed and are infiltrated by lymphocytes and plasma cells. There are changes of interstitial pneumonitis and fibrosis in the alveoli around the affected bronchioles.

GIST BOX 15.5

Chronic Obstructive Pulmonary Disease (COPD)

- ☐ COPD are a group of pathological conditions having chronic, partial or complete, obstruction to the airflow at any level from trachea to the smallest airways.
- ☐ Most common types of COPD are chronic bronchitis and emphysema and quite frequently both coexist.
- ☐ The two most important etiologic factors responsible in chronic bronchitis and emphysema are cigarette smoking and atmospheric pollution.

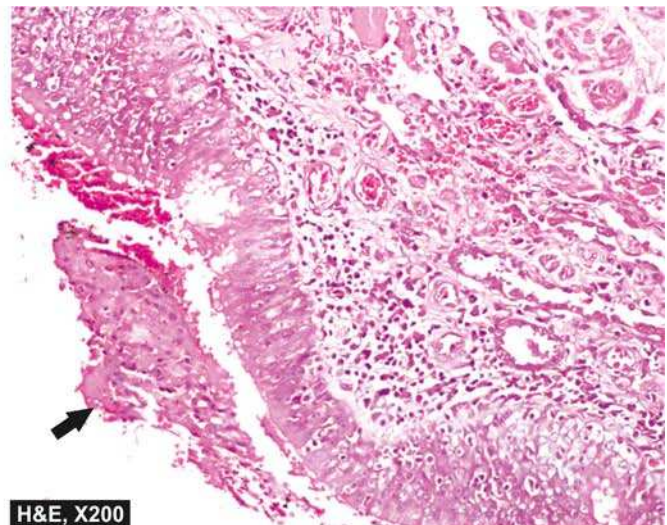

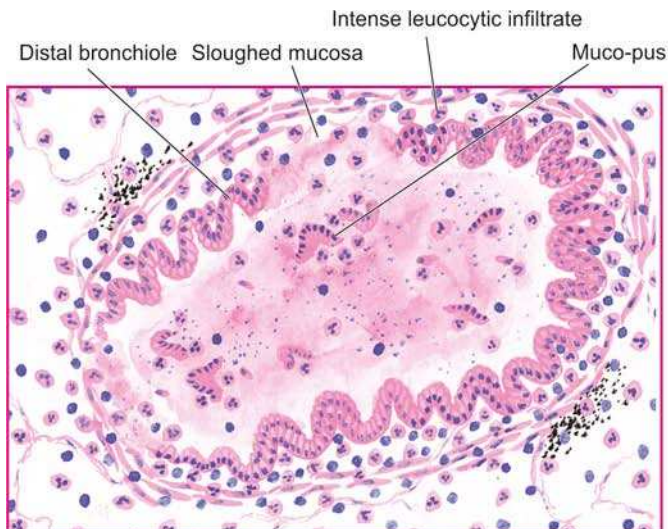

Figure 15.25 Microscopic appearance of a dilated distal bronchiole in bronchiectasis. The bronchial wall is thickened and infiltrated by acute and chronic inflammatory cells. The mucosa is sloughed off at places with exudate of muco-pus in the lumen (arrow).

- ☐ Chronic bronchitis is defined *clinically* as persistent cough with expectoration on most days for at least three months of the year for two or more consecutive years.
- ☐ Emphysema is linked to deficiency of serum α -1-antitrypsin, commonly termed protease-antiprotease hypothesis.
- ☐ In asthma, there is widespread narrowing of the air passage causing bronchospasm.
- ☐ Asthma may be due to allergy (extrinsic) or may occur following viral infection (intrinsic).
- ☐ Bronchiectasis is abnormal and irreversible dilatation of the bronchi and bronchioles (greater than 2 mm in diameter).
- ☐ Bronchiolitis and bronchiolitis obliterans are the inflammatory conditions affecting the small airways occurring predominantly in older paediatric age.

CHRONIC RESTRICTIVE PULMONARY DISEASE

The second large group of diffuse lung disease is 'chronic restrictive pulmonary disease' characterised by reduced expansion of lung parenchyma with decreased total lung capacity. This group of diseases must be distinguished from the foregoing COPD (Table 15.7).

Restrictive lung disease includes 2 types of conditions:

A. Restriction due to chest wall disorder It includes following conditions:

1. Kyphoscoliosis
2. Poliomyelitis
3. Severe obesity
4. Pleural diseases.

As a group, these conditions cause restriction to expansion of lungs due to alterations in chest wall, pleura and neuromuscular apparatus, but are primarily not lung parenchymal diseases.

B. Restriction due to interstitial and infiltrative diseases

Commonly called as '*interstitial lung diseases (ILDs)*', these are diseases characterised by non-infectious diffuse parenchymal involvement of the lung i.e. the alveolar lumina and alveolar epithelium, capillary basement membrane, the intervening space, perivascular tissue and lymphatic tissue. Diffuse lung parenchymal involvement may be primary, or it may be involved secondarily as a part of some other multi-organ disease process. The term 'infiltrative' is used here to denote the radiologic appearance of lungs in chest radiographs which

show characteristic diffuse interstitial ground-glass opacities. The ILDs consist of more than 200 heterogeneous conditions which have common clinical, radiologic, and functional manifestations but diverse pathological features. As a group, ILDs have high mortality and morbidity. Depending upon the underlying pathologic findings, ILDs have been broadly classified into 2 groups, each further subdivided into those with known and unknown causes:

- ◆ Conditions with predominant non-specific inflammation (alveolitis, interstitial inflammation, and fibrosis).
- ◆ Conditions with predominant granulomatous inflammation.

Based on this, an abbreviated classification of ILDs is given in Table 15.8.

The exact **pathogenesis** of ILDs from injury to fibrosis is not known. However, it can be explained on immune basis as under (Fig. 15.26):

- i) In response to various exogenous and endogenous stimuli, there is *local inflammatory reaction* in the alveoli in the form of lymphocytes (both B and T) and macrophages.
- ii) Activated macrophages cause recruitment of neutrophils and also produce fibrogenic and chemotactic *cytokines*. Neutrophils liberate proteases and oxidants which injure the type I pneumocytes resulting in initial microscopic alveolitis, while cytokines cause subsequent proliferation of type II pneumocytes and fibrosis.
- iii) The result is *inflammatory destruction* of the pulmonary parenchyma followed by fibrosis. Eventually, there is widespread destruction of alveolar capillary walls resulting in end-stage lung or 'honeycomb lung'.

The **major common clinical manifestations** of restrictive lung diseases are exertional dyspnoea, non-persistent productive cough, tachypnoea, cyanosis and sometimes haemoptysis but no wheezing so characteristic of COPD.

Important and common examples of ILDs are discussed below.

PNEUMOCONIOSES

Pneumoconiosis is the term used for lung diseases caused by inhalation of dust, mostly at work (*pneumo* = lung; *conis* = dust in Greek). These diseases are, therefore, also called 'dust diseases' or 'occupational lung diseases'.

The type of lung disease varies according to the nature of inhaled dust. Some dusts are inert and cause no reaction and no damage at all, while others cause immunologic damage

Table 15.7 Obstructive versus restrictive pulmonary diseases.

| FEATURE | OBSTRUCTIVE | RESTRICTIVE |
|----------------------------|---|---|
| 1. Airways | Obstructed at any level from trachea to respiratory bronchiole | Reduced expansion of lung parenchyma |
| 2. Pulmonary function test | Increased pulmonary resistance and obstruction of maximal expiratory airflow | Decreased total lung capacity |
| 3. X-ray chest | Variable appearance depending upon the cause | Typically bilateral infiltrates giving ground-glass shadows |
| 4. Examples | <ul style="list-style-type: none"> • Chronic bronchitis • Emphysema • Bronchial asthma • Bronchiectasis | <ul style="list-style-type: none"> • Chest cage disorders (e.g. kyphoscoliosis, poliomyelitis, severe obesity and pleural disease) • Interstitial lung diseases (ILDs) (e.g. pneumoconioses, idiopathic pulmonary fibrosis, immunologic lung diseases, collagen-vascular disease and sarcoidosis) |

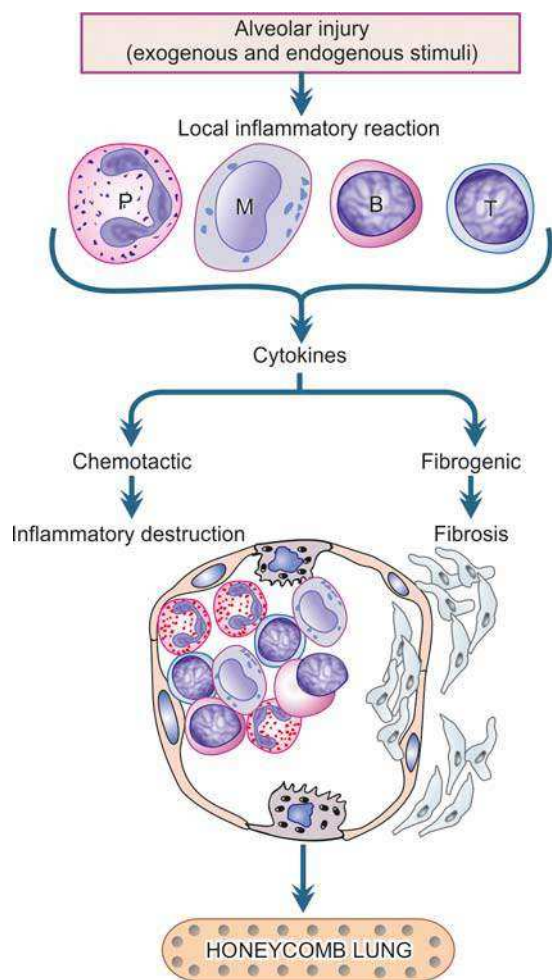

Figure 15.26 Schematic evolution of interstitial lung disease (ILD).

and predispose to tuberculosis or to neoplasia. The factors which determine the extent of damage caused by inhaled dusts are as under:

1. size and shape of the particles;
2. their solubility and physicochemical composition;
3. the amount of dust retained in the lungs;
4. the additional effect of other irritants such as tobacco smoke; and
5. host factors such as efficiency of clearance mechanism and immune status of the host.

In general, most of the inhaled dust particles larger than $5\ \mu\text{m}$ reach the terminal airways where they are ingested by alveolar macrophages. Most of these too are eliminated by expectoration but the remaining accumulate in alveolar tissue. Of particular interest are the particles smaller than $1\ \mu\text{m}$ which are deposited in the alveoli most efficiently. Most of the dust-laden macrophages accumulated in the alveoli die leaving the dust, around which fibrous tissue is formed. Some macrophages enter the lymphatics and reach regional lymph nodes. The tissue response to inhaled dust may be one of the following three types:

- ◆ *Fibrous nodules* e.g. in coal-workers' pneumoconiosis and silicosis.
- ◆ *Interstitial fibrosis* e.g. in asbestosis.
- ◆ *Hypersensitivity reaction* e.g. in berylliosis.

Table 15.8 Classification of interstitial lung diseases (ILDs).

- I. WITH PREDOMINANT FIBROSIS
 1. Pneumoconiosis with inorganic minerals: coal, asbestos, fumes, gases
 2. Idiopathic pulmonary fibrosis (Idiopathic interstitial pneumonias)
 3. Nonspecific interstitial pneumonia
 4. Acute interstitial pneumonia (Hamman-Rich syndrome)
 5. Cryptogenic organising pneumonia
 6. Therapy related-ILD (radiation, antibiotics, chemotherapy)
 7. Connective tissue diseases
 8. Residual effects of ARDS
- II. WITH PREDOMINANT GRANULOMATOUS REACTION
 1. Sarcoidosis (page 154)
 2. Pneumoconiosis with inorganic dusts: silica, beryllium
 3. Granulomatous vasculitis (page 384)
 4. Wegener's granulomatosis (page 383)
- III. IMMUNOLOGIC LUNG DISEASES (EOSINOPHILIC PNEUMONIAS)
 1. Hypersensitivity pneumonitis: with organic dusts
 2. Pulmonary infiltrates with eosinophilia (PIE)
 3. Pulmonary haemorrhage syndromes (Goodpasture's syndrome)
 4. Pulmonary alveolar proteinosis
- IV. SMOKING-ASSOCIATED ILDs
 1. Desquamative interstitial pneumonia (DIP)
 2. Respiratory bronchiolitis-associated ILD
 3. Pulmonary Langerhans cell histiocytosis (eosinophilic granuloma of the lung)

A comprehensive list of various types of occupational lung diseases caused by inorganic (mineral) dusts and organic dusts is presented in **Table 15.9**. The more common examples of pneumoconioses are described here.

COAL-WORKERS' PNEUMOCONIOSIS

This is the commonest form of pneumoconiosis and is defined as the lung disease resulting from inhalation of coal dust particles, especially in coal-miners engaged in handling soft bituminous coal for a number of years, often 20 to 30 years. It exists in 2 forms—a milder form of the disease called *simple coal workers' pneumoconiosis* and an advanced form termed *progressive massive fibrosis* (complicated coal-miners' pneumoconiosis). *Anthracosis*, on the other hand, is not a lung disease in true sense but is the common, benign and asymptomatic accumulation of carbon dust in the lungs of most urban dwellers due to atmospheric pollution and cigarette smoke (*anthracite* refers to coal). Anthracotic pigment is deposited in the macrophages in the alveoli and around the respiratory bronchioles and into the draining lymph nodes but does not produce any respiratory difficulty or radiologic changes.

PATHOGENESIS Anthracosis, simple coal-workers' pneumoconiosis and progressive massive fibrosis are different stages

Table 15.9 Classification of pneumoconioses.

| AGENT | DISEASES |
|------------------------------|--|
| A. INORGANIC (MINERAL) DUSTS | |
| 1. Coal dust | Simple coal-workers' pneumoconiosis Progressive massive fibrosis Caplan's syndrome |
| 2. Silica | Silicosis Caplan's syndrome |
| 3. Asbestos | Asbestosis Pleural diseases Tumours |
| 4. Beryllium | Acute berylliosis Chronic berylliosis |
| 5. Iron oxide | Pulmonary siderosis |
| B. ORGANIC (BIOLOGIC) DUSTS | |
| 1. Mouldy hay | Farmer's lungs |
| 2. Bagasse | Bagassosis |
| 3. Cotton, flax, hemp dust | Byssinosis |
| 4. Bird droppings | Bird-breeders' (bird fancier's) lung |
| 5. Mushroom compost dust | Mushroom-workers' lung |
| 6. Mouldy barley, malt dust | Malt-workers' lung |
| 7. Mouldy maple bark | Maple-bark disease |
| 8. Silage fermentation | Silo-fillers' disease |

in the evolution of fully-developed coal-workers' pneumoconiosis. However, progressive massive fibrosis develops in a small proportion of cases (2-8%) of simple coal-workers' pneumoconiosis. A number of predisposing factors have been implicated in this transformation as follows:

1. Older age of the miners.
2. Severity of coal dust burden engulfed by macrophages.
3. Prolonged exposure (20 to 30 years) to coal dust.
4. Concomitant tuberculosis.
5. Additional role of silica dust.

Activation of alveolar macrophage plays the most significant role in the pathogenesis of progressive massive fibrosis by release of various mediators (Fig. 15.27,A):

- i) *Free radicals* which are reactive oxygen species which damage the lung parenchyma.
- ii) *Chemotactic factors* for various leucocytes (leukotrienes, TNF, IL-8 and IL-6) resulting in infiltration into pulmonary tissues by these inflammatory cells which on activation cause further damage.
- iii) *Fibrogenic cytokines* such as IL-1, TNF and platelet derived growth factor (PDGF) which stimulate healing by fibrosis due to proliferation of fibroblasts at the damaged tissue site.

MORPHOLOGIC FEATURES In life, the pathologic changes in lung in coal-workers' pneumoconiosis are graded by radiologic appearance according to the size and extent of opacities. The pathologic findings at autopsy of lungs in the major forms of coal-workers' pneumoconiosis are considered below under 3 headings: simple coal-workers' pneumoconiosis, progressive massive fibrosis and rheumatoid pneumoconiosis (Caplan's syndrome).

SIMPLE COAL-WORKERS' PNEUMOCONIOSIS *Grossly*, the lung parenchyma shows small, black focal lesions, measuring less than 5 mm in diameter and evenly distributed throughout the lung but have a tendency to be more numerous in the upper lobes. These are termed *coal macules*, and if palpable are called *nodules*. The air spaces around coal macules are dilated with little destruction of alveolar walls (Fig. 15.27,A). Though some workers have called it centrilobular emphysema of coal-miners (page 461), others prefer not to consider it emphysema because there is no significant destruction of alveolar walls. Similar blackish pigmentations are found on the pleural surface and in the regional lymph nodes (Fig. 15.28).

Histologically, the following features are seen (Fig. 15.29):

1. Coal macules are composed of aggregates of dust-laden macrophages. These are present in the alveoli and in the bronchiolar and alveolar walls.
2. There is some increase in the network of reticulin and collagen in the coal macules.
3. Respiratory bronchioles and alveoli surrounding the macules are distended without significant destruction of the alveolar walls.

PROGRESSIVE MASSIVE FIBROSIS *Grossly*, besides the coal macules and nodules of simple pneumoconiosis, there are larger, hard, black scattered areas measuring more than 2 cm in diameter and sometimes massive. They are usually bilateral and located more often in the upper parts of the lungs posteriorly. Sometimes, these masses break down centrally due to ischaemic necrosis or due to tuberculosis forming cavities filled with black semifluid resembling India ink. The pleura and the regional lymph nodes are also blackened and fibrotic (Fig. 15.28).

Histologically, the following features are present:

1. The fibrous lesions are composed almost entirely of dense collagen and carbon pigment.
2. The wall of respiratory bronchioles and pulmonary vessels included in the massive scars are thickened and their lumina obliterated.
3. There is scanty inflammatory infiltrate of lymphocytes and plasma cells around the areas of massive scars.
4. The alveoli surrounding the scars are markedly dilated.

Progressive massive fibrosis probably has immunological pathogenetic basis as described above.

RHEUMATOID PNEUMOCONIOSIS (CAPLAN'S SYNDROME) The development of rheumatoid arthritis in a few cases of coal-workers' pneumoconiosis, silicosis or asbestosis is termed rheumatoid pneumoconiosis or Caplan's syndrome.

Grossly, the lungs have rounded, firm nodules with central necrosis, cavitation or calcification.

Histologically, the lung lesions are modified rheumatoid nodules with central zone of dust-laden fibrinoid necrosis enclosed by palisading fibroblasts and mononuclear cells.

The lung lesions in Caplan's syndrome have immunological basis for their origin as evidenced by detection of rheumatoid factor and antinuclear antibodies.

CLINICAL FEATURES Simple coal-workers' pneumoconiosis is the mild form of disease characterised by chronic cough with black expectoration. The radiological findings

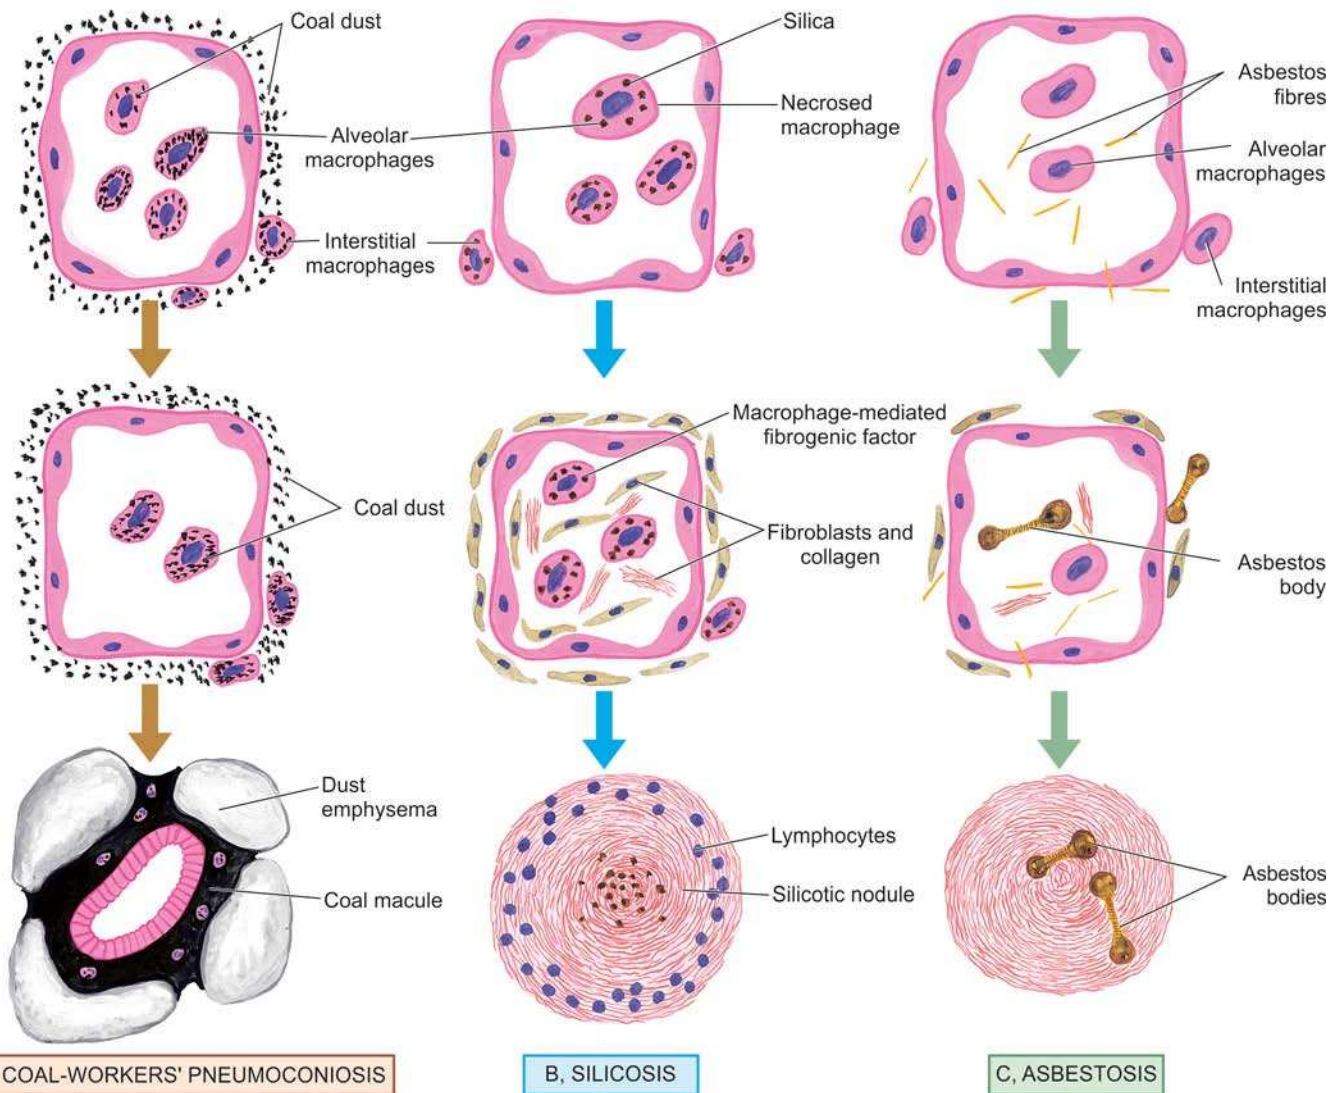

Figure 15.27 Pathogenesis of three common forms of pneumoconiosis. **A, Coal-workers' pneumoconiosis.** The macrophages phagocytose large amount of coal dust particles which are then passed into the interstitial tissue of the lung and aggregate around respiratory bronchiole and cause focal dust emphysema. **B, Silicosis.** The tiny silica particles are toxic to macrophages. The dead macrophages release fibrogenic factor and eventually result in silicotic nodule. **C, Asbestosis.** Asbestos fibres initiate lot of interstitial fibrosis and also form asbestos bodies.

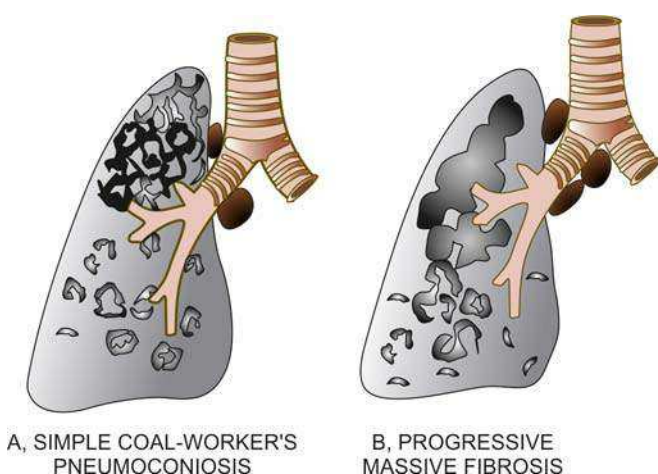

Figure 15.28 Gross appearance of the lungs in simple coal-workers' pneumoconiosis (A) and progressive massive fibrosis (B).

of nodularities in the lungs appear after working for several years in coal-mines. Progressive massive fibrosis is, however, a serious disabling condition manifested by progressive dyspnoea and chronic cough with jet-black sputum. Recurrent bacterial infections may produce purulent sputum. More advanced cases develop pulmonary hypertension and right ventricular hypertrophy (cor pulmonale). The radiological appearance may suggest tuberculosis or cancer. Tuberculosis and rheumatoid arthritis are more common in coal miners than the general population. Coal workers have increased risk of developing carcinomas of the stomach, probably due to swallowing of coal dust containing carcinogens. But bronchogenic carcinoma does not appear to be more common in coal-miners than in other groups.

SILICOSIS

Historically, silicosis used to be called 'knife grinders' lung. Silicosis is caused by prolonged inhalation of silicon dioxide,

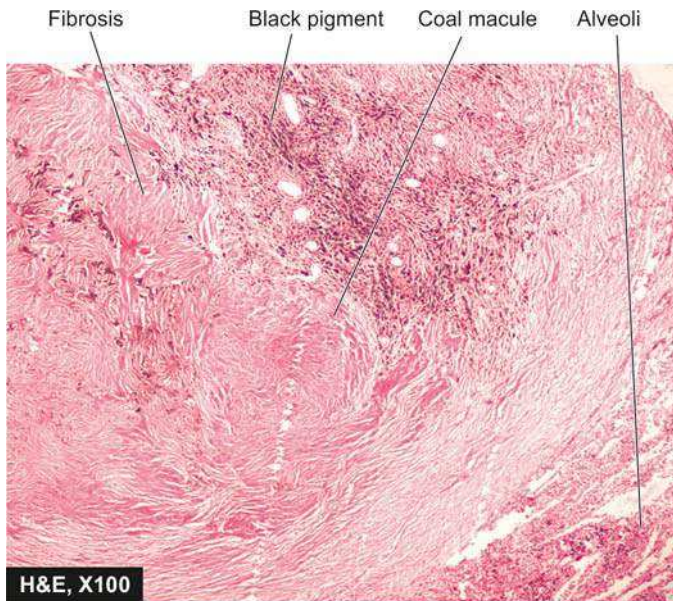

Figure 15.29 Histologic appearance of the lung in coal-workers' pneumoconiosis. Coal macules composed of aggregates of dust-laden macrophages and collagens are seen surrounding respiratory bronchioles. The alveoli and respiratory bronchioles surrounding the coal macule are distended.

commonly called silica. Silica constitutes about one-fourth of earth's crust. Therefore, a number of occupations engaged in siliceous rocks or sand and products manufactured from them are at increased risk. These include miners (e.g. of granite, sandstone, slate, coal, gold, tin and copper), quarry workers, tunnellers, sandblasters, grinders, ceramic workers, foundry workers and those involved in the manufacture of abrasives containing silica. Peculiar to India are the occupational exposure to pencil, slate and agate-grinding industry carrying high risk of silicosis (agate = very hard stone containing silica). According to an Indian Council of Medical Research report, it is estimated that about 3 million workers in India are at high potential risk of silica exposure employed in a variety of occupations including construction workers. An infrequent acute form of silicosis called *accelerated silicosis* produces irregular fibrosis adjoining the alveoli which is filled with lipoproteinaceous exudate and resembles alveolar proteinosis (page 475). However, if not specified, silicosis refers to the common *chronic form* of the disease characterised by formation of small collagenous silicotic nodules.

PATHOGENESIS Silicosis appears after prolonged exposure to silica dust, often a few decades. Besides, it depends upon a number of other factors such as total dose, duration of exposure, the type of silica inhaled and individual host factors. The mechanisms involved in the formation of silicotic nodules are not clearly understood. The following sequence of events has been proposed and schematically illustrated in **Fig. 15.27, B**:

1. Silica particles between 0.5 to 5 μm size on reaching the alveoli are taken by the macrophages which undergo necrosis. New macrophages engulf the debris and thus a repetitive cycle of *phagocytosis and necrosis* is set up.
2. Some silica-laden macrophages are carried to the respiratory bronchioles, alveoli and in the interstitial tissue. Some of the silica dust is transported to the subpleural and interlobar lymphatics and into the regional lymph nodes. The

cellular aggregates containing silica become associated with lymphocytes, plasma cells, mast cells and fibroblasts.

3. Silica dust is *fibrogenic*. Crystalline form, particularly quartz, is more fibrogenic than non-crystalline form of silica.
4. Simultaneously, there is *activation of T and B lymphocytes*. This results in increased serum levels of immunoglobulins (IgG and IgM), antinuclear antibodies, rheumatoid factor and circulating immune complexes as well as proliferation of T cells.
5. As noted above, silica is *cytotoxic* and kills the macrophages which engulf it. The released silica dust activates viable macrophages leading to secretion of macrophage-derived growth factors such as interleukin-1 that favour fibroblast proliferation and collagen synthesis.

MORPHOLOGIC FEATURES *Grossly*, the chronic silicotic lung is studded with well-circumscribed, hard, fibrotic nodules, 1 to 5 mm in diameters. They are scattered throughout the lung parenchyma but are initially more often located in the upper zones of the lungs. These nodular lesions frequently have simultaneous deposition of coal-dust and may develop calcification. The pleura is grossly thickened and adherent to the chest wall. There may be similar fibrotic nodules on the pleura and within the regional lymph nodes. The nodular lesions are detectable as egg-shell shadows in chest X-rays. The lesions may undergo ischaemic necrosis and develop cavitation, or be complicated by tuberculosis and rheumatoid pneumoconiosis (**Fig. 15.30**).

Histologically, the following features are observed (**Fig. 15.31**):

1. The silicotic nodules are located in the region of respiratory bronchioles, adjacent alveoli, pulmonary arteries, in the pleura and the regional lymph nodes.
2. The *silicotic nodules* consist of central hyalinised material with scanty cellularity and some amount of dust. The hyalinised centre is surrounded by concentric laminations of collagen which is further enclosed by more cellular connective tissue, dust-filled macrophages and a few lymphocytes and plasma cells. Some of these nodules may have calcium deposits.

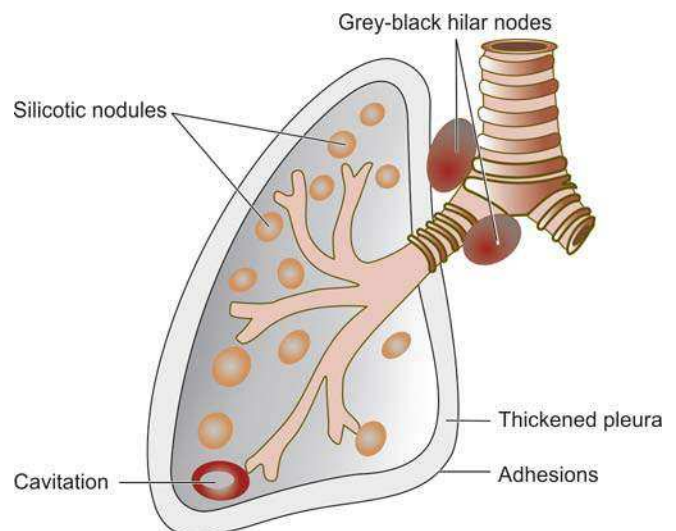

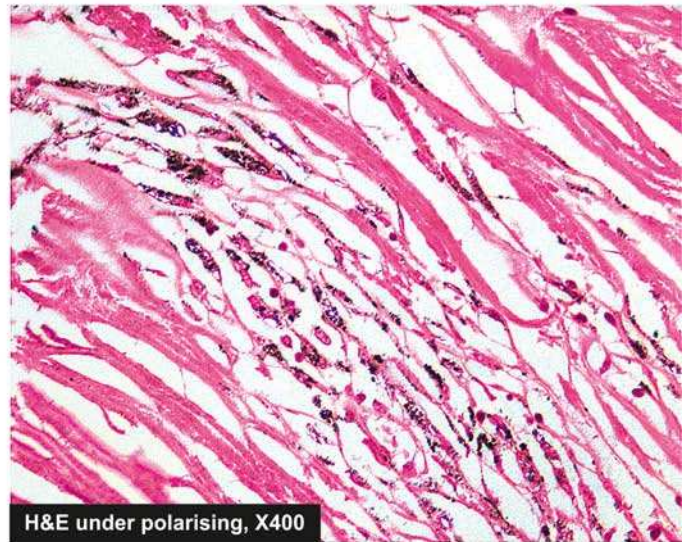

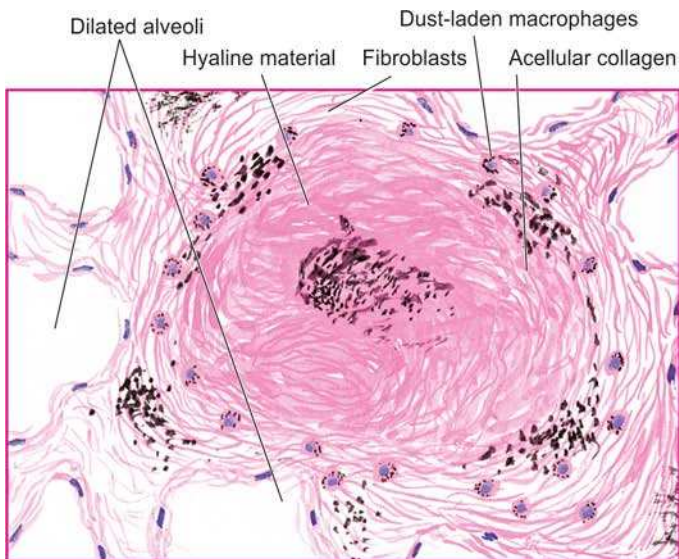

Figure 15.30 Gross appearance of the lung in silicosis, diagrammatic appearance.

H&E under polarising, X400

Figure 15.31 Microscopic picture of the lung in silicosis. The silicotic nodule consists of hyaline centre surrounded by concentric layers of collagen which are further enclosed by fibroblasts and dust-laden macrophages. Polarising microscopy in photomicrograph on right shows bright fibres of silica.

3. The collagenous nodules have cleft-like spaces between the lamellae of collagen which when examined polariscopically may demonstrate numerous birefringent particles of silica.

4. The severe and progressive form of the disease may result in coalescence of adjacent nodules and cause complicated silicosis similar to progressive massive fibrosis of coal-workers' pneumoconiosis (described above).

5. The intervening lung parenchyma may show hyperinflation or emphysema.

6. Cavitation when present may be due to ischaemic necrosis in the nodules, or may reveal changes of tuberculosis or rheumatoid pneumoconiosis (Caplan's syndrome), discussed already.

CLINICAL FEATURES The functional effects of silicosis develop slowly and insidiously. The main presenting complaint is dyspnoea. In time, the patient may develop features of obstructive or restrictive pattern of disease. Other complications such as pulmonary tuberculosis, rheumatoid arthritis (Caplan's syndrome) and cor pulmonale may occur. The chest radiograph initially shows fine nodularity, while later there are larger and coalescent nodules. Silicosis does not carry increased risk of developing bronchogenic carcinoma.

ASBESTOS DISEASE

Asbestos as a mineral is known to mankind for more than 4000 years but its harmful effects have come to light during the last few decades. Asbestos is a Greek word meaning 'unquenchable'. In general, if *coal is lot of dust and little fibrosis, asbestos is little dust and a lot of fibrosis*. Prolonged exposure for a number of years to asbestos dust produces three types of severe diseases: *asbestosis of lungs, pleural disease and tumours*. In nature, asbestos exists as long thin fibrils which are fire-resistant and can be spun into yarns and fabrics suitable for thermal and electrical insulation and has many applications in industries. Particularly at risk are workers engaged in mining, fabrication and manufacture of

a number of products from asbestos such as asbestos pipes, tiles, roofs, textiles, insulating boards, sewer and water conduits, brake lining, clutch castings etc.

There are two major geometric forms of asbestos:

- ◆ *Serpentine* consisting of curly and flexible fibres. It includes the most common chemical form *chrysotile* (white asbestos) comprising more than 90% of commercially used asbestos.

- ◆ *Amphibole* consists of straight, stiff and rigid fibres. It includes the less common chemical forms *crocidolite* (blue asbestos), *amosite* (brown asbestos), *tremolite*, *anthophyllite* and *actinolite*. However, the group of amphibole, though less common, is more important since it is associated with induction of malignant pleural tumours, particularly in association with crocidolite.

In view of long-term harmful effects of asbestos exposure, it has been mostly replaced with synthetic mineral fibres such as fiberglass in developed countries since 1975 but it continues to be used in developing countries of the world.

PATHOGENESIS Overexposure to asbestos for more than a decade may produce asbestosis of the lung, pleural lesions and certain tumours. How asbestos causes all these lesions is not clearly understood but the following mechanisms have been suggested (**Fig. 15.27,C**):

1. The inhaled asbestos fibres are *phagocytosed by alveolar macrophages* from where they reach the interstitium. Some of the engulfed dust is transported via lymphatics to the pleura and regional lymph nodes.

2. The asbestos-laden macrophages release *chemo-attractants* for neutrophils and for more macrophages, thus inciting cellular reaction around them.

3. Asbestos fibres are coated with glycoprotein and endogenous haemosiderin to produce characteristic beaded or dumbbell-shaped *asbestos bodies*.

4. All types of asbestos are *fibrogenic* and result in interstitial fibrosis. Fibroblastic proliferation may occur via macrophage-derived growth factor such as interleukin-1. Alternatively, fibrosis may occur as a reparative response to tissue injury by lysosomal enzymes released from macrophages and neutrophils or by toxic free radicals.

5. A few *immunological abnormalities* such as antinuclear antibodies and rheumatoid factor have been found in cases of asbestosis but their role in the genesis of disease is not clear.
6. Asbestos fibres are *carcinogenic*, the most carcinogenic being crocidolite. There is high incidence of bronchogenic carcinoma in asbestosis which is explained on the basis of the role of asbestos fibres as tumour promoters or by causing cell death of the airways so that it is exposed to the carcinogenic effect of cigarette smoke. The development of pleural mesothelioma in these cases is probably by carrying of asbestos fibres via lymphatics to the pleura.

MORPHOLOGIC FEATURES As stated already, over-exposure to asbestos is associated with 3 types of lesions: asbestosis, pleural disease and certain tumours.

A. ASBESTOSIS The gross pulmonary fibrosis caused by asbestos exposure and histologic demonstration of asbestos bodies on asbestos fibres is termed asbestosis.

Grossly, the affected lungs are small and firm with cartilage-like thickening of the pleura. The sectioned surface shows variable degree of pulmonary fibrosis, especially in the subpleural areas and in the bases of lungs (Fig. 15.32). The advanced cases may show cystic changes.

Histologically, the following changes are observed:

1. There is non-specific interstitial fibrosis.
2. There is presence of characteristic *asbestos bodies* in the involved areas (Fig. 15.33). These are asbestos fibres coated with glycoprotein and haemosiderin and appear beaded or dumbbell-shaped. The coating stains positively for Prussian blue reaction.
3. There may be changes of emphysema in the pulmonary parenchyma between the areas of interstitial fibrosis.
4. The involvement of hilar lymph nodes in asbestosis is not as significant as in silicosis.

B. PLEURAL DISEASE Pleural disease in asbestos exposure may produce one of the following 3 types of lesions:

1. **Pleural effusion** It develops in about 5% of asbestos workers and is usually serious type. Pleural effusion is generally accompanied by subpleural asbestosis.
2. **Visceral pleural fibrosis** Quite often, asbestosis is associated with dense fibrous thickening of the visceral pleura encasing the lung.

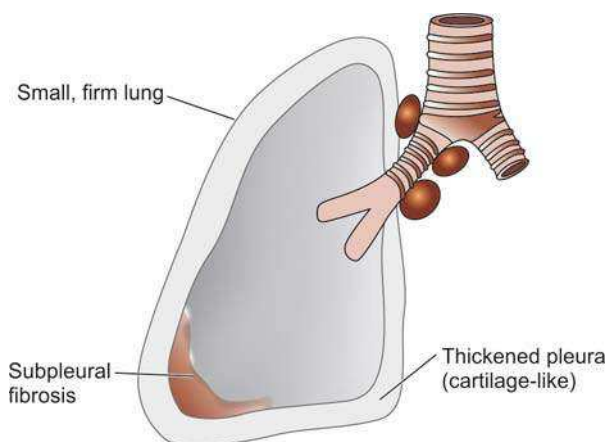

Figure 15.32 Gross appearance of the lung in asbestosis, diagrammatic appearance.

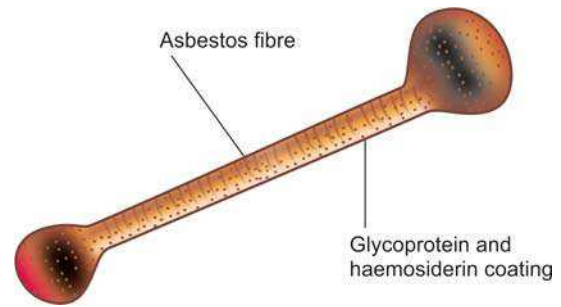

Figure 15.33 Microscopic appearance of asbestos body. An asbestos body is an asbestos fibre coated with glycoprotein and haemosiderin giving it beaded or dumbbell-shaped appearance with bulbous ends.

3. Pleural plaques Fibrocalcific pleural plaques are the most common lesions associated with asbestos exposure.

Grossly, the lesions appear as circumscribed, flat, small (upto 1 cm in diameter), firm or hard, bilateral nodules. They are seen more often on the posterolateral part of parietal pleura and on the pleural surface of the diaphragm. **Microscopically**, they consist of hyalinised collagenous tissue which may be calcified so that they are visible on chest X-ray. Asbestos bodies are generally not found within the plaques.

C. TUMOURS Asbestos exposure predisposes to a number of cancers, most importantly bronchogenic carcinoma (page 478) and malignant mesothelioma (page 486). A few others are: carcinomas of the oesophagus, stomach, colon, kidneys and larynx and various lymphoid malignancies.

1. Bronchogenic carcinoma is the most common malignancy in asbestos workers. Its incidence is 5 times higher in non-smoker asbestos workers than the non-smoker general population and 10 times higher in smoker asbestos workers than the other smokers.

2. Malignant mesothelioma is an uncommon tumour but association with asbestos exposure is present in 30 to 80% of cases with mesothelioma. The exposure need not be heavy because mesothelioma is known to develop in people living near asbestos plants or in wives of asbestos workers.

CLINICAL FEATURES Asbestosis is a slow and insidious illness. The patient may remain asymptomatic for a number of years in spite of radiological evidence of calcific pleural plaques and parenchymatous changes. However, onset of interstitial fibrosis brings about dyspnoea with dry or productive cough. More advanced cases show development of Caplan's syndrome, pulmonary hypertension, cor pulmonale and various forms of cancers.

BERYLLIOSIS

Berylliosis is caused by heavy exposure to dust or fumes of metallic beryllium or its salts. Beryllium was used in the past in fluorescent tubes and light bulbs but currently it is principally used in nuclear and aerospace industries and in the manufacture of electrical and electronic equipment. Two forms of pulmonary berylliosis are recognised—*acute* and *chronic*.

ACUTE BERYLLIOSIS Acute berylliosis occurs in individuals who are unusually sensitive to it and are heavily exposed to it

for 2 to 4 weeks. The pulmonary reaction is in the form of an exudative chemical pneumonitis in which the alveoli are filled with protein-rich fluid with formation of hyaline membrane. The patient develops sudden dyspnoea, hyperapnoea and substernal pain. Most patients recover completely.

CHRONIC BERYLLIOSIS Chronic berylliosis develops in individuals who are sensitised to it for a number of years, often after a delay of 20 or more years. The disease is a cell-mediated hypersensitivity reaction in which the metal beryllium acts as a hapten. The condition is characterised by development of non-caseating epithelioid granulomas like those of sarcoidosis. These granulomas are diffusely scattered throughout the lung parenchyma. The granulomas have giant cells which frequently contain 3 types of inclusions:

1. Birefringent crystals.
2. Concentrically-laminated haematoxyphilic Schaumann or conchoid bodies.
3. Acidophilic stellate-shaped asteroid bodies.

These inclusions are described in giant cells of granulomas in sarcoidosis too (page 155). Similar sarcoid-like granulomas can occur in other organs such as in the liver, kidneys, spleen or lymph nodes in chronic berylliosis.

ILDs ASSOCIATED WITH IMMUNOLOGIC LUNG DISEASES

HYPERSENSITIVITY (ALLERGIC) PNEUMONITIS

Hypersensitivity pneumonitis is a group of immunologically-mediated ILDs occurring in workers inhaling a variety of organic (biologic) antigenic materials. The condition may have an *acute* onset due to isolated exposure or may be *chronic* due to repeated low-dose exposure.

ETIOPATHOGENESIS A list of important organic (biologic) dusts which may be inhaled to produce hypersensitivity pneumonitis is already given in **Table 15.9**. The immunologic mechanisms underlying hypersensitivity pneumonitis from any of these causes appear to be either type III immune-complex disease or type IV delayed-hypersensitivity reaction.

1. **Farmers' lung** is the classic example resulting from exposure to thermophilic actinomycetes generated by humid and warm mouldy hay.
2. **Bagassosis** occurs in individuals engaged in manufacture of paper and cardboard from sugarcane bagasse. Spores of thermophilic actinomycetes grow rapidly in mouldy sugarcane bagasse which are inhaled.
3. **Byssinosis** is an occupational lung disease occurring in workers exposed to fibres of cotton, flax and hemp for a number of years. The role of immunologic mechanisms in byssinosis is not as clear as in exposure to other organic dusts.
4. **Bird-breeders' (Bird-fanciers') lung** occurs in pigeon breeders, parrot breeders, chicken farmers and bird-fanciers who are exposed to bird-droppings and danders from their feathers.
5. **Mushroom-workers' lung** is found in mushroom cultivators exposed to mushroom compost dust.
6. **Malt-workers' lung** is seen in distillery and brewery workers who are exposed to mouldy barley and malt dust.
7. **Maple-bark disease** occurs in those involved in stripping of maple bark and inhale mouldy maple bark (maple tree is

grown in northern hemisphere for timber and its leaf is the national emblem of Canada).

8. Silo-fillers' disease occurs in individuals who enter the *silo* (silo is an airtight store-house of fodder for farm animals) in which toxic fumes of nitric oxide and nitrogen dioxide are formed due to fermentation of silage. The condition is generally rapidly fatal; less often it may lead to ILD.

MORPHOLOGIC FEATURES The pathologic changes primarily involve the alveoli in contrast to bronchiolar involvement in asthma. The changes vary depending upon whether the biopsy is examined in early stage or in late stage.

◆ *In early stage*, the alveolar walls are diffusely infiltrated with lymphocytes, plasma cells and macrophages. A proportion of cases show granulomas consisting of histiocytes and giant cells of foreign body or Langhans' type.

◆ *In chronic cases*, the lungs show interstitial fibrosis with some inflammatory infiltrate. Honeycombing of the lung may be present.

CLINICAL FEATURES The clinical features vary according to the stage. In acute cases, there is generally sudden attack of fever, myalgia, dyspnoea, cough and leucocytosis. In more chronic cases, there are signs of slowly progressive respiratory failure, dyspnoea and cyanosis as seen in other interstitial lung diseases.

PULMONARY INFILTRATES WITH EOSINOPHILIA

Pulmonary eosinophilia, eosinophilic pneumonias or pulmonary infiltration with eosinophilia (PIE) syndrome are a group of immunologically-mediated lung diseases characterised by combination of 2 features:

- ◆ Infiltration of the lungs in chest radiographs.
- ◆ Elevated eosinophil count in the peripheral blood.

ETIOPATHOGENESIS PIE syndrome has a number of diverse causes and pathogenesis. These are as under:

1. **Löffler's syndrome** is characterised by eosinophilia in the blood and typical wandering radiologic shadows, appearing in some part of the lung for a few days, and then disappearing to appear again somewhere else in the lung. The condition is generally self-limiting and mild, associated with slight fever and a few respiratory symptoms. The etiology is unknown.
2. **Tropical pulmonary eosinophilia** is caused by the passage of larvae of worms through the lungs e.g. in filariasis, ascariasis, strongyloidosis, toxocariasis and ancylostomiasis.
3. **Secondary chronic pulmonary eosinophilia** occurs secondary to adverse drug reactions; infection with fungi, bacteria, and helminths; allergic bronchopulmonary aspergillosis and in association with asthma.
4. **Idiopathic chronic eosinophilic pneumonia** is characterised by prominent focal areas of consolidation of the lung. The condition is clinically diagnosed by excluding other known causes of pulmonary eosinophilia.
5. **Hypereosinophilic syndrome** is occurrence of eosinophilia of over 1500/ μ l for more than 6 months without any identifiable cause and without eosinophilic infiltrates in the lungs and other organs.

MORPHOLOGIC FEATURES The lesions in the lungs are similar in all cases of hypersensitivity pneumonitis.

Grossly, the lungs usually show patchy consolidation. **Microscopically**, there is thickening of the alveolar walls by oedema and exudate, chiefly of eosinophils, and some lymphocytes and plasma cells. The alveolar lumina also contain eosinophils. Occasionally, small granulomas may be present.

GOODPASTURE'S SYNDROME

Goodpasture's syndrome or pulmonary haemorrhage syndrome is combination of necrotising haemorrhagic interstitial pneumonitis and rapidly progressive glomerulonephritis. The renal lesions of Goodpasture's syndrome are described on page 655.

ETIOPATHOGENESIS The condition results from immunologic damage produced by anti-basement membrane antibodies formed against antigens common to the glomerular and pulmonary basement membranes. The trigger for initiation of this autoimmune response is not clear; it could be virus infection, exposure to hydrocarbons and smoking.

MORPHOLOGIC FEATURES **Grossly**, the lungs are heavy with red-brown areas of consolidation. **Microscopically**, the features vary according to the stage of the disease:

- ◆ *In acute stage*, there are focal areas of haemorrhages in the alveoli and focal necrosis in the alveolar walls.
- ◆ *In more chronic cases*, there is organisation of the haemorrhage leading to interstitial fibrosis and filling of alveoli with haemosiderin-laden macrophages.

CLINICAL FEATURES The condition occurs commonly in 2nd or 3rd decades of life with preponderance in males. The pulmonary manifestations generally precede the renal disease. Most cases present with haemoptysis accompanied with dyspnoea, fatigue, weakness and anaemia. Renal manifestations soon appear which include haematuria, proteinuria, uraemia and progressive renal failure.

PULMONARY ALVEOLAR PROTEINOSIS

Pulmonary alveolar proteinosis is a rare chronic disease in which the distal airspaces of the lungs are filled with granular, PAS-positive, eosinophilic material with abundant lipid in it. The condition can occur at any age from infancy to old age.

ETIOPATHOGENESIS The etiology and pathogenesis of alveolar proteinosis are unknown. A number of possibilities have been suggested:

1. Since the alveolar material is combination of lipid and protein, it is not simply an overproduction of surfactant.
2. Alveolar proteinosis may have an occupational etiology as seen in patients heavily exposed to silica.
3. It may have an etiologic association with haematologic malignancies.
4. There may be defective alveolar clearance of debris.

MORPHOLOGIC FEATURES **Grossly**, usually both lungs are involved, particularly the lower lobes. The lungs are heavier with areas of consolidation. Sectioned surface exudes abundant turbid fluid.

Histologically, the hallmark of the condition is presence of homogeneous, granular, eosinophilic material which stains brightly with PAS. Often, the material contains cholesterol clefts. There is no significant inflammatory infiltrate in the affected alveoli. Biochemically, the material consists of serum proteins of low molecular weight, cholesterol and phospholipids similar to surfactant. Electron microscopy reveals that the material consists of necrotic alveolar macrophages and desquamated alveolar epithelial cells.

CLINICAL FEATURES The condition is manifested clinically by dyspnoea, cough, chest pain, pyrexia, fatigue and loss of weight. Chest X-ray shows confluent areas of consolidation. Occasionally, alveolar proteinosis may recover spontaneously but more often it is a fatal condition.

ILDs ASSOCIATED WITH CONNECTIVE TISSUE DISEASES

A number of connective tissue diseases or collagen diseases may result in chronic interstitial fibrosis and destruction of blood vessels. These diseases are described in detail in Chapter 3 but the lung involvement in important forms of collagen diseases is briefly considered here.

1. SCLERODERMA (PROGRESSIVE SYSTEMIC SCLEROSIS) The lungs are involved in 80% cases of scleroderma. Interstitial pulmonary fibrosis is the most common form of pulmonary involvement. The disease usually involves the lower lobes and subpleural regions of the lungs and may lead to honeycombing of the lung. There is increased risk of development of cancer of the lung in pulmonary fibrosis in scleroderma.

2. RHEUMATOID ARTHRITIS Pulmonary involvement in rheumatoid arthritis may result in pleural effusion, interstitial pneumonitis, necrobiotic nodules and rheumatoid pneumoconiosis (Caplan's syndrome, page 469). The parenchymatous lesions in rheumatoid arthritis are most commonly seen in the lower lobe. Necrobiotic nodules are the most specific manifestations of rheumatoid disease and closely resemble the subcutaneous nodules commonly found in rheumatoid arthritis.

3. SYSTEMIC LUPUS ERYTHEMATOSUS Patients with systemic lupus erythematosus (SLE) commonly develop some form of lung disease during the course. The most common manifestation of SLE is pleurisy with small amount of pleural effusion that may contain LE cells. Other pulmonary lesions in SLE are interstitial pneumonitis, pulmonary haemorrhage and vasculitis.

4. SJÖGREN'S SYNDROME Patients with Sjögren's syndrome often have rheumatoid arthritis and associated pulmonary changes. Involvement of the bronchial mucous gland by a process similar to that in the salivary glands can lead to inadequate bronchial clearance and repeated infections.

5. DERMATOMYOSITIS AND POLYMYOSITIS Interstitial pneumonitis and interstitial fibrosis commonly accompany dermatomyositis and polymyositis.

6. WEGENER'S GRANULOMATOSIS Wegener's granulomatosis is an necro-inflammatory lesion having 4 components—

granulomas of the upper respiratory tract, granulomas of the lungs, systemic vasculitis (page 384) and focal necrotising glomerulonephritis. *Localised or limited form* of the disease occurs in the lungs without involvement of other organs. Pulmonary involvement is in the form of single or multiple granulomas.

Microscopically, these granulomas have foci of fibrinoid necrosis and intense infiltrate of lymphocytes, plasma cells and macrophages with scattered multinucleate giant cells. Besides necrotising granulomas, there is associated vasculitis.

IDIOPATHIC PULMONARY FIBROSIS

Idiopathic pulmonary fibrosis is the most common form of diffuse interstitial pneumonia and has bad prognosis compared with other forms of lung fibrosis. Diffuse interstitial fibrosis can occur as a result of a number of pathologic entities such as pneumoconiosis, hypersensitivity pneumonitis and collagen-vascular disease. However, in half the cases of diffuse interstitial fibrosis, no apparent cause or underlying disease is identifiable. Such cases are included under the entity '*idiopathic pulmonary fibrosis*' in the United States and '*cryptogenic fibrosing alveolitis*' in the Great Britain.

PATHOGENESIS The pathogenesis of idiopathic pulmonary fibrosis is unknown and the condition is diagnosed by excluding all known causes of interstitial fibrosis. However, a few evidences point toward immunologic mechanism:

1. High levels of autoantibodies such as rheumatoid factor and antinuclear antibodies.
2. Elevated titres of circulating immune complexes.
3. Immunofluorescent demonstration of the deposits of immunoglobulins and complement on the alveolar walls in biopsy specimens.

MORPHOLOGIC FEATURES The lung involvement in idiopathic pulmonary fibrosis is often bilateral and widespread.

Grossly, the lungs are firm, heavier with reduced volume. Honeycombing (i.e. enlarged, thick-walled air spaces) develops in parts of lung, particularly in the subpleural region.

Histologically, the changes vary according to the stage of the disease.

◆ **In early stage**, there is widening of the alveolar septa by oedema and cellular infiltrate by mononuclear inflammatory cells. The alveolar lining cells may show hyperplasia at places and are flattened at other places. There is often formation of hyaline membranes. The alveolar spaces contain exudate consisting of macrophages, lymphocytes and neutrophils. Many of the macrophages contain lamellar bodies derived from surfactant of the necrotic alveolar lining epithelial cells. Based on the observation of desquamative component in the cellular exudate, some authors label the early stage of idiopathic pulmonary fibrosis as '*desquamative interstitial pneumonitis*'.

◆ **In advanced stage**, there is organisation of the alveolar exudate and replacement fibrosis in the alveoli as well as in the interstitial septal wall with variable amount of inflam-

mation. Eventually, there are small cystic areas (honeycomb lung) with alternating areas of fibrosis containing thick-walled and narrowed vessels. This stage is often referred to as '*chronic interstitial pneumonitis*' or '*usual interstitial pneumonitis*'.

CLINICAL FEATURES Middle-aged males are affected more frequently. The usual features are of respiratory difficulty beginning with dry cough and slowly progressing dyspnoea. More advanced cases may develop clubbing of fingers and cor pulmonale. A rapidly progressive form of the idiopathic pulmonary fibrosis with death within 6 weeks to 6 months is termed Hamman-Rich syndrome.

ILDs ASSOCIATED WITH SMOKING

Long-term consequence of smoking is associated with following non-neoplastic respiratory insufficiency:

◆ **Smoking-related COPD** These are chronic bronchitis and emphysema, which frequently coexist as discussed already.

◆ **Smoking-related ILD** These are chronic restrictive pulmonary diseases due to desquamative interstitial pneumonia (DIP), respiratory bronchiolitis-associated ILD, and pulmonary Langerhans cell histiocytosis (eosinophilic granuloma of the lung).

Most forms of smoking-related ILDs have already been discussed. A few others are described here.

DESQUAMATIVE INTERSTITIAL PNEUMONIA (DIP) It is an uncommon condition occurring exclusively in smokers in 4th to 5th decades of life and is more common in males. Most patients present with dyspnoea and cough. Chest X-ray shows peculiar diffuse hazy opacities which characterise all ILDs. DIP was earlier thought to represent forerunner lesion in the sequence of development of idiopathic pulmonary fibrosis. However, DIP has minimal fibrosis and has a far better prognosis on cessation of smoking compared to idiopathic pulmonary fibrosis.

Microscopically, the features are as under:

- i) Hallmark finding is collections of large number of intra-alveolar macrophages having abundant cytoplasm and containing brown-black pigment and are termed as smokers' macrophages.
- ii) The intervening septa contain a few lymphocytes, plasma cells and an occasional eosinophil.
- iii) Late cases show mild interstitial fibrosis.

RESPIRATORY BRONCHIOLITIS ASSOCIATED ILD Respiratory bronchiolitis is a far more common lesion in chronic smokers than DIP and is considered a milder form of DIP having similar clinical presentation. Respiratory bronchiolitis-associated ILD is the term used for advanced cases who develop impaired pulmonary function and radiologic features.

The condition resolves following cessation of smoking.

Microscopically, it is characterised by following features:

- i) Patchy and bronchiolocentric location of smokers' macrophages similar to those seen in DIP.
- ii) Peribronchial infiltrate of lymphocytes and histiocytes.
- iii) There may be mild peribronchial fibrosis.
- iv) Centriacinar emphysema may coexist.

PULMONARY LANGERHANS CELL HISTIOCYTOSIS This is an uncommon smoking-related ILD occurring in younger men (20-40 years). Clinically, the features may vary from an asymptomatic state to a rapidly progressive course. Symptomatic cases present with cough, dyspnoea, weight loss and fever. CT scan shows presence of ill-defined stellate nodules and thin-walled cysts.

Discontinuation of smoking leads to reversal of the condition.

Microscopically, the features are as under:

- i) There is presence of poorly-defined nodules distributed in peribronchiolar location while intervening lung parenchyma is uninvolved.
- ii) Characteristically, these nodules are sclerosing and contain Langerhans cells along with other inflammatory cells.
- iii) Progressive cases have fibrosis with concomitant cystic change.

GIST BOX 15.6

Chronic Restrictive Pulmonary Disease (CRPD)

- ☐ CRPD are diffuse lung diseases having reduced expansion of lung parenchyma. These may be due to chest wall disorders or interstitial lung diseases (ILDs); the latter are more common.
- ☐ Pneumoconioses are occupational lung diseases due to dusts.
- ☐ Commonest form of occupational lung disease is coal-workers' pneumoconiosis which evolves through anthracosis, simple coal-workers' pneumoconiosis and progressive massive fibrosis.
- ☐ Silicosis appears after prolonged exposure to silica dust and the lung is studded with well-circumscribed, hard, fibrotic nodules.
- ☐ Asbestos exposure for more than a decade can lead to asbestosis, pleural disease and some tumours (e.g. bronchogenic carcinoma, mesothelioma).
- ☐ ILDs may occur in granulomatous inflammation e.g. sarcoidosis, Wegener's granulomatosis etc.
- ☐ ILDs associated with immunologic lung diseases are hypersensitivity pneumonitis, pulmonary infiltrate with eosinophilia, Goodpasture's syndrome and alveolar proteinosis.
- ☐ ILDs may occur in some collagen diseases.
- ☐ Idiopathic pulmonary fibrosis is common form of diffuse interstitial pneumonia.
- ☐ Smoking-related ILDs are certain COPDs (chronic bronchitis, emphysema) and some restrictive lung diseases (desquamative interstitial pneumonia, bronchiolitis and pulmonary Langerhans cell histiocytosis).

TUMOURS OF LUNGS

A number of benign and malignant tumours occur in the lungs but the primary lung cancer, commonly termed bronchogenic carcinoma, is the most common (95% of all primary lung tumours). The lung is also the commonest site for metastasis from carcinomas and sarcomas. A histologic classification of various benign and malignant tumours of lungs is given in **Table 15.10**.

BRONCHOGENIC CARCINOMA

The term bronchogenic carcinoma is commonly used for cancer of the lungs which includes carcinomas arising from the respiratory epithelium lining the bronchi, bronchioles and alveoli.

INCIDENCE AND CLASSIFICATION

Lung cancer is the most common primary malignant tumour in men and accounts for nearly 30% of all cancer deaths in both sexes in developing countries. Currently, the incidence of lung cancer in females in the United States has already exceeded breast cancer as a cause of death in women. Cancer of the lung is a disease of middle and late life with peak incidence in 55-65 years of age, after which there is gradual fall in its incidence. Of late, there has been slight decline in lung cancer deaths in males due to smoking cessation efforts which started in the West 4 decades back and has started yielding results. However, worldwide the scene on its incidence and prognosis are quite grim; data from International Agency for

| | 4. Malignant lymphoma |
| V. | SECONDARY TUMOURS |

Research on Cancer estimate that worldwide by the year 2030 there would be about 10 million deaths per year from lung cancer.

There are 5 main histologic types of lung cancer:

- i) Squamous cell or epidermoid carcinoma
- ii) Small cell carcinoma
- iii) Adenocarcinoma (including bronchioalveolar carcinoma)
- iv) Large cell carcinoma
- v) Combined squamous cell carcinoma and adenocarcinoma (adenosquamous carcinoma).

However, for therapeutic purposes, bronchogenic carcinoma can be classified into 3 groups:

1. Small cell carcinomas, SCC (20-25%)
2. Non-small cell carcinomas, NSCC (70-75%) (includes squamous cell carcinoma, adenocarcinoma, and large cell carcinoma)
3. Combined/mixed patterns (5-10%).

As per reports on international data for the last 25 years, while there has been decline in the incidence of small cell carcinoma, incidence of adenocarcinoma of the lung has risen and is most frequent histologic subtype of lung cancer, accounting for almost half of all lung cancers.

ETIOLOGY

The high incidence of lung cancer is associated with a number of etiologic factors, notably *cigarette smoking*.

1. SMOKING The most important factor for high incidence of all forms of bronchogenic carcinoma is tobacco smoking. About 80% of the lung cancer occurs in active smokers. A number of evidences support the positive relationship of lung cancer with tobacco smoking (page 232):

i) Total dose There is a direct statistical correlation between death rate from lung cancer and the total amount of cigarettes smoked e.g.

- a) An average active smoker has 13 times higher risk while a passive smoker has 1.5 times risk of lung cancer than a non-smoker.
- b) The risk of smokers of more than 2 packs (40 cigarettes) per day for 20 years is 60-70 times greater than a non-smoker.
- c) Cessation of smoking by a regular smoker results in gradual decline in the chances of developing lung cancer. After 10 years

of abstinence from smoking, the risk declines but never returns to the non-smoker level.

d) Pipe and cigar smokers, though have higher risk than non-smokers but are at lesser risk than cigarette smokers.

ii) Histologic alterations The association of tobacco smoking is strongest for squamous cell carcinoma and small cell carcinoma of the lung. More than 90% of smokers have sequential epithelial changes in the respiratory tract in the form of squamous metaplasia, dysplasia and carcinoma *in situ* (Fig. 15.34).

iii) Mechanism How tobacco smoking causes lung cancer is not quite clear. However, following facts have been observed:

- a) Analysis of the tar from cigarette smoke has revealed a number of known carcinogens (e.g. polycyclic aromatic hydrocarbons, nitrosamines) and tumour promoters (e.g. phenol derivatives).
- b) In experimental animal studies, it has been possible to induce cancer by skin painting experiments with smoke-tar. However, it has not been possible to reproduce pattern of human respiratory tract cancer, probably because of the difficulty in reproducing human smoking methods in animals.

2. OTHER FACTORS Although smoking is the dominant etiologic factor in lung cancer, 15% cases of lung cancer occur in non-smokers, more so in women probably related to hormonal factors. A few other factors implicated in lung cancer are as follows:

i) Radiation exposure Long-term exposure to radon or patients receiving thoracic radiation have increased risk of lung cancer.

ii) Atmospheric pollution There is increased risk of developing bronchogenic carcinoma in non-smokers living in industrialised and smoky cities than in the less polluted rural areas. It is possible that specific industrial pollutants may be at fault as evidenced by high rates for lung cancer in people living in the neighbourhood of petrochemical industries.

iii) Occupational causes There are a number of well-established occupational causes of lung cancer. These include workers exposed to asbestos, bis-ethers, nickel, beryllium, arsenic, metallic iron and iron-oxide. Some industrial carcinogens and cigarette smoking have cocarcinogenic effect, particularly in uranium mines and asbestos workers.

iv) Dietary factors Susceptibility to respiratory cancers is increased in vitamin A deficiency. Smokers with low vitamin A

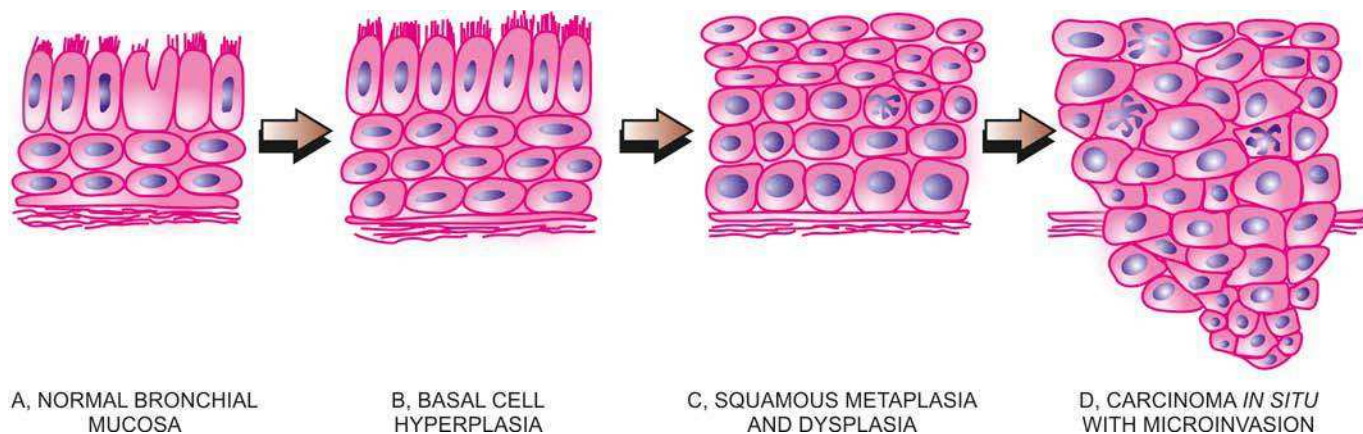

Figure 15.34 Schematic representation of sequential development of squamous cell carcinoma of the lung.

intake have a greater risk of lung cancer than those with vitamin A-rich diet. The incidence of lung cancer is inversely related to socioeconomic level reflecting their dietary pattern.

v) Chronic scarring Peripheral adenocarcinomas occur more frequently in areas of chronic scarring caused by chronic inflammatory changes, old tuberculosis, asbestosis, chronic interstitial fibrosis, old infarcts and in scleroderma.

MOLECULAR PATHOGENESIS

Molecular studies have revealed that there are several genetic alterations in cancer stem cells which produce clones of malignant cells to form tumour mass. Following genetic changes have been found:

1. Activation of growth-promoting oncogenes Mutation in *K-RAS* oncogene has been seen as the dominant change in lung cancer. Besides, there is mutation in tyrosine kinase domain of *EGFR* oncogene in cases of adenocarcinoma lung in non-smokers. Other mutations include *BRAF*, *PIK3CA* and *MYC* family, and overexpression of bcl-2 and other anti-apoptotic proteins.

2. Inactivation of tumour-suppressor genes Inactivation of tumour suppressor genes has been found as another molecular mechanism in lung cancer. Many tumour suppressor genes have been found on chromosome 3p in lung cancer cases. These include inactivation of *p53* and *Rb* gene. Besides, some tumour-acquired promoter genes have been identified in lung cancer e.g. *p16*, *RASSF1A* etc, which cause loss of normal function of growth-regulatory tumour suppressor genes.

3. Autocrine growth factors Studies have shown that lung cancer is a multistep process—initiator carcinogen causing mutation, followed by action of tumour promoters. Nicotine acts as both initiator as well as promoter carcinogen. Derivatives of nicotine in smoke unmask and expresses nicotine acetylcholine receptors which activate the signaling pathway in tumour, blocking the apoptosis. Promoters also include several hormones which are elaborated by lung cancer by autocrine pathway as part of paraneoplastic syndrome.

4. Inherited predisposition Although not common, there are a few examples of inheritance of lung cancer as under:

i) Patients of Li-Fraumeni syndrome who inherit *p53* mutation may develop lung cancer.

ii) Clinical cases of retinoblastoma having mutation in *Rb* gene are predisposed to develop lung cancer if they live up to adulthood.

iii) First-degree relatives of lung cancer patients have a 2-3 fold higher risk of developing lung cancer in their lifetime.

iv) Mutations of cytochrome P450 system have been identified in lung cancer patients; P450 metabolises chemical carcinogen in tobacco smoke (page 211).

5. Molecular targets for therapy and survival prediction Knowledge on the insight into molecular biology and pathogenesis of lung cancer has applications in discovery of newer molecules for targeted therapy, predicting response to treatment and survival:

i) ***EGFR* mutations and NSCC therapy:** It has been reported that 70% cases of NSCC have overexpression of *EGFR* protein or amplification of the *EGFR* gene. *EGFR* belonging to *ERBB* (*HER*) family of proto-oncogenes through mutation in its tyrosine kinase (*TK*) domain plays a role in both extracellular and intracellular signaling resulting in tumour cell proliferation,

metastasis and anti-apoptotic action. Targeted molecular therapy against these mutations in *EGFR* include *EGFR-TK* inhibitor oral therapy.

ii) ***VEGF* and monoclonal therapy:** Although not mutated, VEGF is excessively produced in lung cancer and contributes to tumour angiogenesis. Monoclonal antibody therapy against *EGFR* in conjunction with chemotherapy has been used for curtailing tumour angiogenesis in lung cancer.

iii) ***Molecular signature gene for prediction:*** Proteomic studies at research level have shown that each patient has unique protein pattern in the serum (i.e. molecular signatures) which may be used for early diagnosis, predict drug resistance, response to treatment and survival, but these are yet to be applied in clinical settings.

MORPHOLOGIC FEATURES

Bronchogenic carcinoma can occur anywhere in the lung but the most common location is *hilar*, followed in descending frequency by *peripheral* type.

Grossly, these 2 main types show variation in appearance:

1. Hilar type (Fig. 15.35,A) Most commonly, the lung cancer arises in the main bronchus or one of its segmental branches in the hilar parts of the lung, more often on the right side. The tumour begins as a small roughened area on the bronchial mucosa at the bifurcation. As the tumour enlarges, it thickens the bronchial mucosa producing nodular or ulcerated surface. As the nodules coalesce, the carcinoma grows into a friable spherical mass, 1 to 5 cm in diameter, narrowing and occluding the lumen. The cut surface of the tumour is yellowish-white with foci of necrosis and haemorrhages which may produce cavitory lesions (Table 15.11 sums up a list of common conditions having *pulmonary cavitory lesions* or 'honey-comb lung' during the course of different lung diseases). It is common to find secondary changes in bronchogenic carcinoma of lung such as bronchopneumonia, abscess formation and bronchiectasis as a result of obstruction and intercurrent infections. The tumour soon spreads within the lungs by direct extension or by lymphatics, and to distant sites by lymphatic or haematogenous routes, as described later.

2. Peripheral type (Fig. 15.35,B) A small proportion of lung cancers, chiefly adenocarcinomas including

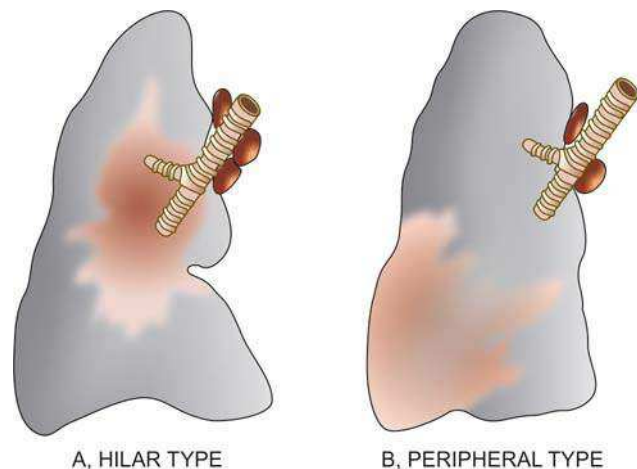

Figure 15.35 The two main gross patterns of bronchogenic carcinoma.

Table 15.11 Conditions producing pulmonary cavities (Honeycomb lung).

- A. INFECTIONS
1. Pulmonary tuberculosis
 2. Primary lung abscess (e.g. due to aspiration)
 3. Secondary lung abscess (e.g. preceding pneumonia, pyaemia, sepsis)
 4. Bronchiectasis
 5. Fungal infections (e.g. aspergillosis, mucormycosis)
 6. Actinomycosis
 7. Nocardiosis
- B. NON-INFECTIOUS CAUSES
1. Pneumoconiosis (e.g. simple coal-workers' pneumoconiosis, silicosis, asbestosis)
 2. Bronchogenic carcinoma
 3. Metastatic lung tumours
 4. Wegener's granulomatosis
 5. Pulmonary infarction
 6. Congenital cysts
 7. Idiopathic pulmonary fibrosis

bronchioloalveolar carcinomas, originate from a small peripheral bronchiole but the exact site of origin may not be discernible. The tumour may be a single nodule or multiple nodules in the periphery of the lung producing pneumonia-like consolidation of a large part of the lung. The cut surface of the tumour is greyish and mucoid.

Histologically, as per current classification outlined in **Table 15.10**, five main histologic types of bronchogenic carcinoma are distinguished which is important because of prognostic and therapeutic considerations. However, from clinical point of view, distinction between small cell (SCC) and non-small cell carcinomas (NSCC) is important

because the two not only differ in morphology, but there are major differences in immunophenotyping and response to treatment discussed above. The major differences between SCC and NSCC of the lung are summed up in **Table 15.12**.

1. Squamous cell (epidermoid) carcinoma This has been the most common histologic subtype of bronchogenic carcinoma until recently and is found more commonly in men, often with history of tobacco smoking. These tumours usually arise in a large bronchus and are prone to massive necrosis and cavitation (**Fig. 15.36**). The tumour is diagnosed microscopically by identification of either intercellular bridges or keratinisation. The tumour may show varying histologic grades of differentiation such as well-differentiated, moderately-differentiated and poorly-differentiated (**Fig. 15.37**). Occasionally, a variant of squamous cell carcinoma, *spindle cell carcinoma*, having biphasic pattern of growth due to the presence of a component of squamous cell carcinoma and the other sarcoma-like spindle cell component, is found.

Usually the spread of squamous cell carcinoma is more rapid than the other histologic types of NSCC. Frequently, the edge of the growth and the adjoining uninvolved bronchi show squamous metaplasia, epithelial dysplasia and carcinoma *in situ*.

2. Small cell carcinoma Small cell carcinomas are frequently hilar or central in location, have strong relationship to cigarette smoking and are highly malignant tumours. They are most often associated with ectopic hormone production because of the presence of neurosecretory granules in majority of tumour cells which are similar to those found in argentaffin or Kulchitsky cells normally found in bronchial epithelium. By immunohistochemistry, these tumour cells are positive for neuroendocrine

Table 15.12 Comparison of features of small cell and non-small cell carcinoma of the lung.

| FEATURE | SMALL CELL CARCINOMA | NON-SMALL CELL CARCINOMA |
|---|--|---|
| 1. <i>Etiologic relationship</i> | Strongly related to tobacco smoking | Smoking implicated; other factors: pollution, chronic scars, asbestos exposure |
| 2. <i>Morphology</i> | | |
| i) Pattern | Diffuse sheets | Squamous or glandular pattern |
| ii) Nuclei | Hyperchromatic, fine chromatin | Pleomorphic, coarse chromatin |
| iii) Nucleoli | Indistinct | Prominent |
| iv) Cytoplasm | Scanty | Abundant |
| v) EM: dense-core granules | Present | Absent |
| 3. <i>Neuroendocrine markers</i> (e.g. chromogranin, synaptophysin, neuron-specific enolase, CD56, CD57) | Present | Absent |
| 4. <i>Epithelial markers</i> (e.g. epithelial membrane antigen, carcinoembryonic antigen, cytokeratin) | Present | Present |
| 5. <i>Mucin</i> | Absent | Present in adenocarcinoma |
| 6. $\beta 2$ <i>microglobulin</i> | Absent to low | Present |
| 7. <i>Peptide hormone production</i> | Gastrin, ACTH, ADH, calcitonin | Parathormone |
| 8. <i>Genetic abnormalities</i> | 3p allele loss, <i>RB</i> and <i>p53</i> mutations | 3p allele loss, <i>EGFR</i> and <i>K-RAS</i> mutations |
| 9. <i>Treatment type</i> | Radiotherapy and/or chemotherapy | Surgical resection possible, limited response to radiotherapy and/or chemotherapy |
| 10. <i>Prognosis</i> | Poor | Better |

Figure 15.36 Squamous cell carcinoma lung, hilar type. Sectioned surface shows grey-white fleshy tumour in the bronchus at its bifurcation and occluding the lumen partly (arrow). The tumour is seen extending directly into adjacent lung parenchyma and hilar nodes.

markers: chromogranin, neuron-specific enolase (NSE) and synaptophysin. Small cell carcinomas have 2 subtypes:

- i) *Pure small cell carcinoma* is composed of uniform, small (or oat-like) cells, larger than lymphocytes with dense, round or oval nuclei having diffuse chromatin, inconspicuous nucleoli and very sparse cytoplasm (*oat* = a form of grain). These cells are organised into cords, aggregates and ribbons or around small blood vessels forming pseudorosettes. The tumour shows frequent and extensive necrosis (**Fig. 15.38**).
- ii) *Combined small cell carcinoma* is a tumour in which there is a definite component of small cell carcinoma with

component of other non-small lung carcinoma such as squamous cell and/or adenocarcinoma.

3. Adenocarcinoma Adenocarcinoma, also called *peripheral carcinoma* due to its location and *scar carcinoma* due to its association with areas of chronic scarring, is the most common bronchogenic carcinoma in women and is slow-growing. Recent estimates on adenocarcinoma place this as the most frequent histologic subtype of lung cancer. A *preinvasive stage* and minimally invasive adenocarcinoma (≤ 3 cm lepidic tumour with ≤ 5 mm invasion) have also been categorised. *Invasive adenocarcinoma* is further subclassified into 5 types:

- i) *Acinar predominant adenocarcinoma* which has predominance of glandular structure and often occurs in the larger bronchi.
- ii) *Papillary predominant adenocarcinoma* which has a pronounced macropapillary configuration and is frequently peripherally located in the lungs and is found in relation to pulmonary scars (*scar carcinoma*).
- iii) *Lepidic predominant (formerly bronchiolo-alveolar carcinoma)* is characterised by cuboidal to tall columnar and mucus-secreting epithelial cells growing along the existing alveoli (*lepidic* = hob nail-like cells spreading along a surface) (**Fig. 15.39**). Ultrastructurally, these tumour cells resemble Clara cells or less often type II pneumocytes.
- iv) *Solid predominant carcinoma* is a poorly-differentiated adenocarcinoma lacking acini, tubules or papillae but having mucus-containing vacuoles in many tumour cells.
- v) *Micropapillary predominant adenocarcinoma* has tumour cells growing in tiny papillary tufts lacking fibrovascular core.

4. Large cell carcinoma These are undifferentiated carcinomas which lack the specific features by which they could be assigned into squamous cell carcinoma or adenocarcinoma. Large cell carcinomas are more common in men, have strong association with cigarette smoking and are highly malignant tumours. The tumour cells have large nuclei, prominent nucleoli, abundant cytoplasm and well-defined cell borders. Variants of large cell undifferentiated carcinomas include *giant cell carcinoma* with prominence

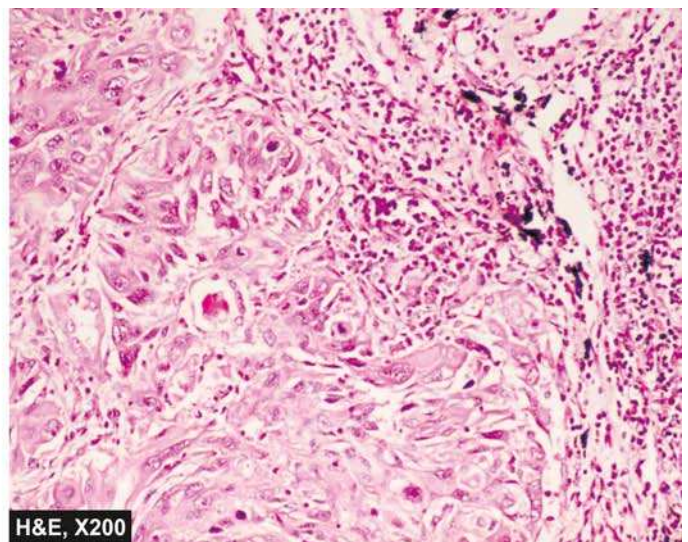

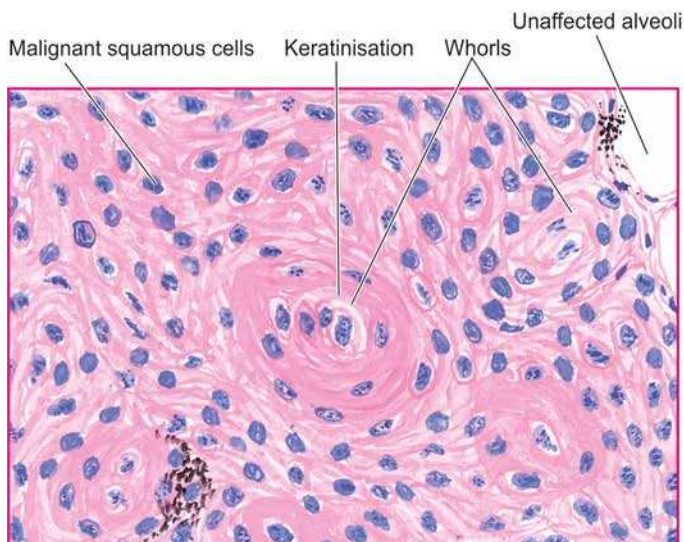

Figure 15.37 Squamous cell carcinoma of the lung. Islands of invading malignant squamous cells are seen. A few well-developed cell nests with keratinisation are evident.

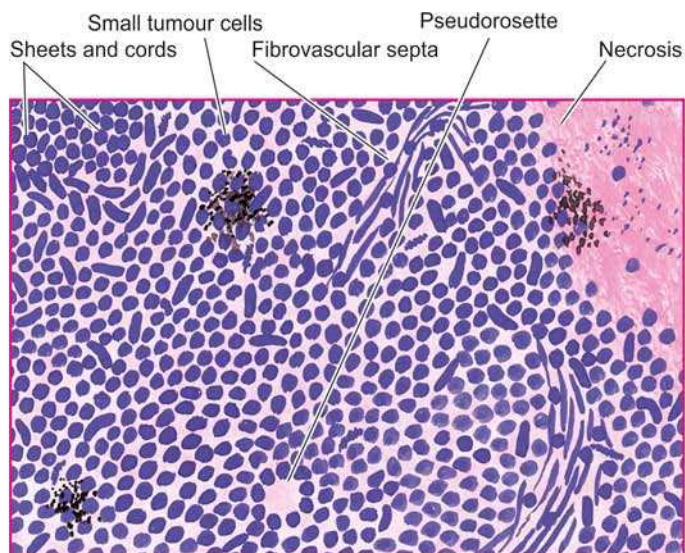

Figure 15.38 Oat cell carcinoma of the lung. The tumour cells are arranged in sheets, cords or aggregates and at places form pseudorosettes. The individual tumour cells are small, uniform, lymphocyte-like with scanty cytoplasm. In box shows cytoplasmic granules positive for chromogranin immunostain.

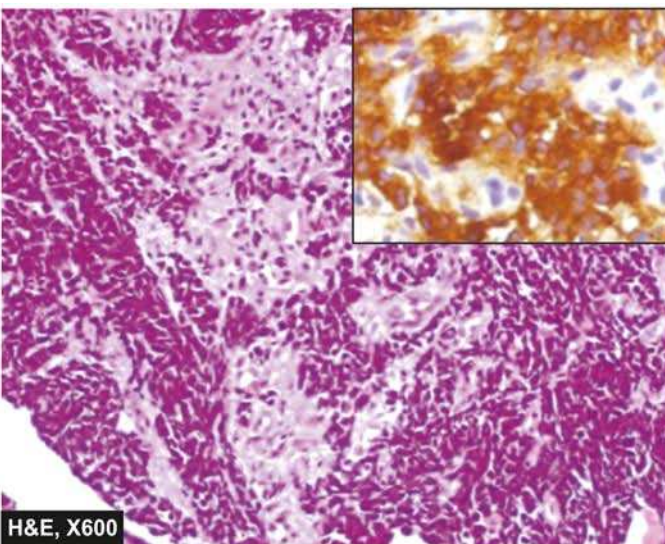

of highly pleomorphic multinucleate cells and *clear cell carcinoma* composed of cells with clear or foamy cytoplasm without mucin.

5. Adenosquamous carcinoma These are a small proportion of peripheral scar carcinomas having clear evidence of both keratinisation and glandular differentiation.

SPREAD

Bronchogenic carcinoma can invade the adjoining structures directly, or may spread by lymphatic and haematogenous routes.

1. Direct spread The tumour extends directly by invading through the wall of the bronchus and destroys and replaces the peribronchial lung tissue. As it grows further, it spreads to the opposite bronchus and lung, into the pleural cavity, the pericardium and the myocardium and along the great vessels

of the heart causing their constriction. Extension of the cancer located at the apex of the lung into the thoracic cage may involve brachial plexus and the sympathetic chain causing pain and sensory disturbances, so called *Pancoast's syndrome*.

2. Lymphatic spread Initially, hilar lymph nodes are affected. Later, lymphatic metastases occur to the other groups leading to spread to mediastinal, cervical, supraclavicular and para-aortic lymph nodes. Invasion of the thoracic duct may produce chylous ascites.

3. Haematogenous spread Distant metastases via blood stream are widespread and early. The sites affected, in descending order of involvement, are: the liver, adrenals, bones, pancreas, brain, opposite lung, kidneys and thyroid.

CLINICAL FEATURES

Symptoms of lung cancer are quite variable and result from local effects, effects due to occlusion of a bronchus, direct and

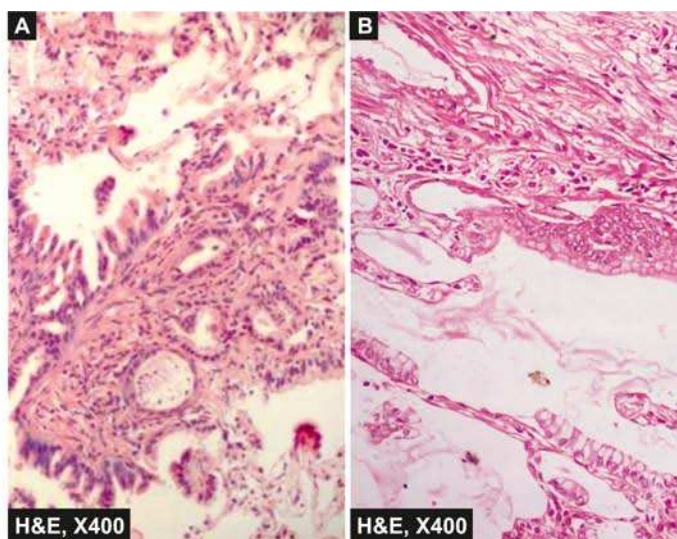

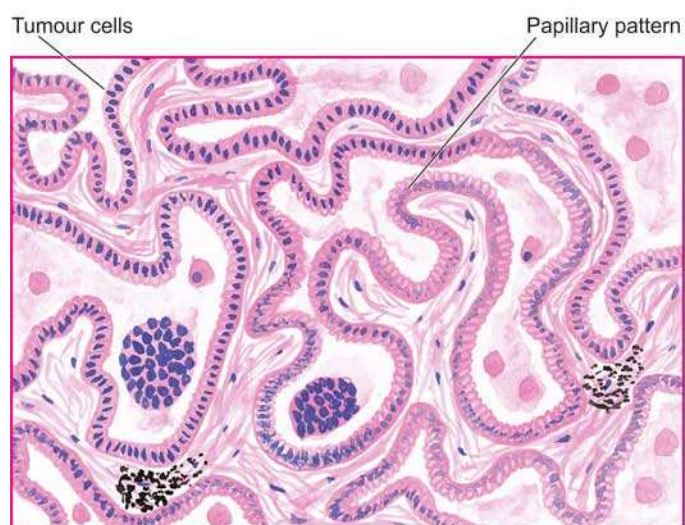

Figure 15.39 Adenocarcinoma lung. A, Photomicrograph shows lepidic growth pattern of tumour cells along the alveoli. B, It shows alveolar walls lined by cuboidal to tall columnar mucin-secreting tumour cells having papillary growth pattern.

distant metastases, and paraneoplastic syndromes. Diagnostic aids include radiologic examination and CT scan of the chest, cytologic examination of the sputum, bronchial washings and bronchioalveolar lavage.

1. LOCAL SYMPTOMS Most common local complaints are cough, chest pain, dyspnoea and haemoptysis (A list of various causes of haemoptysis is summed up in [Table 15.13](#)).

2. BRONCHIAL OBSTRUCTIVE SYMPTOMS Occlusion of a bronchus may result in bronchopneumonia, lung abscess and bronchiectasis in the lung tissue distal to the site of obstruction and cause their attendant symptoms like fever, productive cough, pleural effusion and weight loss.

3. SYMPTOMS DUE TO METASTASES Distant spread may produce varying features and sometimes these are the first manifestation of lung cancer. These include: superior vena caval syndrome, painful bony lesions, paralysis of recurrent nerve and other neurologic manifestations resulting from brain metastases.

4. PARANEOPLASTIC SYNDROMES A number of paraneoplastic syndromes (page 225) are associated with lung cancer. These include the following:

i) Ectopic hormone production Different hormonal syndromes are characteristic of different histologic types of lung cancer. Small cell carcinomas are associated most often with ectopic hormone production. The various hormones elaborated by lung cancer are as follows:

- ACTH, producing Cushing's syndrome.
- ADH, inducing hyponatraemia.
- Parathormone, causing hypercalcaemia.
- Calcitonin, producing hypocalcaemia.
- Gonadotropins, causing gynaecomastia.
- Serotonin, associated with carcinoid syndrome.

ii) Other systemic manifestations These include the following:

- Neuromuscular* e.g. polymyositis, myopathy, peripheral neuropathy and subacute cerebellar degeneration.
- Skeletal* e.g. clubbing and hypertrophic osteoarthropathy.

- Cutaneous* e.g. acanthosis nigricans and dermatomyopathy.
- Cardiovascular* e.g. migratory thrombophlebitis (Trousseau's syndrome), nonbacterial thrombotic endocarditis.
- Haematologic* e.g. abnormalities in coagulation and leukemoid reaction.

STAGING AND PROGNOSIS

The widely accepted clinical staging of lung cancer is according to the TNM classification, combining features of primary Tumours, Nodal involvement and distant Metastases. TNM staging divides all lung cancers into the following 4 stages: *Occult*: Malignant cells in the bronchopulmonary secretions but no evidence of primary tumour or metastasis.

Stage I: Tumour less than 3 cm, with or without ipsilateral nodal involvement, no distant metastasis.

Stage II: Tumour larger than 3 cm, with ipsilateral hilar lymph node involvement, no distant metastasis.

Stage III: Tumour of any size, involving adjacent structures, involving contralateral lymph nodes or distant metastasis.

In general, tumour size larger than 5 cm has worse prognosis. Symptomatic patients, particularly with systemic symptoms, fare far badly than the nonsymptomatic patients. The overall prognosis of bronchogenic carcinoma is dismal. However, 5-year survival rate with surgery combined with radiotherapy or chemotherapy in the last 30 years has doubled from its earlier rate of about 9% to present rate of 15%. Adenocarcinoma and squamous cell carcinoma which are localised, are resectable and have a slightly better prognosis. *Small cell carcinoma has the worst prognosis* since surgical treatment is ineffective though the tumour is sensitive to radiotherapy and chemotherapy.

BRONCHIAL CARCINOID AND OTHER NEUROENDOCRINE TUMOURS

Neuroendocrine tumours of the lung represent a continuum spectrum of lung tumours with progressively increasing aggressiveness which include: typical carcinoid (*least aggressive*), atypical carcinoid, and large cell endocrine carcinoma, and also small cell carcinoma (*most aggressive*). All these tumours arise from neuroendocrine (Kulchitsky) cells of bronchial mucosa. Formerly, bronchial carcinoids used to be classified as 'bronchial adenomas' but now it is known that they are locally invasive and have the capacity to metastasise. Bronchial carcinoids tend to occur at a younger age than bronchogenic carcinoma, often appearing below the age of 40 years, and are not related to cigarette smoking.

MORPHOLOGIC FEATURES Bronchial carcinoids resemble their intestinal counterparts described in Chapter 18.

Grossly, bronchial carcinoids most commonly arise from a major bronchus and project into the bronchial lumen as a spherical polypoid mass, 3-4 cm in diameter. Less commonly, the tumour may grow into the bronchial wall and produce collar-button like lesion. The overlying bronchial mucosa is usually intact. Cut surface of the tumour is yellow-tan in colour.

Histologically, the tumour is composed of uniform cuboidal cells forming aggregates, trabeculae or ribbons

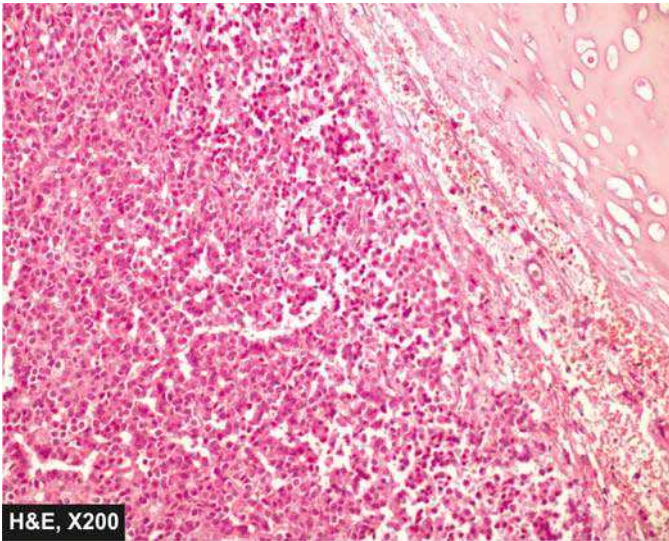

Figure 15.40 Central carcinoid of the lung. The tumour shows a characteristic nested of cells separated by fibrovascular septa. These nests are composed of uniform cuboidal cells having granular cytoplasm.

separated by fine fibrous septa. The tumour cells have abundant, finely granular cytoplasm and oval central nuclei with clumped nuclear chromatin. Mitoses are rare and necrosis is uncommon (**Fig. 15.40**). The secretory granules of bronchial carcinoids resemble those of other foregut carcinoids and stain positively with argyrophilic stains in which exogenous reducing agent is added for the reaction. Immunohistochemically, markers for neuroendocrine are stained positive e.g. NSE, chromogranin, synaptophysin and neurofilaments.

CLINICAL FEATURES Bronchial carcinoids occur at a relatively early age and have equal sex incidence. Most of the symptoms in bronchial carcinoids occur as a result of bronchial obstruction such as cough, haemoptysis, atelectasis and secondary infection. About 5-10% of bronchial carcinoids metastasise to the liver and these cases are capable of producing carcinoid syndrome (page 431).

HAMARTOMA

Hamartoma is a tumour-like lesion composed of an abnormal admixture of pulmonary tissue components and is discovered incidentally as a coin-lesion in the chest-X-ray. Pulmonary hamartomas are of 2 types: chondromatous and leiomyomatous.

◆ **Chondromatous hamartoma** is more common and usually asymptomatic. It forms a solitary, spherical mass, 2-5 cm in diameter, usually at the periphery of the lung. Typically, it shows nodules of cartilage associated with fibrous and adipose tissue admixed with bronchial epithelium.

◆ **Leiomyomatous hamartoma** has a prominent smooth muscle component and bronchiolar structures. They are frequently multiple, 1-2 mm in diameter and are more commonly located near the pleura.

METASTATIC LUNG TUMOURS

Secondary tumours of the lungs are more common than the primary pulmonary tumours. Metastases from carcinomas as

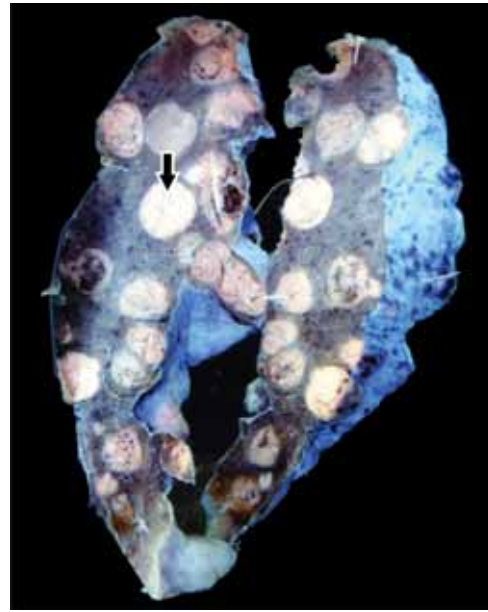

Figure 15.41 Metastatic deposits in the lung. Large parts of the lung parenchyma are replaced by multiple, variable-sized, circumscribed nodular masses which are grey-white in colour. Some of these show areas of haemorrhage and necrosis.

well as sarcomas arising from anywhere in the body may spread to the lung by haematogenous or lymphatic routes, or by direct extension. Blood-borne metastases are the most common since emboli of tumour cells from any malignant tumour entering the systemic venous circulation are likely to be lodged in the lungs. Metastases are most common in the peripheral part of the lung forming single or multiple, discrete nodular lesions which appear radiologically as 'cannon-ball secondaries' (**Fig. 15.41**). Less frequently, the metastatic growth is confined to peribronchiolar and perivascular locations which is due to spread via lymphatics.

Most common sources of metastases in the lungs are: carcinomas of the bowel, breast, thyroid, kidney, pancreas, lung (ipsilateral or contralateral) and liver. Other tumours which frequently metastasise to the lungs are osteogenic sarcoma, neuroblastoma, Wilms' tumour, melanoma, lymphomas and leukaemias.

GIST BOX 15.7 Tumours of Lung

- ☐ Bronchogenic carcinoma is lung cancer arising from the respiratory epithelium lining the bronchi, bronchioles and alveoli.
- ☐ The most important factor for high incidence of all forms of bronchogenic carcinoma is tobacco smoking. About 80% of the lung cancer occurs in active smokers.
- ☐ The most common location of lung cancer is hilar, followed in descending frequency by peripheral type.
- ☐ Five main histologic types of bronchogenic carcinoma are distinguished, which are clinically divided into 2 types: small cell and non-small cell carcinomas (namely squamous cell, adenocarcinoma, large cell, combined small-large cell).
- ☐ Lung cancer may spread directly, or to distant sites by blood or lymphatic route.

- Clinically, lung cancer frequently produces haemoptysis and may be associated with paraneoplastic syndrome of ectopic hormone production.
- Bronchial carcinoid arises from neuroendocrine cells and is associated with carcinoid syndrome.

DISEASES OF PLEURA

NORMAL STRUCTURE Visceral pleura covers the lungs and extends into the fissures while the parietal pleura limits the mediastinum and covers the dome of the diaphragm and inner aspect of the chest wall. The two layers between them enclose pleural cavity which contains less than 15 ml of clear serous fluid.

Microscopically, both the pleural layers are lined by a single layer of flattened mesothelial cells facing each other. Underneath the lining cells is a thin layer of connective tissue.

Diseases affecting the pleura are nearly always secondary to some other underlying disease. Broadly, they fall into inflammations, non-inflammatory pleural effusions, pneumothorax, and tumours.

INFLAMMATIONS

Inflammatory involvement of the pleura is commonly termed *pleuritis* or *pleurisy*. Depending upon the character of resultant exudate, it can be divided into serous, fibrinous and serofibrinous, suppurative or empyema, and haemorrhagic pleuritis.

1. SEROUS, FIBRINOUS AND SEROFIBRINOUS PLEURITIS

Acute inflammation of the pleural sac (acute pleuritis) can result in serous, serofibrinous and fibrinous exudate. Most of the causes of such pleuritis are infective in origin, particularly within the lungs, such as tuberculosis, pneumonias, pulmonary infarcts, lung abscess and bronchiectasis. Other causes include a few collagen diseases (e.g. rheumatoid arthritis and disseminated lupus erythematosus), uraemia, metastatic involvement of the pleura, irradiation of lung tumours and diffuse systemic infections (e.g. typhoid fever, tularaemia, blastomycosis and coccidioidomycosis).

Pleurisy causes pain in the chest on breathing and a friction rub is audible on auscultation. In most patients, the exudate is minimal and is resorbed resulting in resolution. Repeated attacks of pleurisy may result in organisation leading to fibrous adhesions and obliteration of the pleural cavity.

2. SUPPURATIVE PLEURITIS (EMPYEMA THORACIS)

Bacterial or mycotic infection of the pleural cavity that converts a serofibrinous effusion into purulent exudate is termed suppurative pleuritis or empyema thoracis. The most common cause is direct spread of pyogenic infection from the lung. Other causes are direct extension from subdiaphragmatic abscess or liver abscess and penetrating injuries to the chest wall. Occasionally, the spread may occur by haematogenous or lymphatic routes.

In empyema, the exudate is yellow-green, creamy pus that accumulates in large volumes. Empyema is eventually

replaced by granulation tissue and fibrous tissue. In time, tough fibrocollagenic adhesions develop which obliterate the cavity, and with passage of years, calcification may occur. The effect of these is serious respiratory difficulty due to inadequate pulmonary expansion.

3. HAEMORRHAGIC PLEURITIS Haemorrhagic pleuritis differs from haemothorax in having inflammatory cells or exfoliated tumour cells in the exudate. The causes of haemorrhagic pleuritis are metastatic involvement of the pleura, bleeding disorders and rickettsial diseases.

NON-INFLAMMATORY PLEURAL EFFUSIONS

These include fluid collections in the pleural cavity such as hydrothorax, haemothorax and chylothorax.

1. HYDROTHORAX Hydrothorax is non-inflammatory accumulation of serous fluid within the pleural cavities. Hydrothorax may be unilateral or bilateral depending upon the underlying cause. Occasionally, an effusion is limited to part of a pleural cavity by pre-existing pleural adhesions.

The most common cause of hydrothorax, often bilateral, is congestive heart failure. Other causes are renal failure, cirrhosis of liver, Meig's syndrome (page 739), pulmonary oedema and primary and secondary tumours of the lungs.

The non-inflammatory serous effusion in hydrothorax is clear and straw-coloured and has the characteristics of transudate with a specific gravity of under 1.012, protein content below 1 gm/dl and little cellular content.

If the fluid collection in pleural cavity is less than 300 ml (normal is less than 15 ml), no signs or symptoms are produced and may be apparent in chest X-ray in standing posture as obliterated costodiaphragmatic angle. If the pleural cavity contains abundant fluid, it imparts a characteristic opaque radiographic appearance to the affected side with deviation of trachea to the opposite side. In such cases, symptoms such as respiratory embarrassment and dyspnoea are produced which are promptly relieved on withdrawal of fluid.

2. HAEMOTHORAX Accumulation of pure blood in the pleural cavity is termed as haemothorax. The most common causes of haemothorax are trauma to the chest wall or to the thoracic viscera and rupture of aortic aneurysm. It is important to remove the blood from the pleural cavity as early as possible. Otherwise the blood will clot and organise, resulting in fibrous adhesions and obliteration of the pleural cavity.

3. CHYLOTHORAX Chylothorax is an uncommon condition in which there is accumulation of milky fluid of lymphatic origin into the pleural cavity. Chylothorax results most commonly from rupture of the thoracic duct by trauma or obstruction of the thoracic duct such as by malignant tumours, most often malignant lymphomas. Chylothorax is more often confined to the left side. Chylous effusion is milky due to high content of finely emulsified fats in the chyle.

PNEUMOTHORAX

An accumulation of air in the pleural cavity is called pneumothorax. It may occur in one of the three circumstances: spontaneous, traumatic and therapeutic.

i) Spontaneous pneumothorax occurs due to spontaneous rupture of alveoli in any form of pulmonary disease. Most

commonly, spontaneous pneumothorax occurs in association with emphysema, asthma and tuberculosis. Other causes include chronic bronchitis in an old patient, bronchiectasis, pulmonary infarction and bronchial cancer. In young patients, recurrent spontaneous rupture of peripheral subpleural blebs may occur without any cause resulting in disabling condition termed *spontaneous idiopathic pneumothorax*.

ii) **Traumatic pneumothorax** is caused by trauma to the chest wall or lungs, ruptured oesophagus or stomach, and surgical operations of the thorax.

iii) **Therapeutic (artificial) pneumothorax** used to be employed formerly in the treatment of chronic pulmonary tuberculosis in which air was introduced into the pleural sac so as to collapse the lung and limit its respiratory movements.

The *effects* of pneumothorax due to any cause depend upon the amount of air collected in the pleural cavity. If the quantity of air in the pleura is small, it is resorbed. Larger volume of air collection in the pleural cavity causes dyspnoea and pain in the chest. Pneumothorax causes lung collapse and pulls the mediastinum to the unaffected side. Occasionally, the defect in the lungs is such that it acts as flap-valve and allows entry of air during inspiration but does not permit its escape during expiration, creating *tension pneumothorax* which requires urgent relief of pressure so as to relieve severe dyspnoea and circulatory failure.

TUMOURS OF PLEURA

Pleural tumours may be primary or secondary. In line with pulmonary tumours, the secondary tumours in the pleura are more common. The only important primary tumour of pleura is mesothelioma.

MESOTHELIOMA

Mesothelioma is an uncommon tumour arising from mesothelial lining of serous cavities, most often in pleural cavity, and rarely in peritoneal cavity and pericardial sac. Mesotheliomas are of 2 types—*benign (solitary) and malignant (diffuse)*. The biologic behaviour of pleural mesotheliomas is usually predicted by their gross appearance—those forming solitary, discrete masses are generally benign, whereas those which grow diffusely are usually malignant.

Benign (Solitary) Mesothelioma

Benign or solitary mesothelioma is also called as pleural fibroma. *Asbestos exposure plays no role in etiology of benign mesothelioma.*

Grossly, it consists of a solitary, circumscribed, small, firm mass, generally less than 3 cm in diameter. Cut surface shows whorls of dense fibrous tissue.

Microscopically, the tumour is predominantly composed of whorls of collagen fibres and reticulin with interspersed fibroblasts. Rarely, mesothelial-lined clefts are seen in the tumour.

Benign mesothelioma causes no symptoms and is detected as an incidental radiologic finding. Sometimes the tumour is associated with systemic syndrome of osteoarthropathy or hypoglycaemia. Removal of the tumour is generally curative.

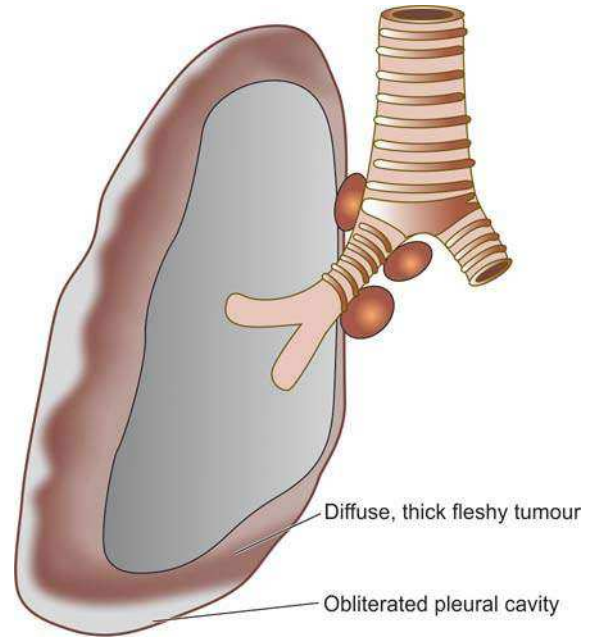

Figure 15.42 Malignant (diffuse) mesothelioma, gross appearance. The tumour is seen to form a thick, white, fleshy coat over the parietal and visceral surfaces.

Malignant (Diffuse) Mesothelioma

Malignant or diffuse mesothelioma is rare. It is a highly malignant tumour associated with high mortality. The tumour is significant in view of its *recognised association with occupational exposure to asbestos* (particularly crocidolite) for a number of years, usually 20 to 40 years (page 472). About 90% of malignant mesotheliomas are asbestos-related. Mechanism of carcinogenicity by asbestos is not quite clear but it appears that prolonged exposure of amphibole type of asbestos is capable of inducing oncogenic mutation in the mesothelium. However, prolonged asbestos-exposure is considered more significant rather than heavy exposure as documented by occurrence of malignant mesothelioma in the family members of asbestos workers. Although combination of cigarette smoking and asbestos exposure greatly increases risk to develop bronchogenic carcinoma, there is no such extra increased risk of developing mesothelioma in asbestos workers who smoke. Role of SV40 (simian vacuolating virus) antigen has also been implicated in the etiology of mesothelioma.

Grossly, the tumour is characteristically diffuse, forming a thick, white, fleshy coating over the parietal and visceral surfaces (**Fig. 15.42**).

Microscopically, malignant mesothelioma may have epithelial, sarcomatoid or biphasic patterns.

i) **Epithelioid pattern** resembles an adenocarcinoma, consisting of tubular and tubulo-papillary formations. The tumour cells are usually well-differentiated, cuboidal, flattened or columnar cells. The tumour can be distinguished from adenocarcinoma by positive immunostaining for calretinin, WT-1 and cytokeratin 5/6.

ii) **Sarcomatoid pattern** consists of spindle cell sarcoma resembling fibrosarcoma. The tumour cells are arranged in a storiform pattern with abundant collagen between them.

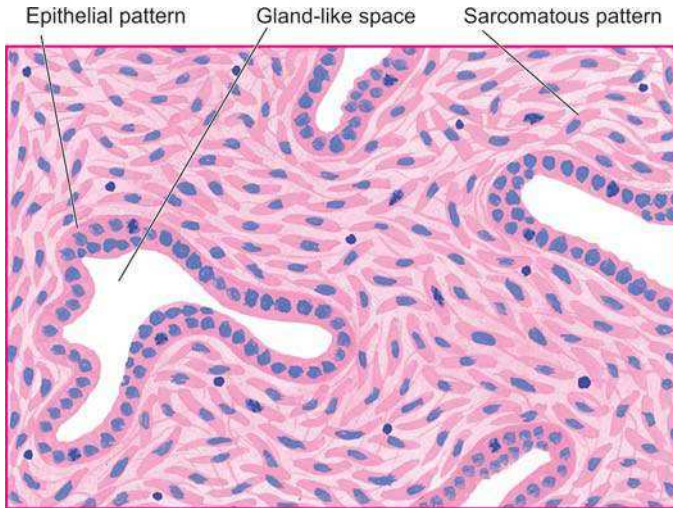

Figure 15.43 Malignant mesothelioma, showing biphasic pattern of growth.

iii) **Mixed pattern** shows mixed growth having epithelial as well as sarcomatoid pattern. Usually, there are slit-like or gland-like spaces lined by neoplastic mesothelial cells separated by proliferating spindle-shaped tumour cells (**Fig. 15.43**).

Asbestos bodies are found in the lungs of most patients with malignant mesothelioma of any histologic type.

Clinical manifestations include chest pain, dyspnoea, pleural effusion and infections. The tumour spreads rapidly by direct invasion into lung and by lymphatic spread into hilar lymph nodes and pericardium. Sometimes distant metastases, particularly to the liver, occur. The prognosis is poor; 50% of patients die within one year of diagnosis.

SECONDARY PLEURAL TUMOURS

Metastatic malignancies in the pleura are more common than the primary tumours and appear as small nodules scattered over the lung surface. The most frequent primary malignant tumours metastasising to the pleura are of the lung and breast through lymphatics, and ovarian cancers via haematogenous route.

GIST BOX 15.8

Diseases of Pleura

- ▣ Inflammatory involvement of the pleura is called pleuritis or pleurisy. It may be serous, fibrinous, serofibrinous, suppurative, and haemorrhagic.
- ▣ Non-inflammatory pleural effusions may be hydrothorax, haemothorax and chylothorax.
- ▣ Pneumothorax is accumulation of air in the pleural cavity. It may be spontaneous, traumatic or therapeutic.
- ▣ Primary tumours of pleura are mesotheliomas which may be benign or malignant.
- ▣ Malignant mesothelioma has strong association with asbestos exposure. It is a diffuse tumour and may be epithelioid, sarcomatoid or mixed type.
- ▣ Metastatic pleural tumours are more common and generally arise from the lung and breast.

CLINICAL CASE 11

A 75 years old man living on his own brought by the neighbour to the emergency department of the hospital with fever, fatigue, malaise, and a productive cough for the last 15 days. He also gives history of chills and rigors.

On examination, he has crepts and rhonchi in both lungs.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 909 (Appendix II)

CLINICAL CASE 12

A 54 years old male complains of persistent productive cough for 2 years. Lately, for the last 2 months there is intermittent blood in the sputum. There is history of progressive loss of weight and appetite for 1 month and occasional chest pain. He has been a chronic smoker, smoking about 20 cigarettes/day for the last 30 years and is an occasional alcoholic.

On examination, pallor: ++, icterus: -ve, clubbing of fingers-grade II. On inspection of chest, left half of chest is not moving equally with respiration. On auscultation, breath sounds absent on left side.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 909 (Appendix II)

16

The Eye, ENT and Neck

EYE

NORMAL STRUCTURE

The structure of the eye is shown diagrammatically in **Fig. 16.1**. The *eyelids* are covered externally by the skin and internally by *conjunctiva* which is reflected over the globe of the eye. The *lacrimal glands* which are compound racemose glands are situated at the outer upper angle of the orbit. The *globe of the eye* is composed of 3 layers: the cornea-sclera, choroid-iris, and retina.

- ◆ The **cornea** is covered by stratified epithelium which may be regarded as continuation of the conjunctiva over the cornea. The subepithelial stroma consists of fibrous connective tissue, and the posterior endothelium-lined thin elastic membrane called Descemet's membrane.
- ◆ The **sclera** is composed of dense fibrous tissue which is thickest at the back of the eyeball.
- ◆ The **choroid** is the vascular membrane in contact with the sclera. The choroid becomes thickened anteriorly forming ciliary body, ciliary processes and contains ciliary muscle.
- ◆ The **iris** is the continuation of the choroid which extends in front of the lens. It is similar in structure to the choroid but contains pigment cells.
- ◆ The **uveal tract** consists of 3 parts—the choroid and ciliary body posteriorly, and the iris anteriorly.
- ◆ The **retina** is part of the central nervous system and corresponds in extent to the choroid which it lines internally. The retina is composed of a number of layers of cells and their synapses which are of 3 types—external photoreceptor cells (rods and cones), intermediate relay layer of bipolar cells, and internal layer of ganglion cells with their axons running into the central nervous system. The *central fovea* is a specially differentiated spot in the retina posteriorly which consists only of photosensitive cones but is devoid of photoreceptor rods and blood vessels. *Macula lutea* or *yellow spot* surrounds the central fovea and though not as sensitive as central fovea, it is more so than the other parts of the retina. At the optic disc, the fibres of the nerve fibre layer of the retina pass into the optic nerve.
- ◆ The **lens** is the biconvex mass of laminated transparent tissue with elastic capsule.
- ◆ The **anterior chamber** is the space filled with the aqueous humour, and is bounded by the cornea in front and the iris behind, with anterior surface of the lens exposed in the pupil.
- ◆ The **posterior chamber** containing aqueous humour is the triangular space between the back of the iris, the anterior surface of the lens and the ciliary body forming its apex at the pupillary margin.
- ◆ The **vitreous chamber** is the large space behind the lens containing gelatinous material, the vitreous humour.

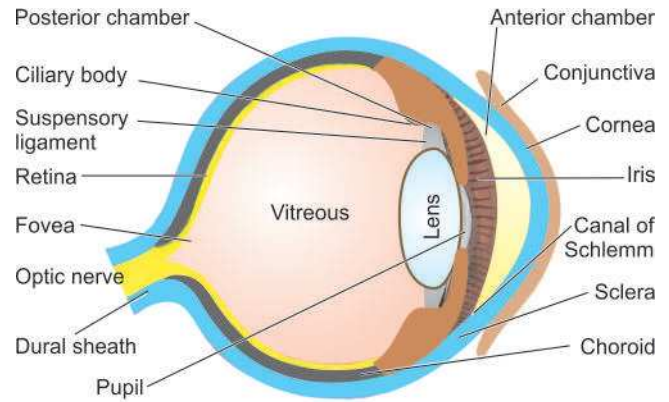

Figure 16.1 Schematic diagram of longitudinal section of the eyeball.

The main *function* of the eye is visual acuity which depends upon a transparent focussing system comprised by the cornea, lens, transparent media consisting of aqueous and vitreous humours, and a normal retinal and neural conduction system. The cornea and lens receive their nutrient demands from the aqueous humour produced by the ciliary processes. The intraocular pressure is normally 15-20 mmHg and depends upon the rate of aqueous production and on the resistance in the outflow system.

CONGENITAL LESIONS

RETROLENTAL FIBROPLASIA (RETINOPATHY OF PREMATURITY) This is a developmental disorder occurring in premature infants who have been given oxygen-therapy at birth. The basic defect lies in the developmental prematurity of the retinal blood vessels which are extremely sensitive to high dose of oxygen-therapy. The peripheral retina is incompletely vascularised in such infants and exposure to oxygen results in vaso-obliteration. On stoppage of oxygen-therapy, vasoproliferation begins leading to neovascularisation, cicatrization and retinal detachment.

RETINITIS PIGMENTOSA Retinitis pigmentosa is a group of systemic and ocular diseases of unknown etiology, characterised by degeneration of the retinal pigment epithelium. The condition can have various inheritance patterns—autosomal dominant, autosomal recessive trait, or sex-linked recessive trait. The earliest clinical finding is night blindness due to loss of rods and may progress to total blindness.

Histologically, there is disappearance of rods and cones of the photoreceptor layer of the retina, degeneration of retinal pigment epithelium and ingrowth of glial membrane on the optic disc.

INFLAMMATORY CONDITIONS

Inflammatory conditions of the eye are designated according to the tissue affected. 'Uveitis' is the commonly used term for the ocular inflammation of the uveal tract which is the most vascular tissue of the eye. However, specific designation is used for the type of tissue of eye inflamed. Some of the important examples are described below.

STYE (HORDEOLUM) Stye or 'external hordeolum' is an acute suppurative inflammation of the sebaceous glands of Zeis, the apocrine glands of Moll and the eyelash follicles. The less common 'internal hordeolum' is an acute suppurative inflammation of the meibomian glands.

CHALAZION Chalazion is a very common lesion and is the chronic inflammatory process involving the meibomian glands. It occurs as a result of obstruction to the drainage of secretions. The inflammatory process begins with destruction of meibomian glands and duct and subsequently involves tarsal plate.

Histologically, the chalazion gives the appearance of a chronic inflammatory granuloma located in the tarsus and contains fat globules in the centre of the granulomas i.e. appearance of a lipogranuloma (Fig. 16.2).

ENDOPHTHALMITIS-PANOPHTHALMITIS Endophthalmitis is an acute suppurative intraocular inflammation. Panophthalmitis is the term used for inflammation involving retina, choroid and sclera and extending to the orbit. Infection may be of exogenous or endogenous origin. The exogenous agents may be bacteria, viruses or fungi introduced into the eye during an accidental or surgical perforating wound. The endogenous agents include opportunistic infections which may cause endophthalmitis via haematogenous route e.g. candidiasis, toxoplasmosis, nocardiosis, aspergillosis and cryptococcosis.

Upon healing, *synechiae* may develop which are adhesions between two iris and cornea (anterior synechiae), or between iris and anterior surface of lens (posterior synechiae).

CONJUNCTIVITIS AND KERATOCONJUNCTIVITIS Conjunctiva and cornea are constantly exposed to various types of physical, chemical, microbial (bacteria, fungi, viruses) and allergic agents and hence prone to develop acute, subacute and chronic inflammations. In the acute stage, there is corneal oedema and infiltration by inflammatory cells, affecting the transparency of the cornea. In the more chronic form of inflammation, there is proliferation of small blood vessels in the normally avascular cornea and infiltration by lymphocytes and plasma cells (pannus formation).

TRACHOMA AND INCLUSION CONJUNCTIVITIS Both these conditions are caused by *Chlamydia* or TRIC agents. Trachoma is caused by *C. trachomatis* while inclusion conjunctivitis is caused by *C. oculogenitalis*. Trachoma is widely prevalent in the developing countries of the world and is responsible for blindness on a large scale. In the early stage of infection, the trachoma agent that infects the conjunctival epithelium, can be recognised in the smears by the intracytoplasmic inclusion bodies formed by the proliferating microorganisms within the cells. Later, the conjunctiva thickens due to dense chronic inflammatory cell infiltrate along with lymphoid follicles and macrophages. The end-result

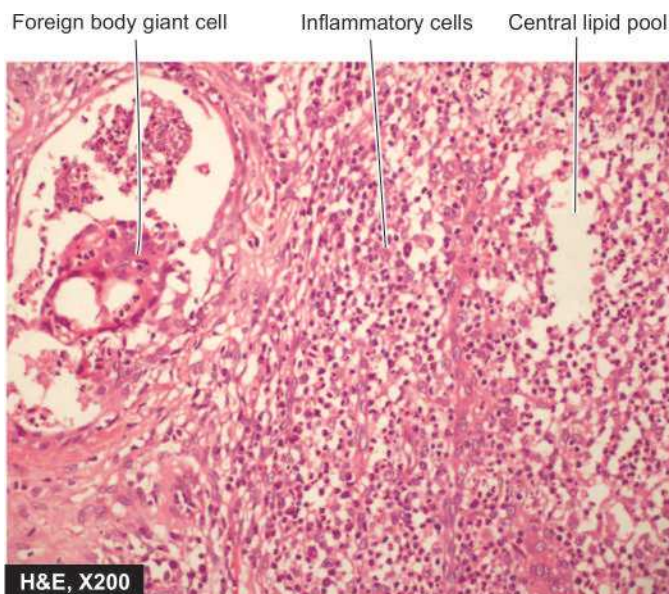

Figure 16.2 Chalazion of the eyelid. There is presence of a lipogranuloma having central pool of fat and surrounded by mixed inflammatory cells and foreign body type multinucleated giant cells.

is extensive corneal and conjunctival cicatrization accounting for blindness in trachoma. Inclusion conjunctivitis, though caused by an organism closely related to trachoma agent, is a much less severe disease and causes mild keratoconjunctivitis.

GRANULOMATOUS UVEITIS A number of chronic granulomatous conditions may cause granulomatous uveitis. These include bacteria (e.g. tuberculosis, leprosy, syphilis), viruses (e.g. CMV disease, herpes zoster), fungi (e.g. aspergillosis, blastomycosis, phycomycosis, histoplasmosis), and certain parasites (e.g. toxoplasmosis, onchocerciasis). Granulomatous uveitis is common in sarcoidosis as well.

SYMPATHETIC OPHTHALMIA (SYMPATHETIC UVEITIS) This is an uncommon condition in which there is bilateral diffuse granulomatous uveitis following penetrating injury to one eye. The condition probably results from an autosensitivity reaction to injured uveal tissue. It leads to a severe visual loss in both the eyes if not diagnosed and treated early.

Histologically, there is granulomatous uveal inflammation consisting of epithelioid cells and lymphocytes affecting both the eyes. There is no necrosis and no neutrophilic or plasma cell infiltration. If lens is also injured, it results in phacoanaphylactic endophthalmitis.

VASCULAR LESIONS

DIABETIC RETINOPATHY Diabetic retinopathy is an important cause of blindness. It is related to the degree and duration of glycaemic control. The condition develops in more than 60% of diabetics 15-20 years after the onset of disease, and in about 2% of diabetics causes blindness. Other ocular complications of diabetes include glaucoma, cataract and corneal disease. Most cases of diabetic retinopathy occur over the age of 50 years. The risk is greater in type 1 diabetes mellitus than in type 2 diabetes mellitus, although in clinical practice there are more patients of diabetic retinopathy due to type 2

diabetes mellitus because of its higher prevalence. Women are more prone to diabetes as well as diabetic retinopathy. Diabetic retinopathy is directly correlated with Kimmelstiel-Wilson nephropathy (page 664).

Histologically, two types of changes are described in diabetic retinopathy—background (non-proliferative) and proliferative retinopathy.

1. Background (non-proliferative) retinopathy This is the initial retinal capillary microangiopathy. The following changes are seen:

- i) Basement membrane shows varying thickness due to increased synthesis of basement membrane substance.
- ii) Degeneration of pericytes and some loss of endothelial cells are found.
- iii) Capillary microaneurysms appear which may develop thrombi and get occluded.
- iv) 'Waxy exudates' accumulate in the vicinity of microaneurysms especially in the elderly diabetics because of hyperlipidaemia.
- v) 'Dot and blot haemorrhages' in the deeper layers of retina are produced due to diapedesis of erythrocytes.
- vi) Soft 'cotton-wool spots' appear on the retina which are microinfarcts of nerve fibre layers. 'Scotomas' appear from degeneration of nerve fibres and ganglion cells.

2. Proliferative retinopathy (retinitis proliferans) After many years, retinopathy becomes proliferative. Severe ischaemia and chronic hypoxia for long period leads to secretion of angiogenic factor by retinal cells and results in the following changes:

- i) Neovascularisation of the retina at the optic disc.
- ii) Friability of newly-formed blood vessels causes them to bleed easily and results in vitreous haemorrhages.
- iii) Proliferation of astrocytes and fibrous tissue around the new blood vessels.
- iv) Fibrovascular and gliotic tissue contracts to cause retinal detachment and blindness.

In addition to the changes on retina, severe diabetes may cause diabetic iridopathy with formation of adhesions

between iris and cornea (peripheral anterior synechiae) and between iris and lens (posterior synechiae). Diabetics also develop cataract of the lens at an earlier age than the general population.

The pathogenesis of blindness in diabetes mellitus is schematically outlined in **Fig. 16.3**.

HYPERTENSIVE RETINOPATHY In hypertensive retinopathy, the retinal arterioles are reduced in their diameter leading to retinal ischaemia. In acute severe hypertension as happens at the onset of malignant hypertension and in toxemia of pregnancy, the vascular changes are in the form of spasms, while in chronic hypertension the changes are diffuse in the form of onion-skin thickening of the arteriolar walls with narrowing of the lumina (page 371).

Features of hypertensive retinopathy include the following (**Fig. 16.4**):

- i) Variable degree of arteriolar narrowing due to arteriosclerosis.
- ii) 'Flame-shaped' haemorrhages in the retinal nerve fibre layer.
- iii) Macular star i.e. exudates radiating from the centre of macula.
- iv) Cotton-wool spots i.e. fluffy white bodies in the superficial layer of retina.
- v) Microaneurysms.
- vi) Arteriovenous nicking i.e. kinking of veins at sites where sclerotic arterioles cross veins.
- vii) Hard exudates due to leakage of lipid and fluid into macula.

Hypertensive retinopathy is classified according to the severity of above lesions from grade I to IV. More serious and severe changes with poor prognosis occur in higher grades of hypertensive retinopathy. Malignant hypertension is characterised by necrotising arteriolitis and fibrinoid necrosis of retinal arterioles.

RETINAL INFARCTS Infarcts of the retina may result from thrombosis or embolism in central artery of the retina, causing ischaemic necrosis of the inner two-third of the retina while occlusion of the posterior ciliary arteries causes ischaemia

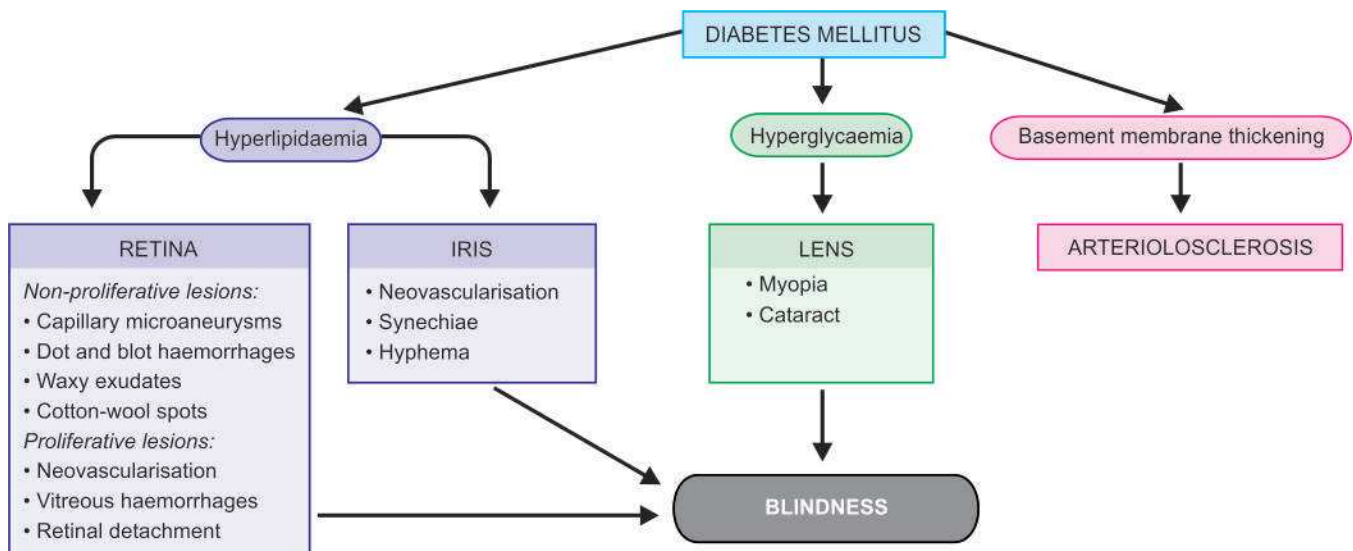

Figure 16.3 Schematic diagram showing the effects of diabetes mellitus on eye in causing blindness.

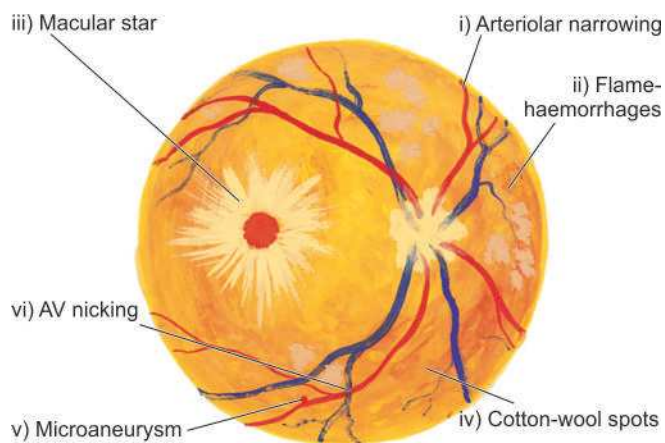

Figure 16.4 Ocular lesions in hypertension.

of the inner photoreceptor layer only. The usual causes of thrombosis and embolism are atherosclerosis, hypertension and diabetes. Occlusion of the central retinal vein produces haemorrhagic infarction of the entire retina.

MISCELLANEOUS CONDITIONS

PINGUECULA AND PTERYGIUM **Pinguecula** is a degenerative condition of the collagen of the bulbar conjunctiva. Clinically, the condition appears as raised yellowish lesions on the interpalpebral bulbar conjunctiva of both eyes in middle-aged and elderly patients.

Histologically, there is characteristic basophilic degeneration of the subepithelial collagen of the conjunctiva. The overlying epithelium may show acanthosis, hyperkeratosis or dyskeratosis.

Pterygium is a lesion closely related to pinguecula but differs from the latter by being located at the limbus and often involves the cornea; hence the lesion is more important clinically.

SENILE MACULAR DEGENERATION Age-related degeneration of the macular region of the retina is an important cause of bilateral central visual loss in the elderly people.

Histologically, in the early stage, there is irregular thickening of the Bruch's membrane that separates retinal pigment epithelium from the choroid, and there is degeneration of the photoreceptor and pigment epithelium. Later, there is ingrowth of capillaries into the choroid, exudation and haemorrhage under the retina which may eventually get organised, heal by fibrosis and result in permanent loss of central vision.

RETINAL DETACHMENT Retinal detachment is the separation of the neurosensory retina from the retinal pigment epithelium. It may occur spontaneously in older individuals past 50 years of age, or may be secondary to trauma in the region of head and neck. Normally, the rods and cones of the photoreceptor layer are interdigitated with projections of the retinal pigment epithelium, but the two can separate readily in some disease processes. There are 3 pathogenetic mechanisms of retinal detachment:

- i) Pathologic processes in the vitreous or anterior segment, causing traction on the retina.
- ii) Collection of serous fluid in the sub-retinal space from inflammation or tumour in the choroid.
- iii) Accumulation of vitreous under the retina through a hole or a tear in the retina.

PHTHISIS BULBI Phthisis bulbi is the end-stage of advanced degeneration and disorganisation of the entire eyeball in which the intraocular pressure is decreased and the eyeball shrinks. The causes of such end-stage blind eye are trauma, glaucoma and intraocular inflammations.

Histologically, there is marked atrophy and disorganisation of all the ocular structures, and markedly thickened sclera. Even osseous metaplasia may occur.

CATARACT The cataract is the opacification of the normally crystalline lens which leads to gradual painless blurring of vision. The various causes of cataract are: senility, congenital (e.g. Down syndrome, rubella, galactosaemia), traumatic (e.g. penetrating injury, electrical injury), metabolic (e.g. diabetes, hypoparathyroidism), association with drugs (e.g. long-term corticosteroid therapy), smoking and heavy alcohol consumption. The most common is, however, idiopathic senile cataract.

Histologically, the changes in the cataractous lens are similar irrespective of the underlying cause. The lens fibres undergo degeneration, fragmentation and liquefaction but the central nucleus remains intact because it is quite sclerotic.

GLAUCOMA Glaucoma is a group of ocular disorders that have in common increased intraocular pressure. Glaucoma is one of the leading causes of blindness because of the ocular tissue damage produced by raised intraocular pressure. In almost all cases, glaucoma occurs due to impaired outflow of aqueous humour, though there is a theoretical possibility of increased production of aqueous by the ciliary body causing glaucoma. The obstruction to the aqueous flow may occur as a result of developmental malformations (**congenital glaucoma**); or due to complications of some other diseases such as uveitis, trauma, intraocular haemorrhage and tumours (**secondary glaucoma**); or may be **primary glaucoma** which is typically bilateral and is the most common type.

There are 2 types of primary glaucoma—*primary open-angle* (chronic simple glaucoma) and *primary angle-closure* (acute congestive glaucoma). Primary open-angle glaucoma is more common type and is usually a genetically-determined disease. Primary angle-closure glaucoma occurs due to shallow anterior chamber and hence narrow angle causing blockage of aqueous outflow.

In all types of glaucoma, degenerative changes appear after some duration and eventually damage to the optic nerve and retina occurs.

PAPILLOEDEMA Papilloedema is oedema of the optic disc resulting from increased intracranial pressure. This is due to anatomic continuation of the subarachnoid space of the brain around the optic nerve so that raised intracranial pressure is passed onto the optic disc area. In *acute papilloedema*, there

is oedema, congestion and haemorrhage at the optic disc. In *chronic papilloedema*, there is degeneration of nerve fibres, gliosis and optic atrophy.

SJÖGREN'S SYNDROME Sjögren's syndrome is characterised by triad of keratoconjunctivitis sicca, xerostomia (sicca syndrome) and rheumatoid arthritis. The condition occurs due to immunologically-mediated destruction of the lacrimal and salivary glands along with another autoimmune disease (page 66).

MIKULICZ'S SYNDROME This is characterised by inflammatory enlargement of lacrimal and salivary glands (page 516). The condition may occur with Sjögren's syndrome, or with some diseases like sarcoidosis, leukaemia, lymphoma and macroglobulinaemia.

TUMOURS AND TUMOUR-LIKE LESIONS

The eye and its adnexal structures are the site of a variety of benign and malignant tumours as well as tumour-like lesions. A brief list of such lesions is given in **Table 16.1**. The morphology of many of these tumours and tumour-like lesions is identical to similar lesions elsewhere in the body. However, a few examples peculiar to the eye are described below.

INFLAMMATORY PSEUDOTUMOURS

These are a group of inflammatory enlargements, especially in the orbit, which clinically look like tumours but surgical exploration and pathologic examination fail to reveal any evidence of neoplasm.

Table 16.1 Tumours and tumour-like lesions of the eye and adnexal structures.

| BENIGN | MALIGNANT |
|-----------------------------------|----------------------------------|
| I. EYELID | |
| Squamous cell papilloma | Squamous cell carcinoma |
| Basal cell papilloma | Basal cell carcinoma |
| Sebaceous adenoma | Sebaceous adenocarcinoma |
| Naevi | Malignant melanoma |
| II. CONJUNCTIVA-CORNEA | |
| Squamous cell papilloma | Squamous cell carcinoma |
| Pseudoepitheliomatous hyperplasia | Mucoepidermoid carcinoma |
| Naevi | Malignant melanoma |
| Haemangioma | |
| III. LACRIMAL GLAND | |
| Pleomorphic adenoma | Carcinoma in pleomorphic adenoma |
| IV. ORBIT | |
| Ectopic glial tissue | Malignant glioma |
| Inflammatory 'pseudotumour' | Malignant lymphoma |
| Meningioma | Rhabdomyosarcoma |
| V. INTRAOCULAR | |
| Naevi | Malignant melanoma |
| Neurofibroma | Retinoblastoma |

The list of malignant tumours is not necessarily as malignant counterparts of benign tumours.

MORPHOLOGIC FEATURES *Grossly*, these lesions are circumscribed and sometimes have fibrous capsule.

Microscopically, many of the lesions can be placed in well-established categories such as tuberculous, syphilitic, mycotic, parasitic, foreign-body granuloma etc, while others show non-specific histologic appearance having abundant fibrous tissue, lymphoid follicles and inflammatory infiltrate with prominence of eosinophils.

SEBACEOUS CARCINOMA

This is the *most frequent tumour of the eyelid* next only to basal cell carcinoma, although it is very rare tumour elsewhere in the body. It arises either from the meibomian glands in the tarsus or from Zeis' glands of eyelash follicles. The tumour is seen mostly in the upper eyelid (basal cell carcinoma is seen more frequently in the lower eyelid).

MORPHOLOGIC FEATURES *Grossly*, the tumour appears as a localised or diffuse swelling of the tarsus, or may be in the form of ulcerated or papillomatous tumour at the lid margin.

Microscopically, the tumour may show well-differentiated lobules of tumour cells with sebaceous differentiation, or may be poorly-differentiated tumour requiring confirmation by fat stains (**Fig. 16.5**). These tumours can metastasise to the regional lymph nodes as well as to distant sites.

UVEAL MALIGNANT MELANOMA

Malignant melanomas arising from neural crest-derived pigment epithelium of the uvea is the most common primary ocular malignancy in the white adults in North America and Europe.

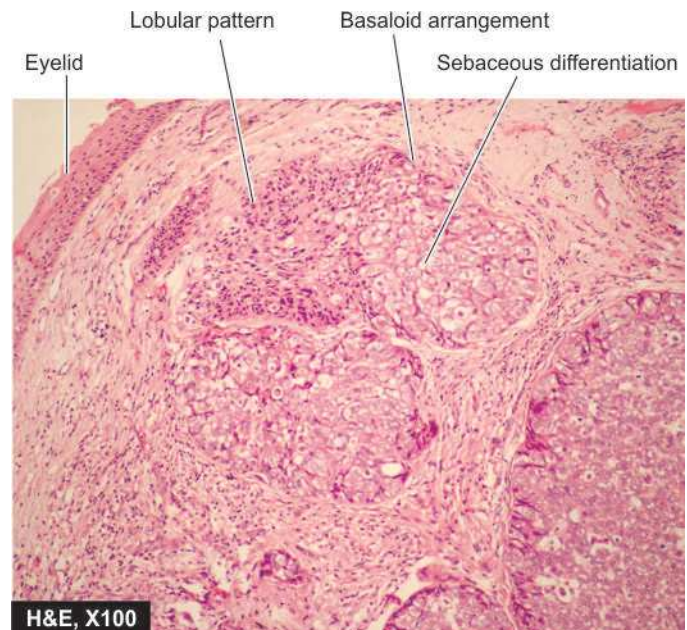

Figure 16.5 Sebaceous carcinoma. The tumour cells are arranged as lobules with peripheral basaloid cells and pale cells in the centre. The cells have sebaceous differentiation appreciated by foamy, vacuolated cytoplasm.

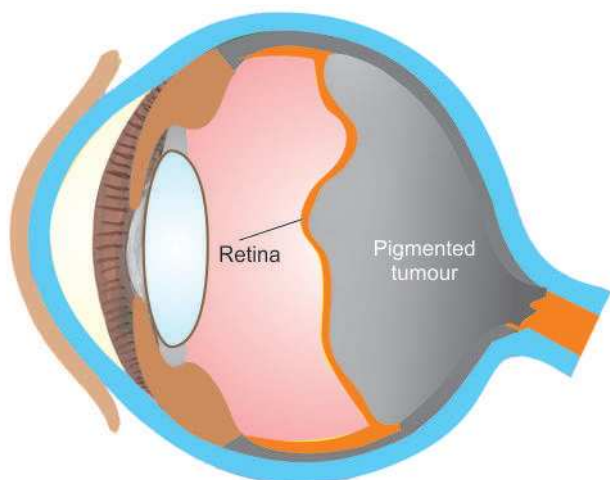

Figure 16.6 Choroidal melanoma appearing as a pigmented mass pushing the retina forward over it.

MORPHOLOGIC FEATURES Grossly, the malignant melanoma appears as a pigmented mass, most commonly in the posterior choroid, and less often in the ciliary body and iris. The mass projects into the vitreous cavity with retina covering it (**Fig. 16.6**).

Microscopically, age-old classification of Callender (1931) which has prognostic significance is still followed with some modifications:

- 1. Spindle A melanoma** is composed of uniform, spindle-shaped cells containing spindled nuclei. Nucleoli are indistinct and mitotic figures are rare. Tumours of this type have the most favourable prognosis (85% 10-year survival).
- 2. Spindle B melanoma** is composed of larger and plump spindle-shaped cells with ovoid nuclei. Nucleoli are conspicuous and a few mitotic figures are present. These tumours carry slightly worse prognosis (80% 10-year survival).
- 3. Epithelioid melanoma** consists of larger, irregular and pleomorphic cells with larger nuclei and abundant acidophilic cytoplasm (**Fig. 16.7**). These tumours are the most malignant of the uveal melanomas and have poor prognosis (35% 10-year survival).
- 4. Mixed cell type melanomas** have features of spindle cell type as well as of epithelioid cell type. These are more common tumours and carry an intermediate prognosis (45% 10-year survival).

In general, uveal malignant melanomas are usually slow-growing, late metastasising and have a better prognosis than malignant melanoma of the skin (page 778). Uveal melanomas spread via haematogenous route and the liver is eventually involved in 90% of cases. Various indicators of bad prognosis include large tumour size and epithelioid cell type.

RETINOBLASTOMA

This is the most common malignant ocular tumour in children. It may be present at birth or recognised in early childhood before the age of 4 years. Retinoblastoma has some peculiar features. About 60% cases of retinoblastoma are sporadic and

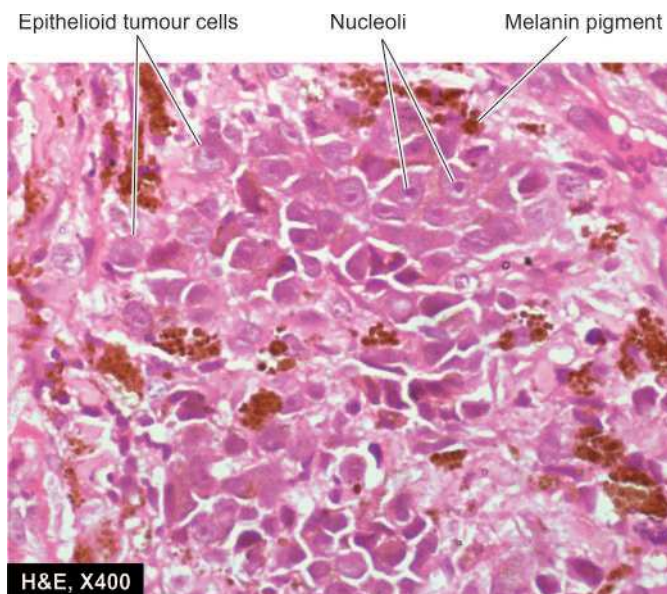

Figure 16.7 Uveal melanoma. The tumour cells are epithelioid in appearance having prominent nucleoli and contain black finely granular melanin pigment in the cytoplasm.

the remaining 40% are familial. Familial tumours are often multiple and multifocal and transmitted as an autosomal dominant trait by retinoblastoma susceptibility gene (*RB*) located on chromosome 13. Such individuals have a higher incidence of bilateral tumours and have increased risk of developing second primary tumour, particularly osteogenic sarcoma (page 832). Retinoblastoma may occur as a congenital tumour too. Clinically, the child presents with leukokoria i.e. white pupillary reflex.

MORPHOLOGIC FEATURES Grossly, the tumour characteristically appears as a white mass within the retina which may be partly solid and partly necrotic. The tumour may be *endophytic* when it protrudes into the vitreous, or *exophytic* when it grows between the retina and the pigment epithelium (**Fig. 16.8**).

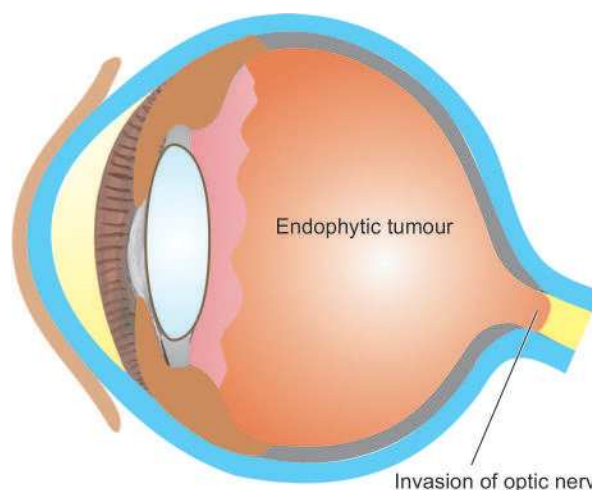

Figure 16.8 Retinoblastoma, showing white mass growing extensively within the posterior part of the eye.

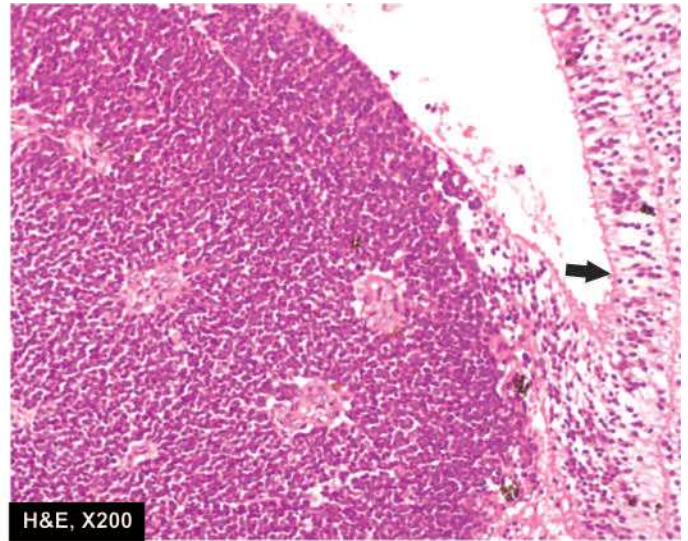

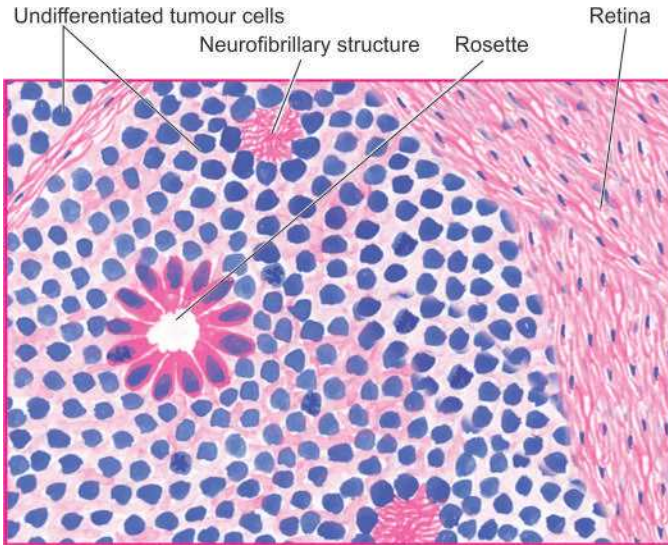

Figure 16.9 Retinoblastoma. The tumour arising from the retina (arrow) shows undifferentiated retinal cells and the typical rosettes.

Microscopically, the tumour is composed of undifferentiated retinal cells with tendency towards formation of photoreceptor elements. In the better differentiated area, the tumour cells are characteristically arranged in rosettes. The rosettes may be of 2 types—*Flexner-Wintersteiner rosettes* characterised by small tumour cells arranged around a lumen with their nuclei away from the lumen, and *Homer-Wright rosettes* having radial arrangement of tumour cells around the central neurofibrillar structure (**Fig. 16.9**). The tumour shows wide areas of necrosis and calcification and dissemination in all directions—into the vitreous, under the retina, into the optic nerve and even into the brain.

Besides direct spread, the tumour can spread widely via haematogenous route as well. Prognosis is determined by the extent of local invasion and distant metastasis.

Salient features of retinoblastoma are contrasted with those of uveal melanoma in **Table 16.2**.

METASTATIC TUMOURS

Ocular metastatic tumours are far more common than primary ocular malignant tumours, choroid and iris being the preferential site for metastasis. Common primary tumours that metastasise to the eye are cancers of the breast in women

and lung in men. Leukaemia and malignant lymphoma also commonly invade ocular tissues.

GIST BOX 16.1 Diseases of Eye

- ▣ Retinopathy of prematurity and retinitis pigmentosa are important congenital diseases of eye.
- ▣ Various tissues of the eye are involved in inflammation: e.g. stye (for sebaceous glands), chalazion (for meibomian glands), endophthalmitis (intraocular tissues), conjunctivitis, keratitis (for cornea), trachoma (for Chlamydial infection of conjunctiva), granulomatous uveitis and sympathetic ophthalmia (autosensitivity reaction).
- ▣ Retinal capillary vessels are affected in diabetes mellitus and hypertension.
- ▣ Pinguecula and pterygium are degeneration of collagen of conjunctiva.
- ▣ Sebaceous carcinoma is malignant tumour of meibomian and Zeis' glands.
- ▣ Uveal melanoma is slow-growing compared to cutaneous melanoma.
- ▣ Retinoblastoma is a malignant ocular tumour in children which disseminates widely.

Table 16.2 Uveal malignant melanoma versus retinoblastoma.

| FEATURE | UVEAL MELANOMA | RETINOBLASTOMA |
|---------------------|--|---|
| 1. Inheritance | Rare | About 40% cases |
| 2. Age | >50 years | Birth to 4 years |
| 3. Race | Common in Caucasians, uncommon in blacks | No predisposition |
| 4. Location | Most commonly choroid | Retina |
| 5. Bilaterality | Rare | Common (30%) |
| 6. Cell of origin | Melanocytes | Retinal neurons |
| 7. Colour of tumour | Grey-black | Creamy |
| 8. Spread | Haematogenous common, rarely via optic nerve | Common via both haematogenous and optic nerve |

EAR

NORMAL STRUCTURE

The ear is divided into 3 parts—the external, middle and inner ear.

◆ The **external ear** comprises the auricle or pinna composed of cartilage, the external cartilaginous meatus and the external bony meatus. The external meatus is lined by stratified epithelium which is continued on to the external layer of the tympanic membrane. The tympanic membrane has middle layer of elastic fibrous tissue and the inner layer of mucous membrane and is supported around the periphery by the annulus.

◆ The **middle ear** consists of 3 parts—the uppermost portion is the *attic*, the middle portion is *mesotympanum*, and the lowermost portion is the *hypotympanum*. Besides, the middle ear has an opening, eustachian tube, the mastoid antrum and cells, and the three ossicles (the malleus, incus and stapes). The middle ear is lined by a single layer of flat ciliated and nonciliated epithelium.

◆ The **inner ear** or labyrinth consists of bony capsule embedded in the petrous bone and contains the membranous labyrinth. The bony capsule consists of 3 parts—posteriorly three semicircular canals, in the middle is the vestibule, and anteriorly contains snail-like cochlea.

Besides the *function* of hearing, the stimulation of vestibular labyrinth can cause vertigo, nausea, vomiting and nystagmus.

INFLAMMATORY AND MISCELLANEOUS LESIONS

OTITIS MEDIA This is the term used for inflammatory involvement of the middle ear. It may be acute or chronic. The usual source of infection is via the eustachian tube and the common causative organisms are *Streptococcus pneumoniae*, *Haemophilus influenzae* and β -*Streptococcus haemolyticus*. Otitis media may be suppurative, serous or mucoid. Acute suppurative otitis media (SOM) clinically presents as tense and hyperaemic tympanic membrane along with pain and tenderness and sometimes mastoiditis as well. Chronic SOM manifests clinically as draining ear with perforated tympanic membrane and partially impaired hearing. Serous or mucoid otitis media refers to non-suppurative accumulation of serous or thick viscid fluid in the middle ear. These collections of fluid are encountered more often in children causing hearing problems and occur due to obstruction of the eustachian tube.

RELAPSING POLYCHONDRITIS This is an uncommon autoimmune disease characterised by complete loss of glycosaminoglycans resulting in destruction of cartilage of the ear, nose, eustachian tube, larynx and lower respiratory tract.

Histologically, the perichondral areas show acute inflammatory cell infiltrate and destruction and vascularisation of the cartilage. Late stage shows lymphocytic infiltration and fibrous replacement.

CHONDRODERMATITIS NODULARIS CHRONICA HELICIS This condition involves the external ear superficially and presents as a 'painful nodule of the ear'. The skin in this location

is in direct contact with the cartilage without protective subcutaneous layer.

Histologically, the nodule shows epithelial hyperplasia with degeneration of the underlying collagen, chronic inflammatory cell infiltrate, vascular proliferation and fibrosis.

CAULIFLOWER EAR This is an acquired deformity of the external ear due to degeneration of cartilage as a result of repeated trauma as occurs in boxers and wrestlers.

Histologically, there is destruction of cartilage forming homogeneous matrix (chondromalacia) and fibrous replacement.

OTOSCLEROSIS This is a dystrophic disease of labyrinth of the temporal bone. The footplate of stapes first undergoes fibrous replacement and is subsequently replaced by sclerotic bone. The exact etiology is not known but the condition has familial preponderance and autosomal dominant trait. It is seen more commonly in young males as a cause for sensorineural type of deafness.

TUMOURS AND TUMOUR-LIKE LESIONS

Tumours and tumour-like conditions are relatively more common in the external than the middle and inner ear. Many of the lesions seen in the external ear are similar to those seen in the skin e.g. *tumour-like lesions* such as epidermal cyst; *benign tumours* like naevi and squamous cell papilloma; and *malignant tumours* such as basal cell carcinoma, squamous cell carcinoma and malignant melanoma. However, tumours and tumour-like lesions which are specific to the ear are described below. These include the following:

- ◆ In the external ear—aural (otic) polyps and cerumen-gland tumours.
- ◆ In the middle ear—cholesteatoma (keratoma) and jugular paraganglioma (glomus jugulare tumour).
- ◆ In the inner ear—acoustic neuroma.

AURAL (OTIC) POLYPS Aural or otic polyps are tumour-like lesions arising from the middle ear as a complication of the chronic otitis media and project into the external auditory canal.

Histologically, they are composed of chronic inflammatory granulation tissue and are often covered by metaplastic squamous epithelium or pseudostratified columnar epithelium.

CERUMEN-GLAND TUMOURS Tumours arising from cerumen-secreting apocrine sweat glands of the external auditory canal are cerumen-gland adenomas or cerumen-gland adenocarcinomas and are counter-parts of sweat gland tumours (hidradenoma and adenocarcinoma) of the skin (page 777). Both these tumours may invade the temporal bone.

CHOLESTEATOMA (KERATOMA) This is a post-inflammatory 'pseudotumour' found in the middle ear or mastoid air cells. There is invariable history of acute or chronic otitis media. A marginal perforation is generally present through

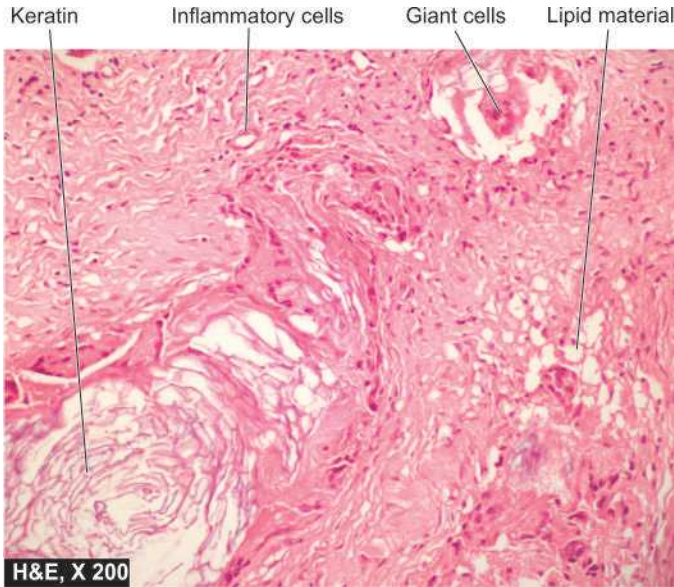

Figure 16.10 Cholesteatoma middle ear. There is chronic inflammatory granulation tissue and foreign body giant cells around the cholesterol clefts and some pink keratinous material.

which the squamous epithelium enters the middle ear and results in exfoliation of squamous and formation of the keratin. Rarely, it may be a primary lesion arising from embryonal rests of squamous epithelium in the temporal bone.

Histologically, the lesion consists of cyst containing abundant keratin material admixed with cholesterol crystals and large number of histiocytes (Fig. 16.10). In advanced cases, there may be pressure erosion of the bone.

JUGULAR PARANGLIOMA (GLOMUS JUGULARE TUMOUR, NON-CHROMAFFIN PARANGLIOMA)

Tumours originating from parasympathetic ganglia are called 'paranglioma' and are named according to the location of the tissue of origin. The one arising from glomus jugulare bodies of the middle ear (jugulotympanic bodies) is called jugular paranglioma or chemodectoma or non-chromaffin paranglioma and is the most common benign tumour of the middle ear. Histologically similar tumours are seen in the carotid bodies and vagus (page 503).

Microscopically, the tumour cells containing neurosecretory granules are arranged in typical organoid pattern or nests. The tumour may extend locally to involve the skull and brain but may rarely metastasise.

ACOUSTIC NEUROMA (ACOUSTIC SCHWANNOMA) This is a tumour of Schwann cells of 8th cranial nerve (page 885). It is usually located in the internal auditory canal and cerebellopontine angle. It is a benign tumour similar to other schwannomas but by virtue of its location and large size, may produce compression of the important neighbouring tissues leading to deafness, tinnitus, paralysis of 5th and 7th nerves, compression of the brainstem and hydrocephalus.

Some recent epidemiologic studies have hinted towards probable association of acoustic neuroma with long-term use of mobile phone.

GIST BOX 16.2

Diseases of Ear

- ▣ Otitis media is acute and chronic inflammation of the middle ear.
- ▣ Aural polyps and cholesteatoma may develop following chronic SOM.
- ▣ Acoustic neuroma is benign tumour of the 8th cranial nerve and is similar to schwannoma.

NOSE AND PARANASAL SINUSES

NORMAL STRUCTURE

The external nose and the septum are composed of bone and cartilage. On the lateral wall of the nasal cavity, there is a system of 3 ridges on each side known as conchae or turbinates—the inferior, middle and superior. The nasal accessory sinuses are air spaces in the bones of the skull and communicate with the nasal cavity. They are the frontal air sinus, maxillary air sinus and the anterior ethmoid air cells, comprising the *anterior group*, while posterior ethmoidal cells and sphenoidal sinus form the *posterior group*. The anterior group drains into the middle meatus while the posterior group drains into the superior meatus and the sphenothmoidal recess.

Microscopically, nasal mucous membranes as well as the lining of the nasal sinus are lined by respiratory epithelium (pseudostratified columnar ciliated cells). Mucous and serous glands lie under the mucous membrane. Besides, the upper and middle turbinate processes and the upper third of the septum are covered with olfactory mucous membrane.

The main physiologic *functions* of the nose are smell, filtration, humidification and warming of the air being breathed.

INFLAMMATORY CONDITIONS

ACUTE RHINITIS (COMMON COLD) Acute rhinitis or common cold is the common inflammatory disorder of the nasal cavities that may extend into the nasal sinuses. It begins with rhinorrhoea, nasal obstruction and sneezing. Initially, the nasal discharge is watery, but later it becomes thick and purulent. The etiologic agents are generally adenoviruses that evoke catarrhal discharge. Chilling of the body is a contributory factor. Secondary bacterial invasion is common. The nasal mucosa is oedematous, red and thickened.

Microscopically, there are numerous neutrophils, lymphocytes, plasma cells and some eosinophils with abundant oedema.

ALLERGIC RHINITIS (HAY FEVER) Allergic rhinitis occurs due to sensitivity to allergens such as pollens. It is an IgE-mediated immune response consisting of an early acute response due to degranulation of mast cells, and a delayed prolonged response in which there is infiltration by leucocytes such as eosinophils, basophils, neutrophils and macrophages accompanied with oedema.

SINUSITIS Acute sinusitis is generally a complication of acute or allergic rhinitis and rarely secondary to dental sepsis.

The ostia are occluded due to inflammation and oedema and the sinuses are full. 'Mucocoele' is filling up of the sinus with mucus while 'empyema' of the sinus occurs due to collection of pus. Acute sinusitis may become chronic due to incomplete resolution of acute inflammation and from damage to the mucous membrane. Sinusitis may rarely spread to produce osteomyelitis and intracranial infections.

NASAL POLYPS Nasal polyps are common and are pedunculated grape-like masses of tissue. They are the end-result of prolonged chronic inflammation causing polypoid thickening of the mucosa. They may be *allergic* or *inflammatory*. They are frequently bilateral and the middle turbinate is the common site. *Antrochoanal polyps* originate from the mucosa of the maxillary sinus and appear in the nasal cavity. Morphologically, nasal and antro-choanal polyps are identical.

Grossly, they are gelatinous masses with smooth and shining surface.

Microscopically, they are composed of loose oedematous connective tissue containing some mucous glands and varying number of inflammatory cells like lymphocytes, plasma cells and eosinophils. Allergic polyps have plenty of eosinophils and hyperplasia of mucous glands. Both inflammatory and allergic polyps are covered by respiratory epithelium which may show squamous metaplasia (Fig. 16.11). Nasal polyps may have superimposed fungal infection.

RHINOSPORIDIOSIS Rhinosporidiosis is caused by a fungus, *Rhinosporidium seeberi*. Typically it occurs in a nasal polyp but may be found in other locations like nasopharynx, larynx and conjunctiva. The disease is common in India and Sri Lanka and sporadic in other parts of the world.

Microscopically, besides the structure of inflammatory or allergic polyp, large number of organisms of the size of erythrocytes with chitinous wall are seen in the thick-walled *sporangia*. Each sporangium may contain a few

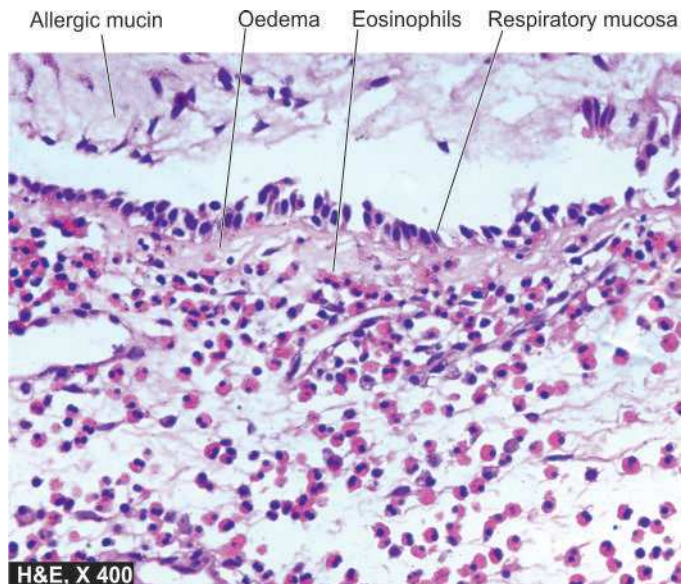

Figure 16.11 Allergic polyp nose. The overlying mucosa is covered partly by respiratory and partly by squamous metaplastic epithelium. The underlying stroma is oedematous and contains inflammatory cells with prominence of eosinophils.

thousand spores. On rupture of a sporangium, the spores are discharged into the submucosa or on to the surface of the mucosa. The intervening tissue consists of inflammatory granulation tissue (plasma cells, lymphocytes, histiocytes, neutrophils) while the overlying epithelium shows hyperplasia, focal thinning and occasional ulceration (Fig. 16.12).

RHINOSCLEROMA This is a chronic destructive inflammatory lesion of the nose and upper respiratory airways caused by diplobacilli, *Klebsiella rhinoscleromatis*. The condition is endemic in parts of Africa, America, South Asia and Eastern Europe. The condition begins as a common cold and progresses to atrophic stage, and then into the nodular stage characterised by small tumour-like submucosal masses.

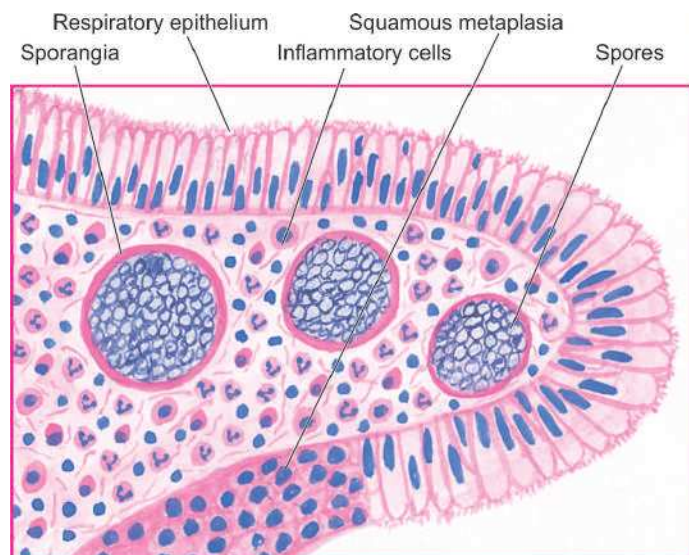

Figure 16.12 Rhinosporidiosis in a nasal polyp. The spores are present in sporangia as well as are intermingled in the inflammatory cell infiltrate.

Histologically, there is extensive infiltration by foamy histiocytes containing the organisms (Mikulicz cells) and other chronic inflammatory cells like lymphocytes and plasma cells.

GRANULOMAS Many types of granulomatous inflammations may involve the nose. These include: tuberculosis, leprosy, syphilis, aspergillosis, mucormycosis, Wegener's granulomatosis and lethal midline granuloma.

1. Tuberculosis or lupus of the nose is uncommon and occurs secondary to pulmonary tuberculosis and usually produces ulcerative lesions on the anterior part of the septum of the nose.

2. Leprosy begins as a nodule that may ulcerate and perforate the septum.

3. Syphilis may involve the nose in congenital form causing destruction of the septum, or in acquired tertiary syphilis in the form of gummas perforating the septum. In either case, characteristic saddle-nose deformity occurs due to collapse of bridge of the nose.

4. Aspergillosis may involve the paranasal sinuses where the septate hyphae grow to form a mass called *aspergilloma*.

5. Mucormycosis is an opportunistic infection caused by *Mucorales* which are non-septate hyphae and involve the nerves and blood vessels.

6. Wegener's granulomatosis is a form of necrotising vasculitis with granuloma formation affecting the upper respiratory tract, lungs and kidneys (page 383). In 15-50% of cases, the condition may evolve into malignant lymphoma.

7. Lethal midline granuloma or polymorphic reticulosis is a rare and lethal lesion of the upper respiratory tract that causes extensive destruction of cartilage and necrosis of tissues and does not respond to antibiotic treatment. Besides the necrosis, lymphoid infiltrates of pleomorphic and atypical cells admixed with small lymphocytes, plasma cells and macrophages are seen. Currently, the condition is considered to be a nasal type extranodal T cell lymphoma that may respond to chemotherapy and radiotherapy (page 360).

TUMOURS

The tumours of nose, nasal cavity and paranasal sinuses are uncommon. However, benign and malignant tumours of epithelial as well as mesenchymal origin can occur.

BENIGN TUMOURS

CAPILLARY HAEMANGIOMA Capillary haemangioma of the septum of nose is a common benign lesion and is similar to its counterparts elsewhere (page 391). If the surface is ulcerated and the lesion contains inflammatory cell infiltrate, it resembles inflammatory granulation tissue and is called '*haemangioma of granulation tissue type*' or '*granuloma pyogenicum*'.

SINONASAL PAPILLOMAS Papillomas may occur in the nasal vestibule, nasal cavity and paranasal sinuses. They are mainly of 2 types—*fungiform papilloma* with exophytic growth, and *inverted papilloma* with everted growth, also called Schneiderian papilloma. Inverted papilloma due to downward growth must not be mistaken for carcinoma (**Fig. 16.13**). Papillomas of either type may be lined with various

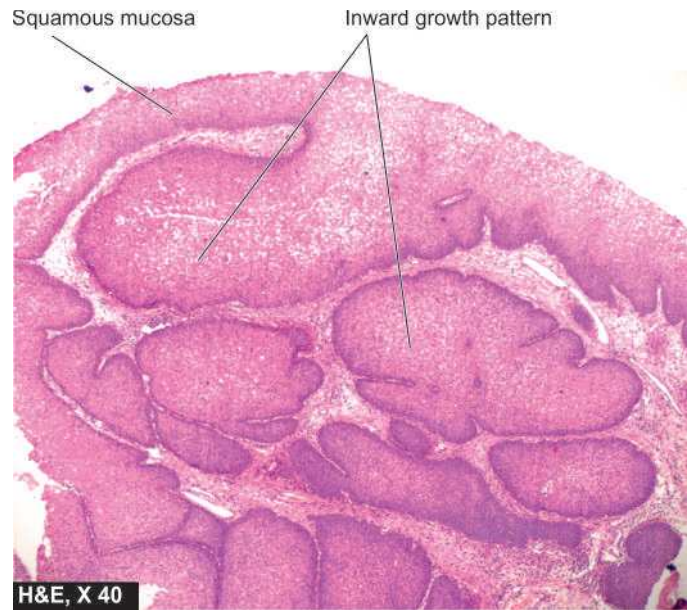

Figure 16.13 Inverted nasal papilloma. There is inverted pattern of growth of differentiated squamous cells with normal base to surface orientation.

combinations of epithelia: respiratory, squamous and mucous type.

MALIGNANT TUMOURS

OLFACTORY NEUROBLASTOMA OR ESTHESIONEUROBLASTOMA It occurs over the olfactory mucosa as a polypoid mass that may invade the paranasal sinuses or skull. It is a highly malignant small cell tumour of neural crest origin that may, at times, be indistinguishable from other small cell malignancies like rhabdomyosarcoma, undifferentiated carcinoma, lymphoma or Ewing's sarcoma. Rosettes are found in about 10% of tumours.

CARCINOMAS Carcinomas of the nasal cavity and paranasal sinuses are called *sinonasal carcinomas*. Most commonly, these are squamous cell carcinomas of varying grades of differentiation; others are adenocarcinoma, small cell neuroendocrine type etc. They are seen more commonly in the elderly with history of heavy smoking and severe chronic sinusitis, and in persons engaged in certain occupations e.g. in nickel refinery workers and in wood workers. The tumour extends locally to involve the surrounding bone and soft tissues and also metastasises widely.

Other types of malignancies found uncommonly in this location are: adenoid cystic carcinoma, mucoepidermoid carcinoma, lymphoma and malignant melanoma.

GIST BOX 16.3

Diseases of Nose and Paranasal Sinuses

- ☐ Nasal polyps are pedunculated masses which are commonly allergic type.
- ☐ Rhinosporidiosis presents as nasal polyp and has sporangia of fungus.
- ☐ Common benign tumours of this region are haemangioma and papilloma.
- ☐ Common malignant tumours are sinonasal carcinoma (usually squamous cell type) and olfactory neuroblastoma.

NORMAL STRUCTURE

The pharynx has 3 parts—the nasopharynx, oropharynx (pharynx proper) and the laryngopharynx. The whole of pharynx is lined by stratified squamous epithelium. The lymphoid tissue of the pharynx is comprised by the tonsils and adenoids.

INFLAMMATORY CONDITIONS

LUDWIG'S ANGINA This is a severe, acute streptococcal cellulitis involving the neck, tongue and back of the throat. The condition was more common in the pre-antibiotic era as a complication of compound fracture of the mandible and periapical infection of the molars. The condition often proves fatal due to glottic oedema, asphyxia and severe toxæmia.

VINCENT'S ANGINA Vincent's angina is a painful condition of the throat characterised by local ulceration of the tonsils, mouth and pharynx. The causative organism is *Vincent's bacillus*. The condition may occur as an acute illness involving the tissues diffusely, or as chronic form consisting of ulceration of the tonsils.

DIPHThERIA Diphtheria is an acute communicable disease caused by *Corynebacterium diphtheriae*. It usually occurs in children and results in the formation of a yellowish-grey pseudomembrane in the mucosa of nasopharynx, oropharynx, tonsils, larynx and trachea. *C. diphtheriae* elaborates an exotoxin that causes necrosis of the epithelium which is associated with abundant fibrinopurulent exudate resulting in the formation of pseudomembrane. Absorption of the exotoxin in the blood may lead to more distant injurious effects such as myocardial necrosis, polyneuritis, parenchymal necrosis of the liver, kidney and adrenals. The constitutional symptoms such as fever, chills, malaise, obstruction of the airways and dyspnoea are quite marked. The condition has to be distinguished from the membrane of streptococcal infection.

TONSILLITIS Tonsillitis caused by staphylococci or streptococci may be acute or chronic.

◆ *Acute tonsillitis* is characterised by enlargement, redness and inflammation. Acute tonsillitis may progress to acute follicular tonsillitis in which crypts are filled with debris and pus giving it follicular appearance.

◆ *Chronic tonsillitis* is caused by repeated attacks of acute tonsillitis in which case the tonsils are small and fibrosed. Acute tonsillitis may pass on to tissues adjacent to tonsils to form peritonsillar abscess or *quinsy*.

PERITONSILLAR ABSCESS (QUINSY) Peritonsillar abscess or quinsy occurs as a complication of acute tonsillitis. The causative organisms are staphylococci or streptococci which are associated with infection of the tonsils. The patient complains of acute pain in the throat, trismus, difficulty in speech and inability to swallow. The glands behind the angle of the mandible are enlarged and tender. Besides the surgical management of the abscess, the patient must be advised tonsillectomy because quinsy is frequently recurrent.

RETROPHARYNGEAL ABSCESS Formation of abscess in the soft tissue between the posterior wall of the pharynx and the vertebral column is called retropharyngeal abscess. It occurs due to infection of the retropharyngeal lymph nodes. It is found in debilitated children. A chronic form of the abscess

in the same location is seen in tuberculosis of the cervical spine (*cold abscess*).

TUMOURS

There are 4 main tumours of note in the pharynx, one benign—nasopharyngeal angiofibroma, and three malignant—nasopharyngeal carcinoma, embryonal rhabdomyosarcoma and malignant lymphoma.

NASOPHARYNGEAL ANGIOFIBROMA This is a peculiar tumour that occurs exclusively in adolescent males (10-20 years of age) suggesting the role of testosterone hormone in its production. Though a benign tumour of the nasopharynx, it may grow into paranasal sinuses, cheek and orbit but does not metastasise.

Microscopically, the tumour is composed of 2 components as the name suggests—numerous small endothelium-lined vascular spaces and the stromal cells which are myofibroblasts (Fig. 16.14). The androgen-dependence of the tumour is confirmed by demonstration by immunostaining for androgen receptors in 75% cases.

NASOPHARYNGEAL CARCINOMA Nasopharyngeal carcinoma is a common cancer in South-East Asia, especially prevalent in people of Chinese descent under 45 years of age. Genetic susceptibility and role of Epstein-Barr virus are considered important factors in its etiology (page 219). In fact, EBV-genome is found virtually in all cases of nasopharyngeal carcinoma. The primary tumour is generally small and undetected, while the metastatic deposits in the cervical lymph nodes may be large.

Microscopically, nasopharyngeal carcinoma has 3 histologic variants:

- i) Non-keratinising squamous cell carcinoma
- ii) Keratinising squamous cell carcinoma
- iii) Undifferentiated (transitional cell) carcinoma

Figure 16.14 Angiofibroma nose. There is admixture of thin-walled blood vessels and spindled stroma. The blood vessels are variable-sized, some having incomplete muscle coat and there is absence of elastic tissue. The stroma has stellate fibroblasts and mast cells.

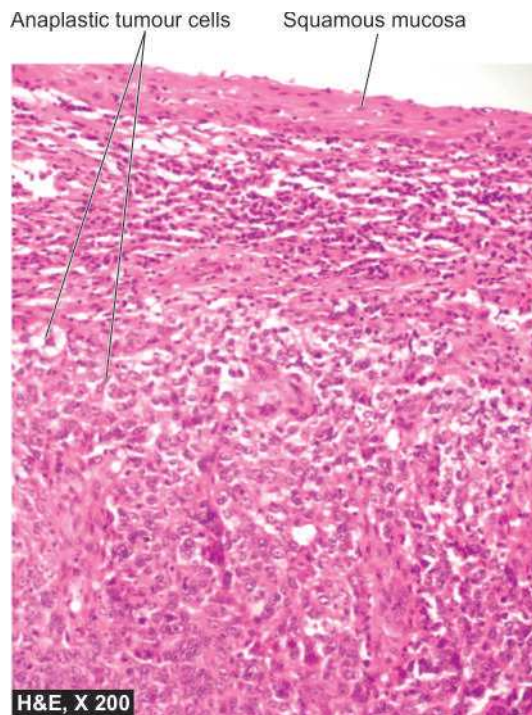

Figure 16.15 Nasopharyngeal carcinoma, non-keratinising. The tumour is composed of undifferentiated anaplastic cells arranged in nests.

Non-keratinising and keratinising squamous cell carcinomas are identical in morphology to typical tumours in other locations. The undifferentiated carcinoma, also called as transitional cell carcinoma, is characterised by masses and cords of cells which are polygonal to spindled and have large vesicular nuclei. A variant of undifferentiated carcinoma is '*lymphoepithelioma*' in which undifferentiated carcinoma is infiltrated by abundant non-neoplastic mature lymphocytes (**Fig. 16.15**).

The prognosis is usually fatal. Undifferentiated carcinoma is radiosensitive.

EMBRYONAL RHABDOMYOSARCOMA Also termed as botryoid rhabdomyosarcoma, this is one of the common malignant tumours in children but can also occur in adults. The lesion is highly cellular and mitotically active. Other locations include vagina, orbit, middle ear, oral cavity, retroperitoneum and bile duct. It is discussed in detail on page 713.

MALIGNANT LYMPHOMA The lymphoid tissue of the nasopharynx and tonsils may be the site for development of malignant lymphomas which resemble similar tumours elsewhere in the body.

GIST BOX 16.4 Diseases of Pharynx

- ☐ Tonsillitis is a common acute and chronic inflammation of tonsils.
- ☐ Nasopharyngeal angiofibroma is a peculiar tumour in adolescent males composed of numerous vascular spaces and myofibroblastic stromal cells.
- ☐ Nasopharyngeal carcinoma is EBV-related squamous or transitional cell tumour.
- ☐ Embryonal (botryoid) rhabdomyosarcoma is a malignant tumour of children seen in nasopharynx, vagina, orbit etc.

LARYNX

NORMAL STRUCTURE

The larynx is composed of cartilages which are bound together by ligaments and muscles and is covered by mucous membrane. The cartilages of the larynx are of 2 types—unpaired and paired.

◆ The *unpaired laryngeal cartilages* are epiglottis, thyroid cartilage (Adam's apple) and cricoid cartilage.

◆ The *paired cartilages* are the arytenoid cartilages which play important part in the movement of vocal cords.

The larynx as well as trachea are lined by respiratory epithelium, except over the true vocal cords and the epiglottis, which are lined by stratified squamous epithelium.

INFLAMMATORY CONDITIONS

ACUTE LARYNGITIS This may occur as a part of the upper or lower respiratory tract infection. Atmospheric pollutants like cigarette smoke, exhaust fumes, industrial and domestic smoke etc predispose the larynx to acute bacterial and viral infections. *Streptococci* and *H. influenzae* cause acute epiglottitis which may be life-threatening. Acute laryngitis may occur in some other illnesses like typhoid, measles and influenza. Acute pseudomembranous (diphtheric) laryngitis occurs due to infection with *C. diphtheriae*.

CHRONIC LARYNGITIS Chronic laryngitis may occur from repeated attacks of acute inflammation, excessive smoking, chronic alcoholism or vocal abuse. The surface is granular due to swollen mucous glands. There may be extensive squamous metaplasia due to heavy smoking, chronic bronchitis and atmospheric pollution.

TUBERCULOUS LARYNGITIS Tuberculous laryngitis occurs secondary to pulmonary tuberculosis. Typical caseating tubercles are present on the surface of the larynx.

ACUTE OEDEMA OF THE LARYNX This hazardous condition is an acute inflammatory condition, causing swelling of the larynx that may lead to airway obstruction and death by suffocation. Acute laryngeal oedema may occur due to trauma, inhalation of irritants, drinking hot fluids or may be infective in origin.

TUMOURS

Both benign and malignant tumours occur in the larynx. The common examples of benign tumours are papillomas and polyps, while laryngeal carcinoma is an important example amongst malignant tumours.

LARYNGEAL PAPILOMA AND PAPILOMATOSIS Juvenile laryngeal papillomas are found in children or adolescents and are often multiple, while the adults have usually a single lesion. Multiple juvenile papillomas may undergo spontaneous regression at puberty. Human papilloma virus (HPV type 11 and 6) has been implicated in the etiology of papillomas of the larynx.

Grossly, the lesions appear as warty growths on the true vocal cords, epiglottis and sometimes extend to the trachea and bronchi.

Microscopically, papillomas are composed of finger-like papillae, each papilla contains fibrovascular core covered by stratified squamous epithelium (**Fig. 16.16**).

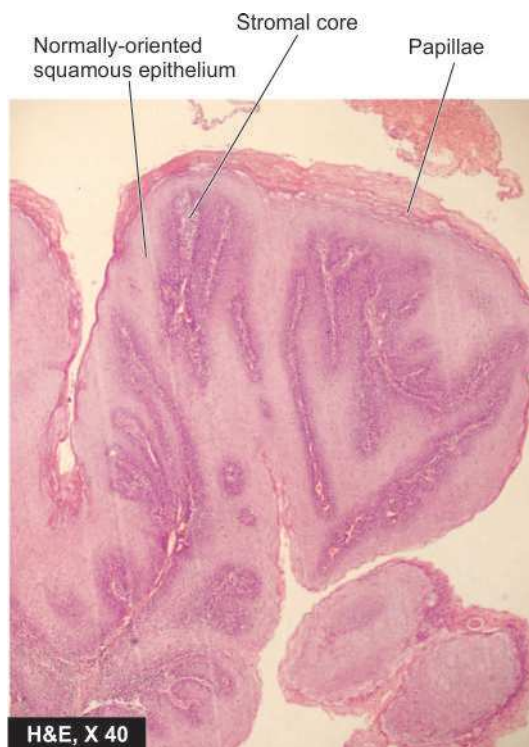

Figure 16.16 Squamous cell papilloma. There is papillomatosis; papillae are covered with well oriented and orderly layers of squamous cells.

LARYNGEAL NODULES Laryngeal nodules or polyps are seen mainly in adults and are found more often in heavy smokers and in individuals subjected to vocal abuse. Therefore, they are known by various synonyms like singers' nodes, preachers' node, and screamers' nodes. The patients have characteristic progressive hoarseness.

Grossly, it is a small lesion, less than 1 cm in diameter, rounded, smooth, usually sessile and polypoid swelling on the true vocal cords.

Microscopically, the nodules have prominent oedema with sparse fibrous tissue and numerous irregular and dilated vascular channels. Sometimes, the subepithelial basement membrane is thickened, resembling amyloid material (**Fig. 16.17**).

LARYNGEAL CARCINOMA Cancer of the larynx in 99% of cases is squamous cell carcinoma. Rarely, adenocarcinoma and sarcoma are encountered. Squamous carcinoma of the larynx occurs in males beyond 4th decade of life. Important etiologic factor is heavy smoking of cigarettes, cigar or pipe; other factors include excessive alcohol consumption, radiation and asbestos exposure.

Carcinoma of the larynx is conventionally classified into *extrinsic* that arises or extends outside the larynx, and *intrinsic* that arises within the larynx. However, based on the anatomic location, laryngeal carcinoma is classified as under:

1. *Glottic* is the most common location, found in the region of true vocal cords and anterior and posterior commissures.
2. *Supraglottic* involving ventricles and arytenoids.
3. *Subglottic* in the walls of subglottis.
4. *Marginal zone* between the tip of epiglottis and aryepiglottic folds.
5. *Laryngo-(hypo-) pharynx* in the pyriform fossa, postcricoid fossa and posterior pharyngeal wall.

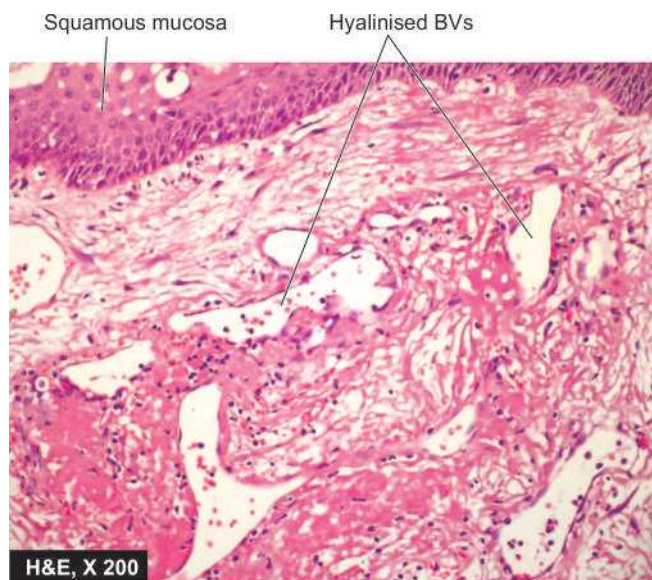

Figure 16.17 Laryngeal nodule. The lesion has intact surface epithelium. The subepithelium has fibromyxoid appearance and contains proliferating blood vessels some of which are hyalinised.

Grossly, the glottic carcinoma is the most common form and appears as a small, pearly white, plaque-like thickening that may be ulcerated or fungated.

Microscopically, keratinising and non-keratinising squamous carcinomas of varying grades are found. Generally, carcinoma of the supraglottic and subglottic regions tends to be more poorly-differentiated than the glottic tumour. Besides the keratinising and non-keratinising squamous carcinoma, 2 special varieties of squamous carcinoma in the larynx are: *verrucous carcinoma* (or Ackerman's tumour) which is a variant of well-differentiated squamous carcinoma, and *spindle cell carcinoma* which has elongated tumour cells resembling sarcoma (pseudosarcoma) at the other extreme of prognosis.

Cervical lymph node metastasis of laryngeal carcinoma are found in a good proportion of cases at the time of diagnosis. Death from laryngeal cancer occurs due to local extension of growth into vital structures like trachea and carotid artery; other causes are bacterial infection, aspiration pneumonia, debility and disseminated metastases.

GIST BOX 16.5 Diseases of Larynx

- Laryngeal papillomas are HPV-induced benign tumours.
- Laryngeal nodules or vocal polyps are composed of oedematous stroma and numerous irregular vascular channels.
- Laryngeal carcinoma is associated with smoking and is commonly squamous cell type.

NECK

NORMAL STRUCTURE

The neck is the region from where important structures like oesophagus, trachea, carotid arteries, great veins and nerve trunks pass through it. Besides, the neck has structures such as

carotid body, sympathetic ganglia, larynx, thyroid, parathyroids and lymph nodes.

Only the tumours and cysts of the neck are considered here while the lesions pertaining to other anatomic structures are described elsewhere in the textbook.

CYSTS OF NECK

The cysts of neck may be medial (midline) or lateral (**Table 16.3**).

MEDIAL (MIDLINE) CERVICAL CYSTS

THYROGLOSSAL CYST Thyroglossal cyst arises from the vestiges of thyroglossal duct that connects the foramen caecum at the base of the tongue with the normally located thyroid gland. The cyst is located in the midline, generally at the level of hyoid bone, and rarely at the base of the tongue.

Microscopically, the cyst is lined by respiratory and/or stratified squamous epithelium.

MIDLINE DERMOID CYST Dermoid cyst located in the midline of the neck occurs due to sequestration of dermal cells along the lines of closure of embryonic clefts. The cyst contains paste-like pultaceous material.

Microscopically, it is lined by epidermis and contains skin adnexal structures.

LATERAL CERVICAL CYSTS

BRANCHIAL (LYMPHOEPITHELIAL) CYST Branchial or lymphoepithelial cyst arises from incomplete closure of 2nd or 3rd branchial clefts. The cyst is generally located anterior to the sternocleidomastoid muscle near the angle of the mandible. The cyst is 1-3 cm in diameter and is filled with serous or mucoid material.

Microscopically, true to its name, the cyst has an *epithelial lining*, usually stratified squamous or respiratory epithelium, and *subepithelial lymphoid* tissue aggregates or follicles with germinal centres (**Fig. 16.18**).

PARATHYROID CYST Parathyroid cyst is a lateral cyst of the neck usually located deep to the sternocleidomastoid muscle at the angle of the mandible. These may be microscopic cysts or larger. They are generally thin-walled, filled with clear watery fluid.

Table 16.3 Cysts of the neck.

- | |

| 2. Midline dermoid cyst |
| II. LATERAL CERVICAL CYSTS |
| 1. Branchial (lymphoepithelial) cyst |
| 2. Parathyroid cyst |
| 3. Cervical thymic cyst |
| 4. Cystic hygroma |

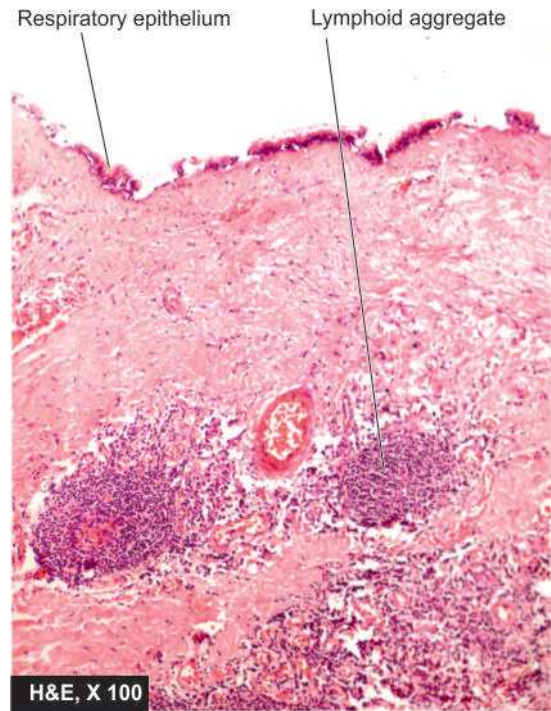

Figure 16.18 Lymphoepithelial (branchial) cyst. The cyst is lined by stratified squamous epithelium and its wall contains lymphoid aggregates or follicles with germinal centres.

Microscopically, parathyroid cyst is lined by flattened cuboidal to low columnar epithelium and the cyst wall may contain any type of parathyroid cells.

CERVICAL THYMIC CYST Cervical thymic cyst originates from cystic degeneration of Hassall's corpuscles. It is generally located in the left lateral side of the neck.

Microscopically, the cyst is lined by stratified squamous epithelium and the cyst wall may contain thymic structures.

CYSTIC HYGROMA Cystic hygroma is a lateral swelling at the root of the neck, usually located behind the sternocleidomastoid muscle. It may be present congenitally or may manifest in the first 2 years of life. It is usually multilocular and may extend into the mediastinum and pectoral region.

Microscopically, cystic hygroma is a diffuse lymphangioma containing large cavernous spaces lined by endothelium and containing lymph fluid (page 393).

TUMOURS

Tumours of the neck may be primary or metastatic in cervical lymph nodes.

PRIMARY TUMOURS

A few important examples of primary tumours in the neck are carotid body tumour, torticollis and malignant lymphomas. Tumours of thyroid, however, are discussed separately in Chapter 25.

CAROTID BODY TUMOUR (CHEMODECTOMA, CAROTID BODY PARAGANGLIOMA) Carotid body tumour arises in the carotid bodies which are situated at the bifurcation of the common carotid arteries. Carotid bodies are normally part of the chemoreceptor system and the cells of this system are sensitive to changes in the pH and arterial oxygen tension and are also the storage site for catecholamines. Histologically similar tumours are found in other parasympathetic ganglia represented by the vagus and glomus jugulare (jugulotympanic bodies, page 496). Carotid body paragangliomas, as they are currently called, are rare tumours and occur between 3rd and 6th decades of life with slight female preponderance. A few (5%) are bilateral and some show familial incidence.

Grossly, they are small, firm, dark tan, encapsulated nodules.

Microscopically, well-differentiated tumour cells form characteristic organoid or alveolar pattern, as is the case with all other neuroendocrine tumours. The tumour cells contain dark neurosecretory granules containing catecholamines.

These tumours are mostly benign but recurrences are frequent; about 10% may metastasise widely.

TORTICOLLIS (FIBROMATOSIS COLLI, WRY NECK) This is a deformity in which the head is bent to one side while the chin points to the other side. The deformity may occur as congenital torticollis or may be an acquired form. The *acquired form* may occur secondary to fracture dislocation of the cervical spine, Pott's disease of the cervical spine, scoliosis, spasm of the muscles of neck, exposure to chill causing myositis, and contracture following burns or wound healing. The *congenital or primary torticollis* appears at birth or within the first few weeks of life as a firm swelling in the lower third of the sternocleidomastoid muscle. The etiology is unknown but about half the cases are associated with breech delivery.

Grossly, the muscle is contracted, shortened and fibrous.

Microscopically, abundant dense fibrous tissue separates the muscle fibres.

MALIGNANT LYMPHOMAS Various forms of non-Hodgkin's lymphomas and Hodgkin's disease occur in the cervical lymph nodes which are described in Chapter 12.

SECONDARY TUMOURS

Cervical lymph nodes are common site for metastases of a large number of carcinomas. These include: squamous cell carcinoma of the lips, mouth, tongue, larynx and oesophagus; transitional cell carcinoma of the pharynx and nasopharynx; thoracic and abdominal cancers such as of the stomach, lungs, ovaries, uterus and testis.

GIST BOX 16.6 Diseases of Neck

- ☐ Cysts in the neck may be midline (thyroglossal, dermoid) or lateral cervical (branchial, parathyroid, thymic, cystic hygroma).
- ☐ Neck is the site for primary carotid body tumour and various tumours of thyroid.
- ☐ Many metastatic tumours from several carcinomas in the head and neck, thoracic and abdominal viscera occur in cervical lymph nodes.

✿ CLINICAL CASE 13

A 20 years old medical student presents to ENT outpatient with complaints of nasal obstruction and partial loss of smell for 2 weeks. There is a history of perennial sneezing, increased nasal discharge and frequent nagging headache for the last 2 years for which he has been taking intermittent antibiotics, painkillers and anti-allergic whenever the symptoms get worse.

On local examination, the septum of nose is normal but there is soft polypoid mass, 1.5 cm in diameter, projecting from ostium of maxillary sinus into the nasal cavity.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 910 (Appendix II)

17

The Oral Cavity and Salivary Glands

ORAL SOFT TISSUES

NORMAL STRUCTURE

The oral cavity is the point of entry for digestive and respiratory tracts. The mucous membrane of the mouth consists of squamous epithelium covering vascularised connective tissue. The epithelium is keratinised over the hard palate, lips and gingiva, while elsewhere it is non-keratinised. Mucous glands (minor salivary glands) are scattered throughout the oral mucosa. Sebaceous glands are present in the region of the lips and the buccal mucosa only. Lymphoid tissue is present in the form of tonsils and adenoids.

The oral cavity is the site of numerous congenital and acquired diseases. Besides, many systemic diseases have oral manifestations. Some of the commonly occurring conditions are discussed here.

DEVELOPMENTAL ANOMALIES

1. FACIAL CLEFTS *Cleft upper lip (harelip) and cleft palate*, alone or in combination, are the commonest developmental anomalies of the face. These occur from the failure of fusion of facial processes.

2. FORDYCE'S GRANULES Fordyce's granules are symmetric, small, light yellow macular spots on the lips and buccal mucosa and represent collections of sebaceous glands. They remain undeveloped until puberty but occur quite commonly in adults.

3. LEUKOEDEMA This is an asymptomatic condition occurring in children and is characterised by symmetric, grey-white areas on the buccal mucosa. Histologically, there is pronounced intracellular oedema. There is no increased malignant potential compared to leukoplakia discussed below.

4. DEVELOPMENTAL DEFECTS OF THE TONGUE These are as under:

i) Macroglossia is the enlargement of the tongue, usually due to lymphangioma or haemangioma, and sometimes due to amyloid tumour.

ii) Microglossia and aglossia are rare congenital anomalies representing small-sized and absence of tongue respectively.

iii) Fissured tongue (scrotal, furrowed or grooved tongue) is a genetically-determined condition characterised by numerous small furrows or grooves on the dorsum of the tongue. It is often associated with mild glossitis.

iv) Bifid tongue is a rare condition occurring due to failure of the two lateral halves of the tongue to fuse in the midline.

v) Tongue tie occurs when the lingual fraenum is quite short, or when the fraenum is attached near the tongue tip.

vi) Hairy tongue is not a true developmental defect, but is mentioned here because of its similarity with other conditions discussed here. The filiform papillae are hypertrophied and elongated. These 'hairs' (papillae) are stained black, brown or yellowish-white by food, tobacco, oxidising agents or by oral flora.

MUCOCUTANEOUS LESIONS

Lesions of the oral mucosa occur in many diseases of the skin (Chapter 24) and they are similar in morphology. Some of these are listed as under:

LICHEN PLANUS Characteristically, oral lichen planus appears as interlacing network of whitening or keratosis on the buccal mucosa but other oral tissues such as gingiva, tongue and palate may also be involved.

VESICULAR LESIONS A number of vesicular or bullous diseases of the skin have oral lesions.

i) Pemphigus vulgaris Vesicular oral lesions appear invariably in all cases at some time in the course of pemphigus vulgaris. In about half the cases oral lesions are the initial manifestations.

ii) Pemphigoid Vesicles or bullae appear on oral mucosa as well as on conjunctiva in pemphigoid and are seen more often in older women.

iii) Erythema multiforme Subepithelial vesicles may occur on the skin as well as mucosae.

iv) Stevens-Johnson syndrome It is a rather fatal and severe form of erythema multiforme involving oral and other mucous membranes occurring following ingestion of sulfa drugs.

v) Epidermolysis bullosa It is a hereditary condition having subepidermal bullae on the skin as well as has oral lesions.

INFLAMMATORY AND PIGMENTARY DISEASES

STOMATITIS Inflammation of the mucous membrane of the mouth is called stomatitis. It can occur in the course of several different diseases.

i) Aphthous, ulcers (Canker sores) These are the commonest form of oral ulcerations. The etiology is unknown but may be precipitated by emotional factors, stress, allergy, hormonal imbalance, nutritional deficiencies, gastrointestinal disturbances, trauma etc. The condition is characterised by painful oral ulcers, 1 cm or more in size. Recurrent *aphthae* may form a part of Behcet's syndrome and inflammatory bowel disease.

ii) Herpetic stomatitis It is an acute disease occurring in infants and young children. It is the most common manifestation of primary infection with herpes simplex virus.

The lesions are in the form of vesicles around the lips. Similar lesions may appear on the genital skin. Recurrent attacks occur due to stress, emotional upsets and upper respiratory infections.

iii) Necrotising stomatitis (Noma or Cancrum oris) This occurs more commonly in poorly-nourished children like in kwashiorkor; infectious diseases such as measles, immunodeficiencies and emotional stress. The lesions are characterised by necrosis of the marginal gingiva and may extend on to oral mucosa, causing cellulitis of the tissue of the cheek. The condition may progress to gangrene of the cheek.

iv) Mycotic infections Fungal infections commonly involving the oral mucosa are actinomycosis and candidiasis.

◆ *Cervicofacial actinomycosis* is the commonest form of the disease developing at the angle of the mandible (page 153).

◆ *Candidiasis (moniliasis or thrush)* is caused by *Candida albicans* which is a commensal in the mouth. It appears as an opportunistic infection in immunocompromised host. There are erythematous lesions on the palate and angular cheilitis.

GLOSSITIS **Acute glossitis** characterised by swollen papillae occurs in eruptions of measles and scarlet fever. In **chronic glossitis**, the tongue is raw and red without swollen papillae and is seen in malnutrition such as in pellagra, ariboflavinosis and niacin deficiency. In iron deficiency anaemia, pernicious anaemia and sprue, there is *chronic atrophic glossitis* characterised by atrophied papillae and smooth raw tongue.

SYPHILITIC LESIONS Oral lesions may occur in primary, secondary, tertiary and congenital syphilis (page 151).

i) Extragenital chancre of *primary syphilis* occurs most commonly on the lips.

ii) *Secondary syphilis* shows maculopapular eruptions and mucous patches in the mouth.

iii) In the *tertiary syphilis*, gummas or diffuse fibrosis may be seen on the hard palate and tongue.

iv) Oral lesions of the *congenital syphilis* are fissures at the angles of mouth and characteristic peg-shaped notched Hutchinson's incisors.

TUBERCULOUS LESIONS Involvement of the mouth in tuberculosis is rare. The lesions are in the form of ulcers or elevated nodules.

HIV INFECTION HIV infection of low grade as well as full-blown acquired immunodeficiency syndrome (AIDS) are associated with oral manifestations such as opportunistic infections, malignancy, hairy leukoplakia and others; these are listed in **Table 17.1**. About half the cases of Kaposi's sarcoma have intraoral lesions as part of systemic involvement (page 395).

PIGMENTARY LESIONS Oral and labial melanotic pigmentation may be observed in certain systemic and metabolic disorders such as Addison's disease, Albright syndrome, Peutz-Jeghers syndrome and haemochromatosis. All types of pigmented naevi as well as malignant melanoma can occur in oral cavity. Exogenous pigmentation such as due to deposition of lead sulfide can also occur.

TUMOURS AND TUMOUR-LIKE LESIONS

Benign and malignant tumours as also a number of tumour-like lesions and premalignant lesions are encountered in

Table 17.1 Oral manifestations of AIDS.

the oral soft tissues. A list of such lesions is presented in **Table 17.2**.

A. TUMOUR-LIKE LESIONS

A number of proliferative lesions arising from the oral tissues are tumour-like masses which clinically may resemble neoplasms. Some of these are as under:

FIBROUS GROWTHS Fibrous growths of the oral soft tissues are very common. These are not true tumours (unlike intraoral fibroma and papilloma), but are instead inflammatory or irritative in origin. A few common varieties are as under:

Table 17.2 Classification of tumours and tumour-like lesions of the oral soft tissues.

| | |
|-------------------------|--|

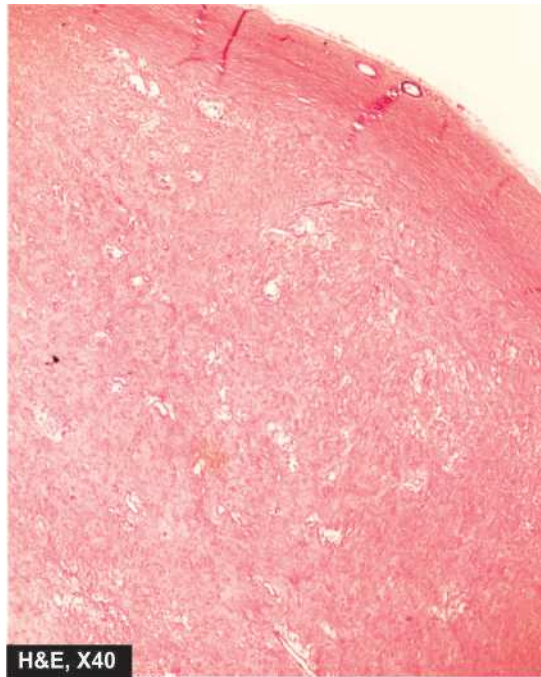

Figure 17.1 Fibrous epulis in the gingiva.

i) **Fibroepithelial polyps** occur due to irritation or chronic trauma. These are composed of reparative fibrous tissue, covered by a thin layer of stratified squamous epithelium.

ii) **Fibrous epulis** is a lesion occurring on the gingiva and is localised hyperplasia of the connective tissue following trauma or inflammation in the area (**Fig. 17.1**). *Giant cell epulis* is a variant seen more commonly in females as reactive change to trauma; the lesion shows numerous osteoclast-like giant cells and vascular stroma.

iii) **Denture hyperplasia** occurs in edentulous or partly edentulous patients. The lesion is an inflammatory hyperplasia in response to local irritation by ill-fitting denture or an elongated tooth.

PYOGENIC GRANULOMA This is an elevated, bright red swelling of variable size occurring on the lips, tongue, buccal mucosa and gingiva. It is a vasoproliferative inflammatory lesion. *Pregnancy tumour* is a variant of pyogenic granuloma.

MUCOCELE Also called mucous cyst or retention cyst, it is a cystic dilatation of the mucous glands of the oral mucosa. The cyst often ruptures on distension and incites inflammatory reaction due to mucous extravasation (**Fig. 17.2**).

RANULA It is a large mucocele located on the floor of the mouth. The cyst is lined by true epithelial lining.

DERMOID CYST This tumour-like mass in the floor of the mouth represents a developmental malformation. The cyst is lined by stratified squamous epithelium. The cyst wall contains sebaceous glands, sweat glands, hair follicles and other mature tissues.

B. BENIGN TUMOURS

Different parts of the mouth have a variety of mesodermal tissues and keratinising and non-keratinising epithelium. Therefore, majority of neoplasms arising from the oral tissues

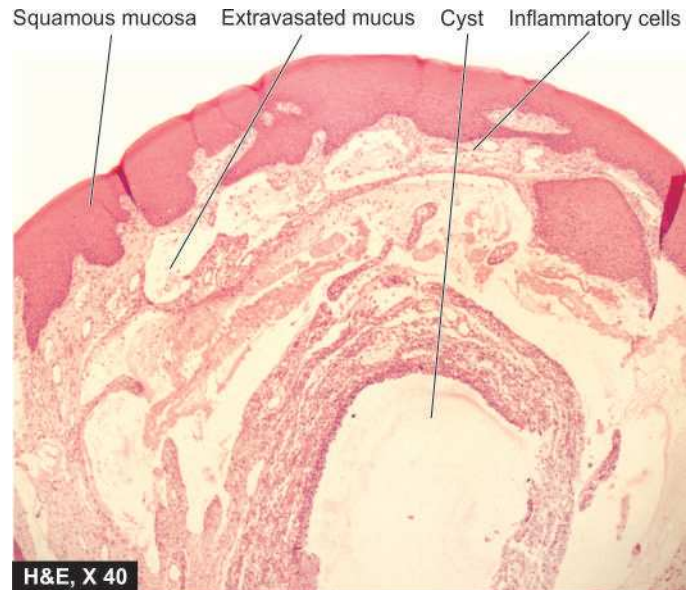

Figure 17.2 Mucous retention cyst (mucocele). There is inflammatory reaction around extravasated mucus.

are just like their counterparts in other parts of the body. Some of the common benign tumours of the mouth are as under:

SQUAMOUS PAPILLOMA Papilloma can occur anywhere in the mouth and has the usual papillary or finger-like projections.

Microscopically, each papilla is composed of vascularised connective tissue covered by squamous epithelium.

HAEMANGIOMA Haemangioma can occur anywhere in the mouth; when it occurs on the tongue it may cause macroglossia. It is most commonly capillary type, although cavernous and mixed types may also occur.

LYMPHANGIOMA Lymphangioma may develop most commonly on the tongue producing macroglossia; on the lips producing macrocheilia, and on the cheek. *Cystic hygroma* is a special variety of lymphangioma occurring in children on the lateral side of neck.

Microscopically, lymphangioma is characterised by large lymphatic spaces lined by endothelium and containing lymph (page 393).

FIBROMA Although most common benign oral mucous membrane mass is fibroma appearing as a discrete superficial pedunculated mass, it appears to be non-neoplastic in nature. It probably arises as a response to physical trauma.

Microscopically, fibroma is composed of collagenic fibrous connective tissue covered by stratified squamous epithelium.

FIBROMATOSIS GINGIVAE This is a fibrous overgrowth of unknown etiology involving the entire gingiva. Sometimes the fibrous overgrowth is so much that the teeth are covered by fibrous tissue.

TUMOURS OF MINOR SALIVARY GLANDS Minor salivary glands present in the oral cavity may sometimes be the site of origin of salivary tumours similar to those seen in the major salivary glands (page 516). Pleomorphic adenoma is a common example.

GRANULAR CELL TUMOUR Earlier called as granular cell myoblastoma, it is benign tumour which now by electron microscopic studies is known to be mesenchymal in origin than odontogenic. The most common location is the tongue but may occur in any other location on the oral cavity. It occurs exclusively in females. A similar lesion seen in infants is termed as congenital epulis.

Microscopically, the tumour is composed of large polyhedral cells with granular, acidophilic cytoplasm. The covering epithelium usually shows pronounced pseudo-epitheliomatous hyperplasia.

OTHER RARE BENIGN TUMOURS Some other rare benign tumours which can occur in the oral soft tissues are: neurilemmoma, neurofibroma, lipoma, giant cell granuloma, rhabdomyoma, leiomyoma, solitary plasmacytoma, osteoma, chondroma, naevus and vascular oral lesions seen in hereditary haemorrhagic telangiectasia (Osler-Rendu-Weber syndrome) and encephalofacial angiomatosis (Sturge-Weber syndrome).

C. ORAL LEUKOPLAKIA (WHITE LESIONS)

DEFINITION Leukoplakia (*white plaque*) may be clinically defined as a white patch or plaque on the oral mucosa, exceeding 5 mm in diameter, which cannot be rubbed off nor can be classified into any other diagnosable disease. A number of other lesions are characterised by the formation of white patches listed in **Table 17.3**. However, from the pathologist's point of view, the term 'leukoplakia' is reserved for epithelial thickening which may range from completely benign to atypical and to premalignant cellular changes.

INCIDENCE It occurs more frequently in males than females. The lesions may be of variable size and appearance. The sites of predilection, in descending order of frequency, are: cheek mucosa, angles of mouth, alveolar mucosa, tongue, lip, hard and soft palate, and floor of the mouth. In about 4-6% cases of leukoplakia, carcinomatous change is reported. However, it is difficult to decide which white lesions may undergo malignant

transformation, but speckled or nodular form is more likely to progress to malignancy. Therefore, it is desirable that all oral white patches be biopsied to exclude malignancy.

ETIOLOGY The etiological factors are similar to those suggested for carcinoma of the oral mucosa (discussed below). *It has the strongest association with the use of tobacco in various forms*, e.g. in heavy smokers (especially in pipe and cigar smokers) and improves when smoking is discontinued, and in those who chew tobacco containing products e.g. *paan*, *paan masaala*, *zarda*, *gutka* etc. The condition is also known by other names such as *smokers' keratosis* and *stomatitis nicotina*. Other etiological factors implicated are chronic friction such as with ill-fitting dentures or jagged teeth, and local irritants like excessive consumption of alcohol and very hot and spicy foods and beverages. A special variety of leukoplakia called '*hairy leukoplakia*' has been described in patients of AIDS and has hairy or corrugated surface but is not related to development of oral cancer.

MORPHOLOGIC FEATURES *Grossly*, the lesions of leukoplakia may appear white, whitish-yellow, or red-velvety of more than 5 mm diameter and variable in appearance. They are usually circumscribed, slightly elevated, smooth or wrinkled, speckled or nodular.

Histologically, leukoplakia is of 2 types:

1. Hyperkeratotic type This is characterised by an orderly and regular hyperplasia of squamous epithelium with hyperkeratosis on the surface (**Fig. 17.3, A**).

2. Dysplastic type When the changes such as irregular stratification of the epithelium, focal areas of increased and abnormal mitotic figures, hyperchromatism, pleomorphism, loss of polarity and individual cell keratinisation are present, the lesion is considered as epithelial dysplasia. The sub-epithelial tissues usually show an inflammatory infiltrate composed of lymphocytes and plasma cells. The extent and degree of the epithelial changes indicate the degree of severity of the epithelial dysplasia. Usually, mild dysplasia may revert back to normal if the offending etiologic factor is removed, whereas severe dysplasia indicates that the case may progress to carcinoma. *Erythroplasia* is a form of dysplastic leukoplakia in which the epithelial atypia is more marked and thus has higher risk of developing malignancy. If the epithelial dysplasia is extensive so as to involve the entire thickness of the epithelium, the lesion is called carcinoma *in situ* which may progress to invasive carcinoma (**Fig. 17.3, B**).

D. MALIGNANT TUMOURS

Squamous Cell (Epidermoid) Carcinoma

Oral cancer is a disease with very poor prognosis because it is not recognised and treated when small and early.

INCIDENCE Squamous cell (epidermoid) carcinoma comprises 90% of all oral malignant tumours and 5% of all human malignancies. The peak incidence in the UK and the USA is from 55 to 75 years of age, whereas in India it is seen at a relatively younger age (40 to 45 years). Oral cancer is a very frequent malignancy in India, Sri Lanka and some Eastern countries, probably related to habits of betel-nut chewing and reversed smoking (page 199). There is a definite male preponderance.

A, LEUKOPLAKIA, HYPERKERATOSIS TYPE

B, LEUKOPLAKIA, DYSPLASTIC TYPE

Figure 17.3 Leukoplakia oral mucosa. A, *Hyperkeratosis type*. There is keratosis and orderly arrangement of increased number of layers of stratified mucosa. B, *Dysplastic type*. The number of layers is increased and the individual cells in layers show features of cytologic atypia and mitosis but there is no invasion across the basement membrane.

It can occur anywhere in the mouth but certain sites are more commonly involved. These sites, in descending order of frequency, are: the lips (more commonly lower), tongue, anterior floor of mouth, buccal mucosa in the region of alveolar lingual sulcus, and palate (**Fig. 17.4**).

ETIOLOGY As with other forms of cancer, the etiology of squamous cell carcinoma is unknown. But a number of etiological factors have been implicated:

Strong association

- i) Tobacco smoking and tobacco chewing causing leukoplakia is the most important factor as discussed above.
- ii) Chronic alcohol consumption.
- iii) Human papilloma virus infection, particularly HPV 16, 18 and 33 types.

Weak association

- i) Chronic irritation from ill-fitting denture or jagged teeth.
- ii) Submucosal fibrosis as seen in Indians consuming excess of chillies.
- iii) Poor orodental hygiene.
- iv) Nutritional deficiencies.
- v) Exposure to sunlight (in relation to lip cancer).
- vi) Exposure to radiation.
- vii) Plummer-Vinson syndrome, characterised by atrophy of the upper alimentary tract.

The most common molecular alterations in oncogenes seen in squamous cell carcinoma of the oral cavity are in *p16*, *p53*, *p63*, *cyclin D*, *PTEN*, and *EGFR*.

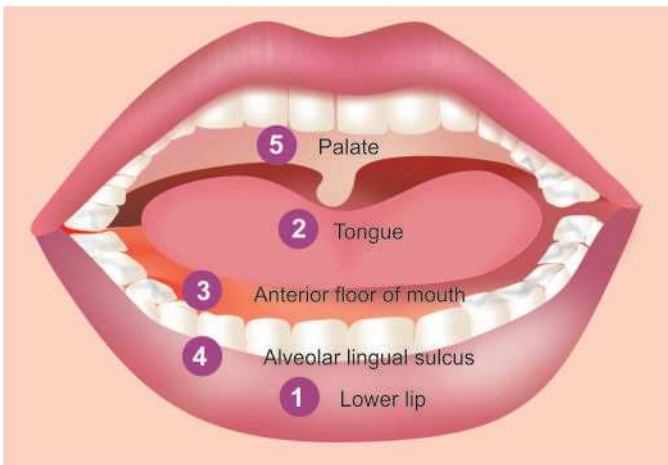

Figure 17.4 Frequency of occurrence of squamous cell carcinomas in the oral cavity.

MORPHOLOGIC FEATURES *Grossly*, squamous cell carcinoma of oral cavity may have the following types (**Fig. 17.5**):

- i) **Ulcerative type**—is the most frequent type and is characterised by indurated ulcer and firm everted or rolled edges.
- ii) **Papillary or verrucous type**—is soft and wart-like growth.
- iii) **Nodular type**—appears as a firm, slow growing submucosal nodule.
- iv) **Scirrhus type**—is characterised by infiltration into deeper structures.

All these types may appear on a background of leukoplakia or erythroplasia of the oral mucosa. Enlarged cervical lymph nodes may sometimes be present.

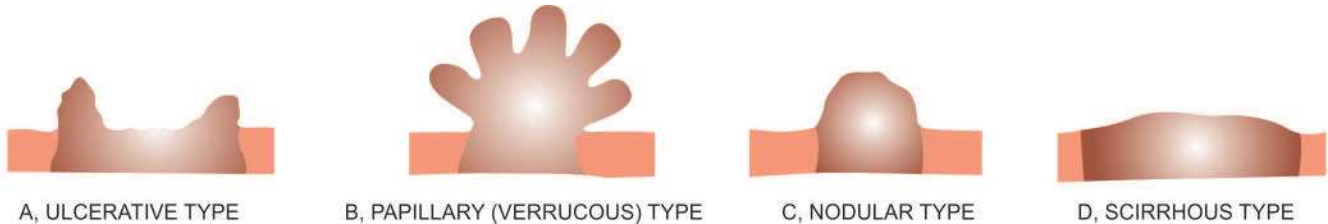

Figure 17.5 Squamous cell (Epidermoid) carcinoma of oral cavity, patterns of gross appearance.

Histologically, squamous cell carcinoma ranges from well-differentiated keratinising carcinoma to highly-undifferentiated neoplasm (page 774). Changes of epithelial dysplasia are often present in the surrounding areas of the lesion. Carcinoma of the lip and intraoral squamous carcinoma are usually always well-differentiated (**Fig. 17.6**).

Carcinoma of the lip has a more favourable prognosis due to visible and easily accessible location and less frequent metastasis to the regional lymph nodes. However, intraoral squamous carcinomas have poor prognosis because they are detected late and metastasis to regional lymph nodes occur early, especially in the case of carcinoma of tongue and soft palate.

Verrucous carcinoma, on the other hand, is composed of very well-differentiated squamous epithelium with minimal atypia and hence has very good prognosis.

Other Malignant Tumours

Other less common malignant neoplasms which may be encountered in the oral cavity are: malignant melanoma, lymphoepithelial carcinoma, malignant lymphoma, malignant tumours of minor salivary glands, and various sarcomas like rhabdomyosarcoma, liposarcoma, alveolar soft part sarcoma, Kaposi's sarcoma and fibrosarcoma. Metastatic tumours can also occur in the soft tissues of the mouth.

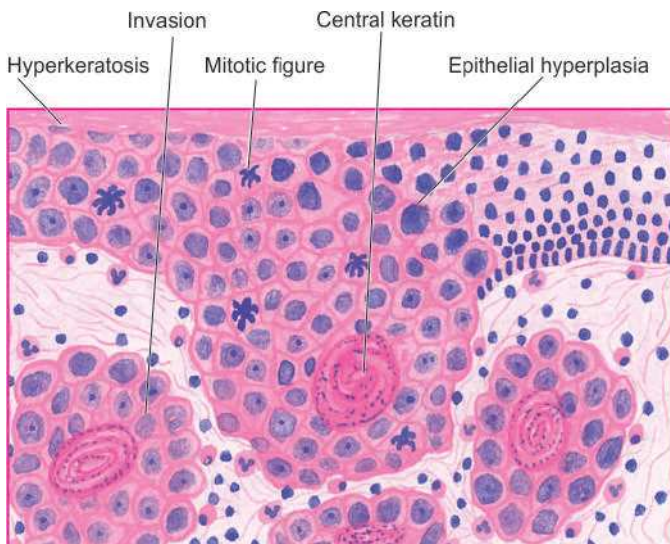

Figure 17.6 Oral mucosa showing epithelial dysplasia progressing to invasive squamous cell carcinoma. There is keratosis, irregular stratification, cellular pleomorphism, increased and abnormal mitotic figures and individual cell keratinisation, while a few areas show superficial invasive islands of malignant cells in the subepithelial soft tissues.

GIST BOX 17.1 Diseases of Oral Soft Tissues

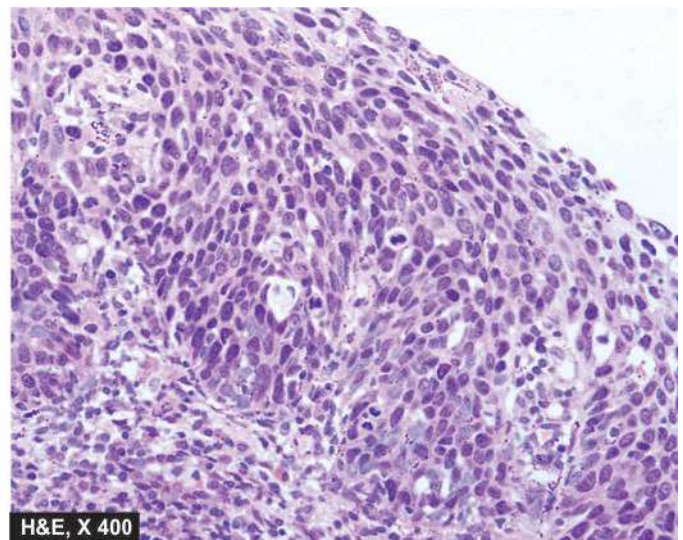

- ☐ Benign lesions of the oral soft tissues are fibrous growths, pyogenic granuloma, haemangioma, lymphangioma etc.
- ☐ Oral leukoplakia is white patch, commonly due to use of tobacco, and may be hyperkeratotic or dysplastic type.
- ☐ Squamous cell carcinoma is the most common oral malignant tumour. Its locations, in descending order of frequency, are the lower lip, tongue, anterior floor of mouth, buccal mucosa and palate.
- ☐ Intraoral cancer has a bad prognosis while that of lip has a favourable outcome.

TEETH AND PERIODONTAL TISSUES

Although care of the teeth belongs to the field of dental profession, the fully educated medical doctor should be familiar with certain principal diseases of teeth and periodontal tissues, especially about dental caries, periapical abscess and periodontitis, and common cysts and odontogenic tumours of the jaw. But first, a brief account of normal structure of these tissues is presented.

NORMAL STRUCTURE

The teeth are normally composed of 3 calcified tissues, namely: *enamel*, *dentin* and *cementum*; and the *pulp* which is composed of connective tissue. The teeth are peculiar than other calcified

tissues of the body by being surrounded by the portion of oral mucosa called the gingiva or gum, and that they are part of a highly specialised odontogenic apparatus; other parts of this apparatus being the mandible and maxilla.

Embryologically, odontogenic development takes place from primitive structure, the *dental lamina* or primitive oral cavity, as follows:

- ◆ Inner epithelial layer of the dental lamina is ectoderm-derived columnar to cuboidal oral epithelium called **ameloblasts** which secrete enamel matrix, also called enamel organ.
- ◆ Mesoderm-derived connective tissue gives rise to structures in the **dental papilla** (i.e. dental pulp or core of loose connective tissue, blood vessels and nerves).
- ◆ Outer margin of the dental papilla differentiates into **odontoblasts**, which continue with ameloblastic epithelium; odontoblasts secrete dentin.

The normal structure of tooth in an adult is as follows (Fig. 17.7, A):

Enamel is the outer covering of teeth composed almost entirely of inorganic material (as in bone) which can be demonstrated in ground sections only because it is lost in decalcified section.

Dentin lies under the enamel and comprises most of the tooth substance. It is composed of organic material in the form of collagen fibrils as well as inorganic material in the form of calcium phosphates as in bone. Dentin is composed of odontoblasts or dentin cells which are counterparts of osteocytes in bone but differ from the latter in having odontoblast processes. Dentin in the crown of tooth is covered with thicker layer of enamel.

Cementum is the portion of tooth which covers the dentin at the root of tooth and is the site where periodontal ligament is attached. Cementum is similar to bone in morphology and composition.

Dental pulp is inner to dentine and occupies the pulp cavity and root canal. It consists of connective tissue, blood vessels and nerves.

Nests of odontogenic epithelium are normally present in the jaw and may develop into cysts and tumours.

INFLAMMATORY DISEASES

DENTAL CARIES

Dental caries is the most common disease of dental tissues, causing destruction of the calcified tissues of the teeth.

ETIOPATHOGENESIS Dental caries is essentially a disease of modern society, associated with diet containing high proportion of refined carbohydrates. It has been known for almost 100 years that mixture of sugar or bread with saliva in the presence of acidogenic bacteria of the mouth, especially streptococci, produces organic acids which can decalcify enamel and dentin. Enamel is largely composed of inorganic material which virtually disintegrates. Dentin contains organic material also which is left after decalcification. Bacteria present in the oral cavity cause proteolysis of the remaining organic material of dentin, completing the process of destruction. Diets rich in carbohydrates do not require much chewing and thus the soft and sticky food gets clung to the teeth rather than

being cleared away, particularly in the areas of occlusal pits and fissures. '*Bacterial plaques*' are formed in such stagnation areas. If these plaques are not removed by brushing or by vigorous chewing of fibrous foods, the process of tooth decay begins. There is evidence that consumption of water containing one part per million (ppm) fluoride is sufficient to reduce the rate of tooth decay in children.

MORPHOLOGIC FEATURES Caries occurs chiefly in the areas of pits and fissures, mainly of the molars and premolars, where food retention occurs, and in the cervical part of the tooth.

Grossly, the earliest change is the appearance of a small, chalky-white spot on the enamel which subsequently enlarges and often becomes yellow or brown and breaks down to form carious cavity. Eventually, the cavity becomes larger due to fractures of enamel. Once the lesion reaches enamel-dentin junction, destruction of dentine also begins.

Microscopically, inflammation (pulpitis) and necrosis of pulp take place. There is evidence of reaction of the tooth to the carious process in the form of *secondary dentin*, which is a layer of odontoblasts laid down under the original dentin (Fig. 17.7, B).

SEQUELAE OF CARIES Carious destruction of dental hard tissues frequently produces pulpitis and other inflammatory lesions like apical granuloma and apical abscess. Less common causes of these lesions are fracture of tooth and accidental exposure of pulp by the dentist.

1. Pulpitis Pulpitis may be acute or chronic.

a) *Acute pulpitis* is accompanied by severe pain which may be continuous, throbbing or dull, and is accentuated by heat or cold. It is often accompanied by mild fever and leucocytosis.

b) *Chronic pulpitis* occurs when pulp is exposed widely. It is often not associated with pain. Chronically inflamed pulp tissue may protrude through the cavity forming polyp of the pulp. It may be partly covered by implanted squamous epithelium.

2. Apical granuloma Pulpitis may lead to spread of infection through the apical foramen into the tissues surrounding the root of the tooth.

Histologically, there is chronic inflammatory reaction with formation of granulation tissue and inclusion of nests or strands of squamous epithelium derived from remnants of odontogenic epithelium normally present in the periodontal membrane. An apical granuloma may develop into a dental (radicular) cyst as discussed below.

3. Apical abscess An apical granuloma or acute pulpitis may develop into apical abscess. Acute abscess is very painful, while pus in chronic abscess may escape through root canal and cause further complications like osteomyelitis, cellulitis, cerebral abscess, meningitis and cavernous sinus thrombosis.

PERIODONTAL DISEASE

Chronic inflammation and degeneration of the supporting tissues of teeth resulting in teeth loss is a common condition.

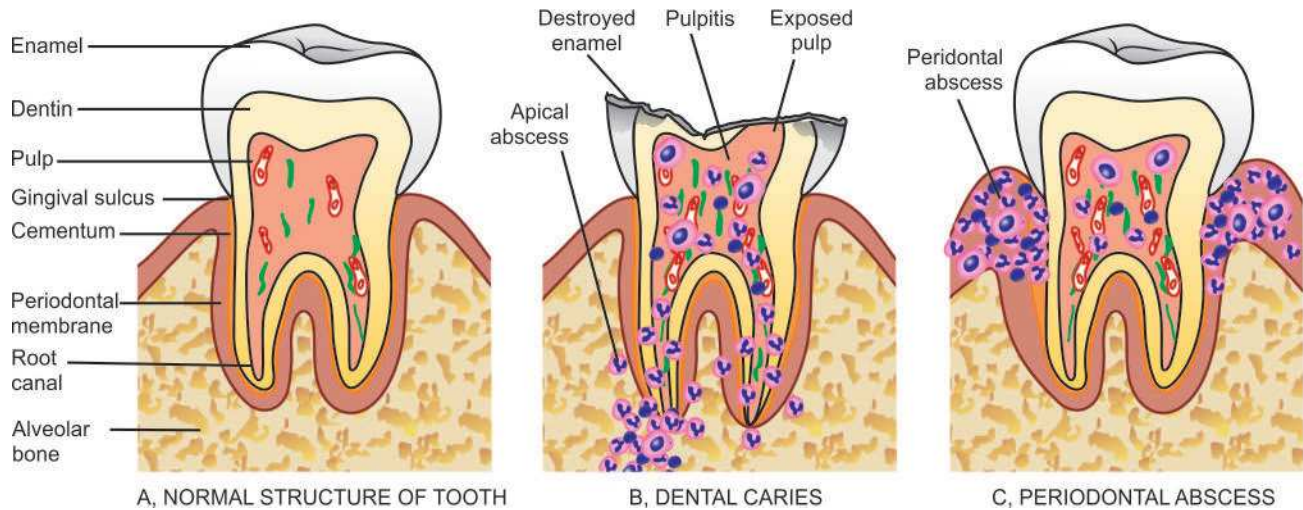

Figure 17.7 The normal structure of molar tooth in longitudinal section embedded in the jaw (A) contrasted with dental caries (B) and periodontal disease (C). In caries, there is complete destruction of enamel, deposition of secondary dentine and evidence of pulpitis (B), while there is formation of abscess in the periodontal tissue in chronic marginal gingivitis (C).

Besides inflammation, other diseases associated with gingival swelling are leukaemia, scurvy, fibrous hyperplasia and epulis.

The inflammatory periodontal disease affects adults more commonly. Pregnancy, puberty and use of drugs like dilantin are associated with periodontal disease more often. The disease begins as *chronic marginal gingivitis*, secondary to bacterial plaques around the teeth such as due to calculus (tartar) on the tooth surface, impacted food, uncontrolled diabetes, tooth-decay and ill-fitting dental appliances. The gingival sulcus acts as convenient site for lodgement of food debris and bacterial plaque leading to formation of periodontal pocket from which purulent discharge can be expressed by digital pressure.

Microscopically, chronic marginal gingivitis is characterised by heavy chronic inflammatory cell infiltrate, destruction of collagen, and epithelial hyperplasia so as to line the pocket (Fig. 17.7, C). Untreated chronic marginal gingivitis slowly progresses to *chronic periodontitis* or *pyorrhoea* in which there is inflammatory destruction of deeper tissues. At this stage, progressive resorption of alveolar bone occurs and the tooth ultimately gets detached.

EPITHELIAL CYSTS OF THE JAW

The epithelium-lined cysts of dental tissue can have inflammatory or developmental origin. A classification of such cysts is given in Table 17.4.

A. INFLAMMATORY CYSTS

Radicular Cyst

Radicular cyst, also called as apical, periodontal or simply dental cyst, is the most common cyst originating from the dental tissues. It arises consequent to inflammation following destruction of dental pulp such as in dental caries, pulpitis, and apical granuloma. The epithelial cells of Malassez, which are nests of odontogenic epithelium embedded in the

periodontium, proliferate within apical granuloma under the influence of inflammation, leading to the formation of an epithelium-lined cystic cavity. Most often, radicular cyst is observed at the apex of an erupted tooth and sometimes contains thick pulaceous material.

Histologically, the radicular cyst is lined by nonkeratinised squamous epithelium. Epithelial rete processes may penetrate the underlying connective tissues. Radicular cyst of the maxilla may be lined by respiratory epithelium. The cyst wall is fibrous and contains chronic inflammatory cells (lymphocytes, plasma cells with Russell bodies and macrophages) hyaline bodies and deposits of cholesterol crystals which may be associated with foreign body giant cells (Fig. 17.8).

Table 17.4 Classification of epithelial cysts of jaw.

| (i) | Dentigerous (follicular) cyst |
| (ii) | Eruption cyst |
| (iii) | Gingival cyst |
| (iv) | Primordial cyst (odontogenic keratocyst) |
| 2. | <i>Non-odontogenic and fissural cysts</i> |
| (i) | Nasopalatine duct (Incisive canal, Median anterior maxillary) cyst |
| (ii) | Nasolabial (nasoalveolar) cyst |
| (iii) | Globulomaxillary cyst |
| (iv) | Dermoid cyst |

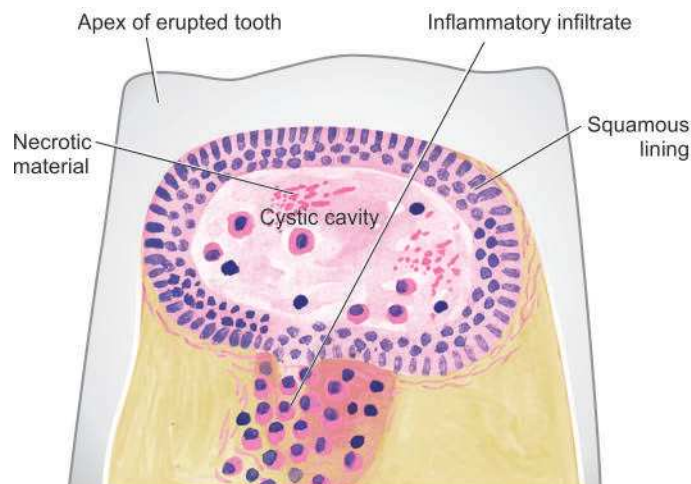

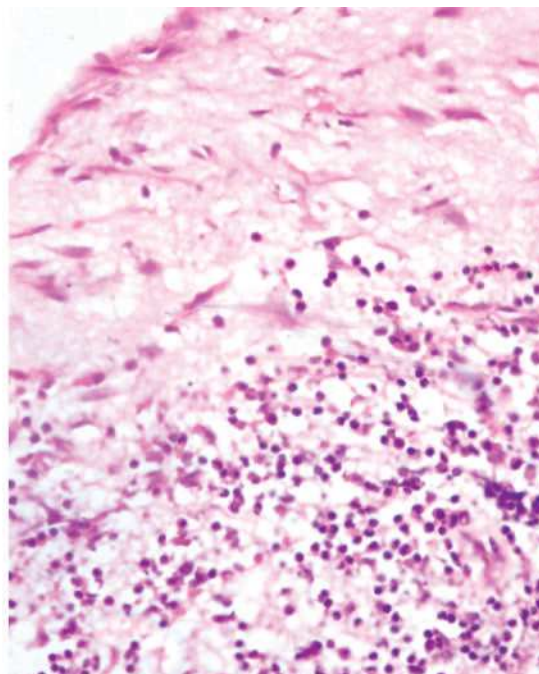

Figure 17.8 Dental (Radicular) cyst. The cyst wall is composed of fibrous tissue and is lined by non-keratinised squamous epithelium. The cyst wall is densely infiltrated by chronic inflammatory cells, chiefly lymphocytes, plasma cells and macrophages.

B. DEVELOPMENTAL CYSTS

Odontogenic Cysts

DENTIGEROUS (FOLLICULAR) CYST Dentigerous cyst arises from enamel of an unerupted tooth. The mandibular third molars and the maxillary canines are most often involved. Dentigerous cysts are less common than radicular cysts and occur more commonly in children and young individuals. These cysts are more significant because of reported occurrence of ameloblastoma and carcinoma in them.

Histologically, dentigerous cyst is composed of a thin fibrous tissue wall lined by stratified squamous epithelium. Thus, the cyst may resemble radicular cyst, except that chronic inflammatory changes so characteristic of radicular cyst, are usually absent in dentigerous cyst (**Fig. 17.9**).

ERUPTION CYST This is a cyst lying over the crown of an unerupted tooth and is lined by stratified squamous epithelium. It is thus a form of dentigerous cyst.

GINGIVAL CYST It arises from the epithelial rests in the gingiva and is lined by keratinising squamous epithelium.

PRIMORDIAL CYST (ODONTOGENIC KERATOCYST) Primordial cyst, like dentigerous cyst, also arises from tooth-forming epithelium. The common location is mandibular third molar. Multiple primordial cysts occur in association with naevoid basal cell carcinoma syndrome. Primordial cysts have a marked tendency to recur (50%).

Histologically, the cyst wall is thin and is lined by regular layer of keratinising stratified squamous epithelium. Inflammatory changes are generally absent.

Non-odontogenic and Fissural Cysts

NASOPALATINE DUCT (INCISIVE CANAL, MEDIAN, ANTERIOR MAXILLARY) CYST This is the most common non-odontogenic (fissural) cyst and arises from the epithelial remnants of the nasopalatine duct.

Histologically, the cyst is lined by stratified squamous epithelium, respiratory epithelium, or both.

NASOLABIAL (NASOALVEOLAR) CYST This cyst is situated in the soft tissues at the junction of median nasal, lateral nasal and maxillary processes, at the ala of the nose, and sometimes extending into the nostril.

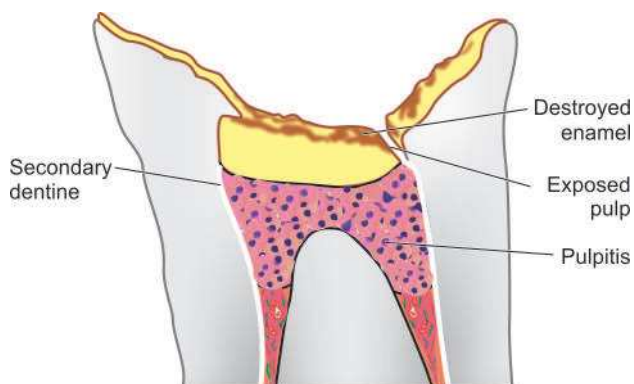

Figure 17.9 Dentigerous (Follicular) cyst. The cyst is composed of thin fibrous tissue wall and is lined by stratified squamous epithelium. A partly formed unerupted tooth is also seen in the wall. Inflammatory changes are conspicuously absent.

Histologically, the cyst is lined by squamous or respiratory epithelium, or both.

GLOBULOMAXILLARY CYST This is an intraosseous cyst and is rare.

DERMOID CYST The dermoid cyst is common in the region of head and neck, especially in the floor of the mouth. The cyst arises from remains in the midline during closure of mandibular and branchial arches.

ODONTOGENIC TUMOURS

Odontogenic tumours are a group of uncommon lesions of the jaw derived from the odontogenic apparatus. These tumours are usually benign but some have malignant counterparts. An abbreviated WHO classification is presented in **Table 17.5**.

A. BENIGN ODONTOGENIC TUMOURS

Ameloblastoma

Ameloblastoma is the most common benign but locally invasive epithelial odontogenic tumour. It is most frequent in the 3rd to 5th decades of life. Preferential sites are the mandible in the molar-ramus area and the maxilla. The tumour originates from dental epithelium of the enamel itself or its epithelial residues. Sometimes, the tumour may arise from the epithelial lining of a dentigerous cyst or from basal layer of oral mucosa. Radiologically, typical picture is of a multilocular destruction of the bone. Rare instances of an extraosseous example, presence of an embedded tooth, or unilocular ameloblastoma can occur. Tumour with histologic resemblance to ameloblastoma can occur occasionally in the long bone, like adamantinoma of the tibia.

Grossly, the tumour is greyish-white, usually solid, sometimes cystic, replacing and expanding the affected bone.

Table 17.5 Classification of odontogenic tumours.

| | |
|--------------|---|
| A. BENIGN | |
| a) | <i>Epithelial origin</i> |
| 1. | Ameloblastoma |
| 2. | Adenomatoid odontogenic tumour (Adenoameloblastoma) |
| 3. | Calcifying epithelial odontogenic tumour |
| b) | <i>Mesenchymal origin</i> |
| 1. | Odontogenic myxoma |
| 2. | Odontogenic fibroma |
| 3. | Cementoma |
| c) | <i>Mixed epithelial-mesenchymal origin</i> |
| 1. | Ameloblastic fibroma |
| 2. | Ameloblastic fibro-odontoma |
| 3. | Complex odontomas |
| B. MALIGNANT | |
| a) | <i>Epithelial origin</i> |
| 1. | Malignant ameloblastoma |
| 2. | Ameloblastic carcinoma |
| b) | <i>Mesenchymal origin</i> |
| | Ameloblastic fibrosarcoma |

Histologically, ameloblastoma can show different patterns as follows:

i) *Follicular pattern* is the most common. The tumour consists of follicles of variable size and shape and separated from each other by fibrous tissue. The structure of follicles is similar to that of enamel organ consisting of central area of stellate cells resembling stellate reticulum, and peripheral layer of cuboidal or columnar cells resembling epithelium. The central stellate areas may show cystic changes (**Fig. 17.10**).

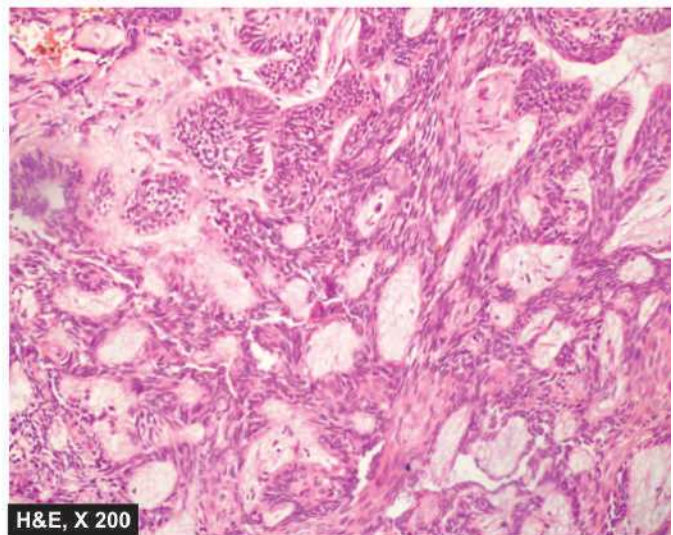

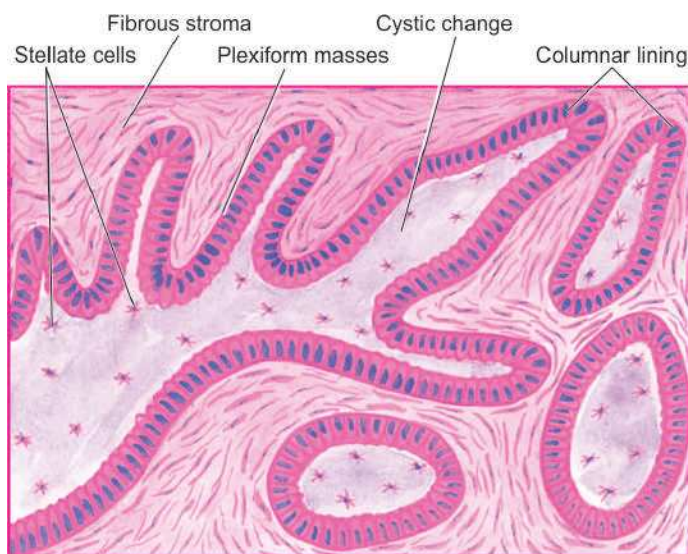

Figure 17.10 Ameloblastoma, follicular and plexiform patterns. Epithelial follicles are composed of central area of stellate cells and peripheral layer of cuboidal or columnar cells. Plexiform areas show irregular plexiform masses and network of strands of epithelial cells. A few areas show central cystic change.

ii) *Plexiform pattern* is the next common pattern after follicular pattern. The tumour epithelium is seen to form irregular plexiform masses or network of strands. The stroma is usually scanty. Microcyst formation can occur in the stroma.

iii) *Acanthomatous pattern* is squamous metaplasia within the islands of tumour cells.

iv) *Basal cell pattern* of ameloblastoma is similar to basal cell carcinoma of the skin.

v) *Granular cell pattern* is characterised by appearance of acidophilic granularity in the cytoplasm of tumour cells.

Combination of more than one morphologic pattern may also be seen.

Tumour cells in ameloblastoma exhibit positive immunostaining for cytokeratin and laminin as are seen in developing tooth.

Odontogenic Adenomatoid Tumour (Adeno-ameloblastoma)

This is a benign tumour seen more often in females in their 2nd decade of life. The tumour is commonly associated with an unerupted tooth and thus closely resembles dentigerous cyst radiologically. Unlike ameloblastoma, adenomatoid odontogenic tumour is not invasive nor does it recur after enucleation.

Histologically, the lesion has extensive cyst formations. The wall of cyst contains scanty fibrous connective tissue in which are present characteristic tubule-like structures composed of epithelial cells and hence the name 'adenomatoid' (gland-like).

Calcifying Epithelial Odontogenic Tumour

This is a rare lesion which is locally invasive and recurrent like ameloblastoma. It is seen commonly in 4th and 5th decades and occurs more commonly in the region of mandible.

Histologically, the tumour consists of closely packed polyhedral epithelial cells having features of nuclear pleomorphism, giant nuclei and rare mitotic figures. The stroma is often scanty and appears homogeneous and hyalinised in which small calcified deposits are seen which are a striking feature of this tumour.

Odontogenic Myxoma (Myxofibroma)

Odontogenic myxoma is a locally invasive and recurring tumour.

Microscopically, it is characterised by abundant mucoid stroma and loose stellate cells in which are seen a few strands of odontogenic epithelium.

Ameloblastic Fibroma

This is a benign tumour consisting of epithelial and connective tissues derived from odontogenic apparatus. It resembles ameloblastoma but can be distinguished from it because ameloblastic fibroma occurs in younger age group (below 20 years) and the clinical behaviour is always benign.

Histologically, it consists of epithelial follicles similar to those of ameloblastoma, set in a very cellular connective tissue stroma.

Odontomas

Odontomas are hamartomas that contain both epithelial and mesodermal dental tissue components. There are 3 subtypes:

i) **Complex odontoma** is always benign and consists of enamel, dentin and cementum which are not differentiated, so that the structure of actual tooth is not identifiable.

ii) **Compound odontoma** is also benign and is comprised of differentiated dental tissue elements forming a number of denticles in fibrous tissue.

iii) **Ameloblastic fibro-odontoma** is a lesion that resembles ameloblastic fibroma with odontoma formation.

Cementomas

Cementomas are a variety of benign lesions which are characterised by the presence of cementum or cementum-like tissue. Five types of cementomas are described:

i) **Benign cementoblastoma (true cementoma)** is a solitary lesion of jaw, characterised by features comparable to those of osteoid osteoma and osteoblastoma.

ii) **Cementifying fibroma** consists of cellular fibrous tissue containing calcified masses of cementum-like tissue.

iii) **Periapical cemental dysplasia (Periapical fibrous dysplasia)** is most common and resembles cementifying fibroma except that it contains more fibrous tissue as well as cementum-like tissue.

iv) **Multiple apical cementomas** are found on the apical region of teeth and detected incidentally in postmenopausal women.

v) **Gigantiform cementoma** is a large lobulated mass of cementum-like tissue. Sometimes, there are multiple such masses in the jaw.

B. MALIGNANT ODONTOGENIC TUMOURS

Malignant odontogenic tumours are rare.

Odontogenic Carcinoma

i) *Malignant ameloblastoma* is the term used for the uncommon metastasising ameloblastoma.

ii) *Ameloblastic carcinoma* is the term employed for the ameloblastic tumour having cytologic features of malignancy in the primary tumour.

iii) *Primary intraosseous carcinoma* may develop within the jaw from the rests of odontogenic epithelium.

iv) Rarely, carcinomas may arise from the odontogenic epithelium lining the *odontogenic cysts*.

Odontogenic Sarcomas

The only example of odontogenic sarcoma is a rare ameloblastic fibrosarcoma. This tumour resembles ameloblastic fibroma but

the mesodermal component in it is malignant (sarcomatous) whereas the ameloblastic epithelium remains differentiated and benign.

GIST BOX 17.2

Diseases of Teeth and Periodontal Tissues

- ▣ Normal tooth is composed of enamel, dentin and cementum and central pulp.
- ▣ In dental caries, there is destruction of enamel and occurrence of pulpitis.
- ▣ Chronic periodontal inflammation causes periodontitis and pyorrhea.
- ▣ Common inflammatory cyst of the jaw is radicular cyst while common developmental cyst is dentigerous cyst.
- ▣ Benign odontogenic tumours of the jaw originate from epithelium (e.g. ameloblastoma) or mesenchyme (e.g. myxoma).
- ▣ Odontogenic carcinoma and sarcoma are uncommon malignant tumours.

SALIVARY GLANDS

NORMAL STRUCTURE

There are two main groups of salivary glands—major and minor. The major salivary glands are the three paired glands: parotid, submandibular and sublingual. The minor salivary glands are numerous and are widely distributed in the mucosa of oral cavity. The main duct of the parotid gland drains into the oral cavity opposite the second maxillary molar, while the ducts of submandibular and sublingual glands empty in the floor of the mouth. At times, heterotopic salivary gland tissue may be present in lymph nodes near or within the parotid gland.

Histologically, the salivary glands are tubuloalveolar glands and may contain mucous cells, serous cells, or both. The parotid gland is purely serous. The submandibular gland is mixed type but is predominantly serous, whereas the sublingual gland, though also a mixed gland, is predominantly mucous type. Similarly, minor salivary glands may also be serous, mucous or mixed type.

The secretory acini of the major salivary glands are drained by ducts lined by:

- ◆ low cuboidal epithelium in the intercalated portion,
- ◆ tall columnar epithelium in the intralobular ducts, and
- ◆ simpler epithelium in the secretory ducts.

The product of major salivary glands is *saliva* which performs various functions such as lubrication for swallowing and speech, and has enzyme amylase and antibacterial properties too.

INFLAMMATORY AND SALIVARY FLOW DISEASES

SIALORRHOEA (PTYALISM)

Increased flow of saliva is termed sialorrhoea or ptyalism. It occurs commonly due to: stomatitis, teething, mentally retarded state, schizophrenia, neurological disturbances, increased gastric secretion and sialosis (i.e. uniform, symmetric, painless hypertrophy of salivary glands).

XEROSTOMIA

Decreased salivary flow is termed xerostomia. It is associated with the following conditions: Sjögren's syndrome, sarcoidosis, mumps parotitis, Mikulicz's syndrome, megaloblastic anaemia, dehydration, drug intake (e.g. antihistamines, antihypertensives, antidepressants).

SIALADENITIS

Inflammation of salivary glands, sialadenitis, may be acute or chronic; the latter being more common.

ETIOLOGY Sialadenitis can occur due to the following causes:

1. Viral infections The most common inflammatory lesion of the salivary glands particularly of the parotid glands, is mumps occurring in children of school-age. It is characterised by triad of pathological involvement—*epidemic parotitis (mumps)*, *orchitis-oophoritis*, and *pancreatitis* (Fig. 17.11). Involvement of the testis and pancreas may lead to their atrophy. Less commonly, cytomegalovirus infection may occur in parotid glands of infants and young children.

2. Bacterial and mycotic infections Bacterial infections may cause acute sialadenitis more often. Sometimes there are recurrent attacks of acute parotitis when parotitis becomes chronic.

i) **Acute sialadenitis** The causes are as follows:

- a) Acute infectious fevers
- b) Acute postoperative parotitis (ascent of microorganisms up the parotid duct from the mouth)
- c) General debility
- d) Old age
- e) Dehydration.

ii) **Chronic sialadenitis** This may result from the following causes:

a) **Recurrent obstructive type.** Recurrent obstruction due to calculi (sialolithiasis), stricture, surgery, injury etc. may cause repeated attacks of acute sialadenitis by ascending infection and then chronicity.

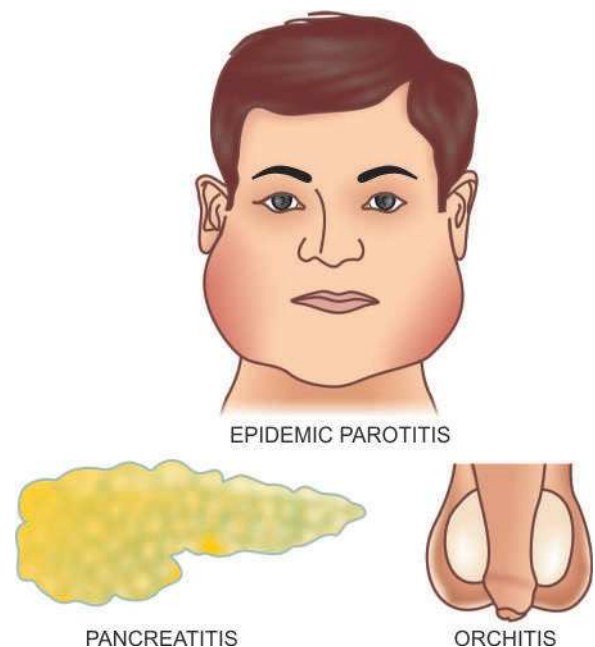

Figure 17.11 Lesions in mumps.

b) *Recurrent non-obstructive type.* Recurrent mild ascending infection of the parotid gland may occur due to non-obstructive causes which reduce salivary secretion like due to intake of drugs causing hyposalivation (e.g. antihistamines, antihypertensives, antidepressants), effect of irradiation and congenital malformations of the duct system.

c) *Chronic inflammatory diseases.* Tuberculosis, actinomycosis and other mycoses may rarely occur in the salivary glands.

3. Autoimmune disease Inflammatory changes are seen in salivary glands in 2 autoimmune diseases:

i) *Sjögren's syndrome* characterised by triad of dry eyes (keratoconjunctivitis sicca), dry mouth (xerostomia) and rheumatoid arthritis (page 66).

ii) *Mikulicz's syndrome* is the combination of inflammatory enlargement of salivary and lacrimal glands with xerostomia.

MORPHOLOGIC FEATURES Irrespective of the underlying etiology of sialadenitis, there is swelling of the affected salivary gland, usually restricted by the fibrous capsule. Acute stage is generally associated with local redness, pain and tenderness with purulent ductal discharge. Late chronic cases may be replaced by firm fibrous swelling.

Microscopically, acute viral sialadenitis in mumps shows swelling and cytoplasmic vacuolation of the acinar epithelial cells and degenerative changes in the ductal epithelium. There is interstitial oedema, fibrinoid degeneration of the collagen and dense infiltration by mononuclear cells (lymphocytes, plasma cells and macrophages). *Chronic and recurrent sialadenitis* is characterised by increased lymphoid tissue in the interstitium, progressive loss of secretory tissue and replacement by fibrosis.

TUMOURS OF SALIVARY GLANDS

The major as well as minor salivary glands can give rise to a variety of benign and malignant tumours (Table 17.6). The major glands, particularly the parotid glands (85%), are the most common sites. Majority of parotid gland tumour (65-85%) are benign, while in the other major and minor salivary glands 35-50% of the tumours are malignant. Most of the salivary gland tumours originate from the ductal lining epithelium and the underlying myoepithelial cells; a few arise from acini. Recurrent tumours of the parotid glands, due to their location, are often associated with facial palsy and obvious scarring following surgical treatment.

A. BENIGN SALIVARY GLAND TUMOURS

Adenomas

The adenomas of the salivary glands are benign epithelial tumours. They are broadly classified into 2 major groups—pleomorphic and monomorphic adenomas.

Pleomorphic Adenoma (Mixed Salivary Tumour)

This is the most common tumour of major (60-75%) and minor (50%) salivary glands. Pleomorphic adenoma is the commonest tumour in the parotid gland and occurs less often in other major and minor salivary glands. The tumour is commoner in women and is seen more frequently in 3rd to 5th decades of life. The tumour is solitary, smooth-surfaced, sometimes

Table 17.6 Classification of salivary gland tumours.

| | |
|----|--|
| A. | BENIGN |
| 1. | Adenomas |

| 2. | Mesenchymal tumours (rare) |
| B. | MALIGNANT |
| 1. | Mucoepidermoid carcinoma (15%) |
| 2. | Malignant mixed tumour |
| | i) Carcinoma in pleomorphic adenoma (3-5%) |
| | ii) Carcinosarcoma (rare) |
| | iii) Metastasising mixed salivary tumour (rare) |
| 3. | Adenoid cystic carcinoma (cylindroma) (5%) |
| 4. | Acinic cell carcinoma (5%) |
| 5. | Adenocarcinoma (10%) |
| 6. | Epidermoid carcinoma (1%) |
| 7. | Undifferentiated carcinoma (< 1%) |
| 8. | Miscellaneous (2%) |

nodular, painless and slow-growing. It is often located below and in front of the ear (Fig. 17.12).

MORPHOLOGIC FEATURES *Grossly*, pleomorphic adenoma is a circumscribed, pseudoencapsulated, rounded, at times multilobulated, firm mass, 2-5 cm in diameter, with bosselated surface. The cut surface is grey-white and bluish, variegated, semitranslucent, usually solid but occasionally may show small cystic spaces. The consistency is soft and mucoid.

Microscopically, the pleomorphic adenoma is characterised by pleomorphic or 'mixed' appearance in which there are epithelial elements present in a stromal matrix of mucoid, myxoid and chondroid tissue (Fig. 17.13):

◆ **Epithelial component** may form various patterns like ducts, acini, tubules, sheets and strands of cells of ductal or myoepithelial origin. The ductal cells are cuboidal or columnar, while the underlying myoepithelial cells may be polygonal or spindle-shaped resembling smooth muscle cells. The material found in the lumina of duct-like structures is PAS-positive epithelial mucin. Focal areas of squamous metaplasia and keratinisation may be present.

Immunohistochemically, the tumour cells are immunoreactive for epithelial (cytokeratin, EMA, CEA) as well as myoepithelial (actin, vimentin and S-100) antibodies.

◆ **Stromal elements** are present as loose connective tissue, and as myxoid, mucoid and chondroid matrix, which simulates cartilage (*pseudocartilage*). However, true cartilage and even bone may also be observed in a small proportion of these tumours.

Based on morphology, immunohistochemistry, ultra-structure and molecular characteristics, the mesenchymal matrix of the tumour has been assigned as a product of

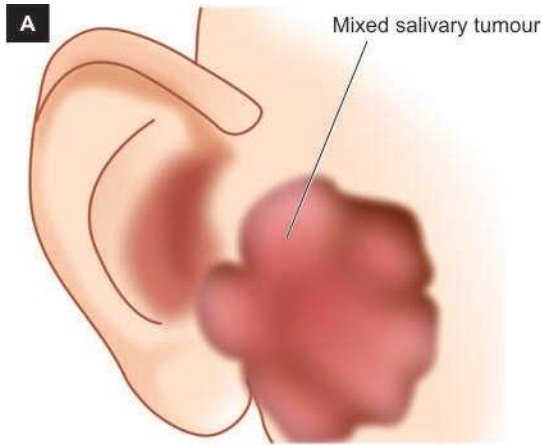

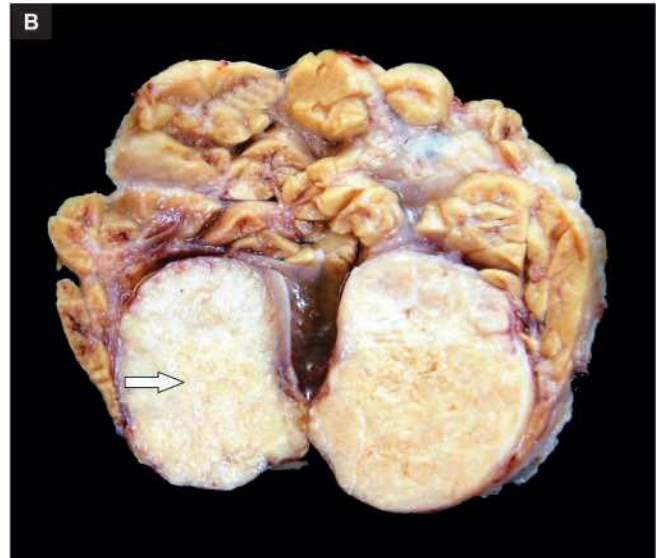

Figure 17.12 Pleomorphic adenoma (mixed salivary tumour) of the parotid gland. A, Diagrammatic location. B, Sectioned surface of the parotid gland shows lobules of grey-white circumscribed tumour having semitranslucent parenchyma (arrow).

epithelial origin and are actually modified myoepithelial cells as seen by S-100 immunostain positivity.

The epithelial and mesenchymal elements are intermixed and either of the two components may be dominant in any tumour.

PROGNOSIS Pleomorphic adenoma is notorious for recurrences, sometimes after many years. The main factors responsible for the tendency to recur are incomplete surgical removal due to proximity to the facial nerve, multiple foci of tumour, pseudoencapsulation, and implantation in the surgical field. Although the tumour is entirely benign, under exceptionally rare circumstances, an ordinary pleomorphic adenoma may metastasise to distant sites which too will have benign appearance as the original tumour. However, actual malignant transformation can also occur in a pleomorphic adenoma (*vide infra*).

Monomorphic Adenomas

These are benign epithelial tumours of salivary glands without any evidence of mesenchyme-like tissues. Their various forms are as under:

WARTHIN'S TUMOUR (PAPILLARY CYSTADENOMA LYMPHOMATOSUM, ADENOLYMPHOMA) It is a benign tumour of the parotid gland comprising about 8% of all parotid neoplasms, seen more commonly in men from 4th to 7th decades of life. Rarely, it may arise in the submandibular gland or in minor salivary glands. *Histogenesis* of the tumour has been much debated; most accepted theory is that the tumour develops from parotid ductal epithelium present in lymph nodes adjacent to or within parotid gland.

MORPHOLOGIC FEATURES *Grossly*, the tumour is encapsulated, round or oval with smooth surface. The

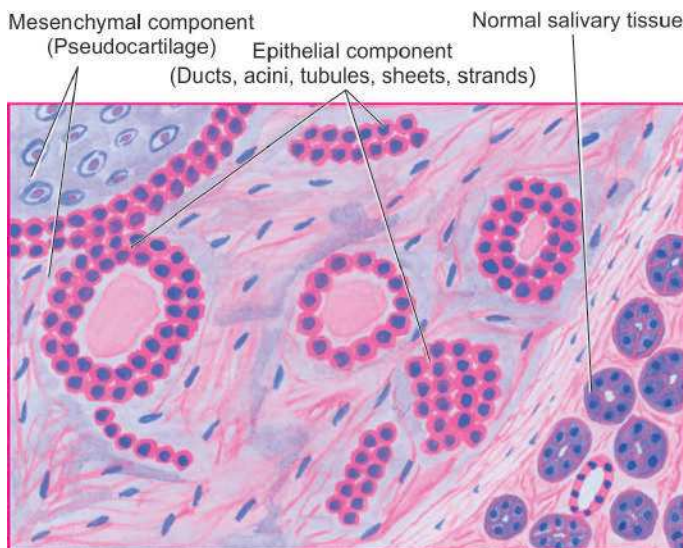

Figure 17.13 Pleomorphic adenoma. The epithelial element is comprised of ducts, acini, tubules, sheets and strands of cuboidal and myoepithelial cells. These are seen randomly admixed with mesenchymal elements composed of pseudocartilage which is the matrix of myxoid, chondroid and mucoid material.

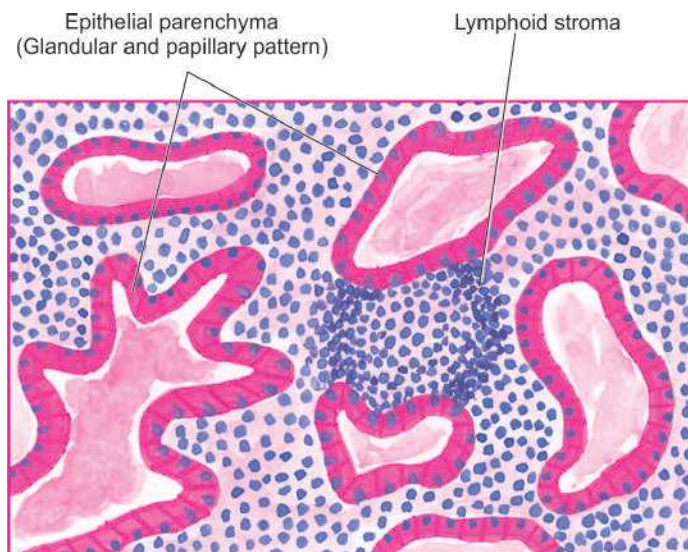

Figure 17.14 Warthin's tumour, showing eosinophilic epithelium forming glandular and papillary, cystic pattern with intervening stroma of lymphoid tissue.

cut surface shows characteristic slit-like or cystic spaces, containing milky fluid and having papillary projections.

Microscopically, the tumour shows 2 components: epithelial parenchyma and lymphoid stroma (**Fig. 17.14**):

- ◆ **Epithelial parenchyma** is composed of glandular and cystic structures having papillary arrangement and is lined by characteristic eosinophilic epithelium. Variants of epithelial patterns include presence of mucous goblet cells and sebaceous differentiation.
- ◆ **Lymphoid stroma** is present under the epithelium in the form of prominent lymphoid tissue, often with germinal centres.

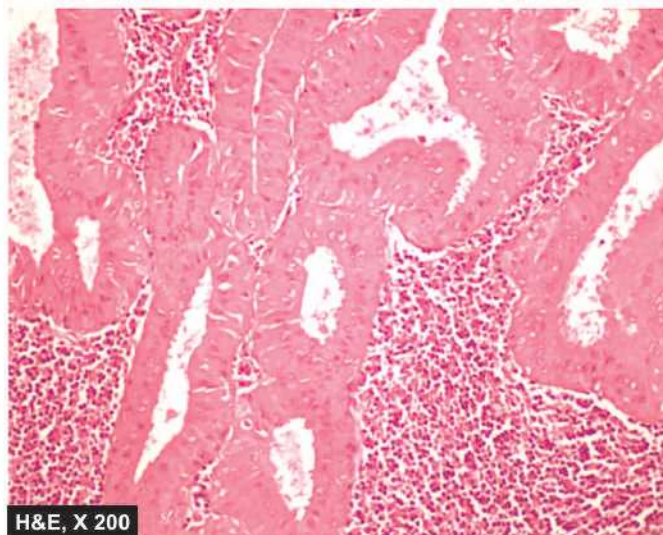

OXYPHIL ADENOMA (ONCOCYTOMA) It is a benign slow-growing tumour of the major salivary glands. The tumour consists of parallel sheets, acini or tubules of large cells with glandular eosinophilic cytoplasm (oncocytes). It is also called as mitochondrioma because of cytoplasmic granularity due to mitochondria.

OTHER TYPES OF MONOMORPHIC ADENOMAS There are some uncommon forms of monomorphic adenomas:

- i) *Myoepithelioma* is an adenoma composed exclusively of myoepithelial cells which may be arranged in tubular, alveolar or trabecular pattern.
- ii) *Basal cell adenoma* is characterised by the type and arrangement of cells resembling basal cell carcinoma of the skin.
- iii) *Clear cell adenoma* has spindle-shaped or polyhedral cells with clear cytoplasm.

Miscellaneous Benign Tumours

A number of mesenchymal tumours can rarely occur in salivary glands. These include: fibroma, lipoma, neurilemmomas, neurofibroma, haemangioma and lymphangioma.

B. MALIGNANT SALIVARY GLAND TUMOURS

Mucoepidermoid Carcinoma

The status of 'mucoepidermoid tumour' as an intermediate grade tumour in the older classification has undergone upgradation to mucoepidermoid carcinoma now having the following peculiar features:

1. It is the most *common malignant* salivary gland tumour (both in the major and minor glands).
2. The *parotid gland* amongst the major salivary glands and the minor salivary glands in the *palate* are the most common sites.
3. Common age group affected is 30-60 years but it is also the most common malignant salivary gland tumour affecting *children and adolescents*.
4. It is the most common example of *radiation-induced* malignant tumour, especially therapeutic radiation.

MORPHOLOGIC FEATURES **Grossly**, the tumour is usually circumscribed but not encapsulated. It varies in size from 1 to 4 cm.

Microscopically, the tumour is classified into low, intermediate and high grade depending upon the degree of differentiation and tumour invasiveness. The tumour is composed of combination of 4 types of cells: mucin-producing, squamous, intermediate and clear cells. Well-differentiated tumours have predominance of mucinous cells, while poorly differentiated have more solid and infiltrative pattern (**Fig. 17.15**).

Malignant Mixed Tumour

Malignant mixed tumour comprises three distinct clinico-pathologic entities:

1. Carcinoma arising in benign mixed salivary gland tumour (carcinoma *ex* pleomorphic adenoma)
2. Carcinosarcoma
3. Metastasising mixed salivary tumour.

Figure 17.15 Mucoepidermoid carcinoma. The tumour shows combination of mucinous, squamous and intermediate cells and having infiltrative border.

Carcinoma *ex* pleomorphic adenoma is more common (3-5%) while the other two are rare tumours. The slow-growing adenoma may have been present for a number of years when suddenly it undergoes rapid increase in its size, becomes painful and the individual may develop facial palsy. Malignant transformation occurs in later age (6th decade) than the usual age for pleomorphic adenoma (4th to 6th decades). It may occur in primary tumour but more often occurs in its recurrences.

MORPHOLOGIC FEATURES *Grossly*, the tumour is poorly-circumscribed with irregular infiltrating margin. Cut section may show haemorrhages, necrosis and cystic degeneration.

Microscopically, besides the typical appearance of pleomorphic adenoma, malignant areas show cytologic features of carcinoma such as anaplasia, nuclear hyperchromatism, large nucleolisation, mitoses and evidence of invasive growth. All types of usual salivary gland carcinomas (described below) may develop in pleomorphic adenoma.

Adenoid Cystic Carcinoma (Cylindroma)

This is a highly malignant tumour due to its typical infiltrative nature, especially along the nerve sheaths.

Histologically, adenoid cystic carcinoma is characterised by cribriform appearance i.e. the epithelial tumour cells of duct-lining and myoepithelial cells are arranged in duct-like structures or masses of cells, having typical fenestrations or cyst-like spaces and hence the name 'adenoid cystic'. These cystic spaces contain PAS-positive basophilic material (Fig. 17.16).

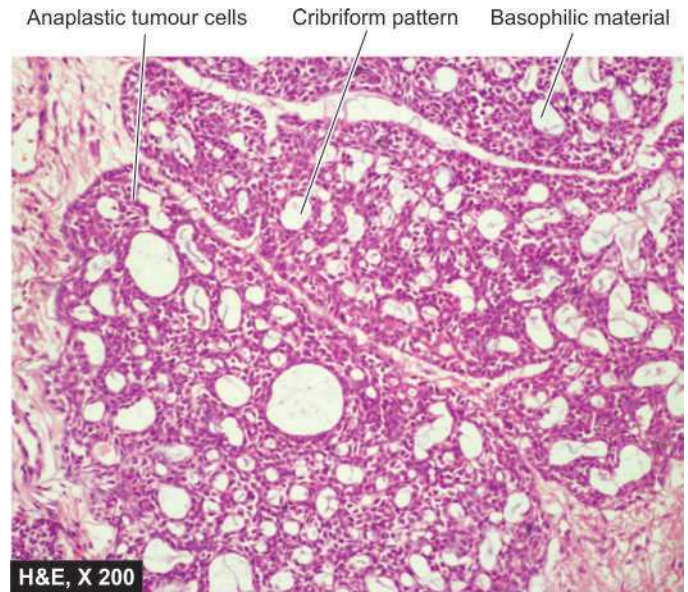

Figure 17.16 Adenoid cystic carcinoma. It shows nests of tumour cells having fenestrations containing basophilic material.

Acinic Cell Carcinoma

This is a rare tumour composed of acinic cells resembling serous cells of normal salivary gland. These cells are arranged in sheets or acini and have characteristic basophilic granular cytoplasm. The degree of atypia may vary from a benign cytologic appearance to cellular features of malignancy.

Adenocarcinoma

Adenocarcinoma of the salivary gland does not differ from adenocarcinoma elsewhere in the body. It may have some variants such as mucoid adenocarcinoma, clear-cell adenocarcinoma and papillary cystadenocarcinoma.

Epidermoid Carcinoma

This rare tumour has features of squamous cell carcinoma with keratin formation and has intercellular bridges similar to its appearance elsewhere in the body. The tumour commonly infiltrates the skin and involves the facial nerve early.

Undifferentiated Carcinoma

This highly malignant tumour consists of anaplastic epithelial cells which are too poorly differentiated to be placed in any other known category.

Miscellaneous Malignant Tumours

Some rare malignant tumour of epithelial and mesenchymal origin are melanoma, sebaceous carcinoma, undifferentiated carcinoma, lymphoma, fibrosarcoma and leiomyosarcoma. All these tumours are similar in morphology to such tumours elsewhere in the body.

Besides, metastatic involvement of major salivary glands or the adjacent lymph nodes is common, especially from epidermoid carcinoma and malignant melanoma.

GIST BOX 17.3 Diseases of Salivary Glands

- ▣ Salivary flow disturbances include sialorrhoea (hyper-salivation) and xerostomia (decreased salivation).
- ▣ Sialadenitis is inflammation of the parotid glands, commonly due to mumps in children, and may be accompanied with orchitis-oophoritis and pancreatitis.
- ▣ Most common benign tumour of the salivary glands is pleomorphic adenoma. It is composed of epithelial and stromal elements.
- ▣ About 5% of mixed salivary tumours show malignant change.
- ▣ Warthin's tumour is a monomorphic adenoma and has cystic spaces lined by papillary arrangement lined by epithelial cells with eosinophilic cytoplasm and lymphoid stroma.
- ▣ Mucoepidermoid carcinoma, adenoid cystic carcinoma, and acinic cell carcinoma are some of the other malignant salivary gland tumours.

CLINICAL CASE 14

A 50 years old roadside tailor reports to surgeon with right lateral cervical lymphadenopathy and progressive pallor for 2 months. He has a non-healing ulcer with intermittent bleeding in the vestibule on right side for the last 2 years. He further gives history of chewing and keeping a bolus of tobacco throughout the day when he is awake on the same side of cheek ever since early adulthood.

On examination, there is induration around the ulcer in the vestibule. Multiple matted lymph nodes are palpable on lateral cervical region.

1. **Discuss the clinical correlation with pathogenesis of the features.**
2. **What is the probable diagnosis?**
3. **How will you investigate and confirm the diagnosis?**

Answers on page 910 (Appendix II)

18

The Gastrointestinal Tract

OESOPHAGUS

NORMAL STRUCTURE

The oesophagus is a muscular tube extending from the pharynx to the stomach. In an adult, this distance measures 25 cm. However, from the clinical point of view, the distance from the incisor teeth to the gastro-oesophageal (GE) junction is about 40 cm. The region of proximal oesophagus at the level of cricopharyngeus muscle is called the *upper oesophageal sphincter*, while the portion adjacent to the anatomic gastro-oesophageal junction is referred to as *lower oesophageal sphincter*.

Histologically, the wall of the oesophagus consists of mucosa, submucosa, muscularis propria and adventitia/serosa.

◆ The **mucosa** is composed of non-keratinising stratified squamous epithelium overlying lamina propria except at the lower end for a distance of 0.5 to 1.5 cm. The basal layer of the epithelium may contain some melanocytes, argyrophil cells and Langerhans' cells. At the lower end of the oesophagus, there is sudden change from stratified squamous epithelium to mucin-secreting columnar epithelium; this is called the *junctional mucosa*.

◆ The **submucosa** consists of loose connective tissue with sprinkling of lymphocytes, plasma cells, and occasional eosinophil and mast cell. Mucus-producing glands are scattered throughout the submucosa.

◆ The **muscularis propria** is composed of 2 layers of smooth muscle—an inner circular coat and an outer longitudinal coat. The proximal portion of oesophagus contains skeletal muscle fibres from cricopharyngeus muscle. The parasympathetic nerve supply by the vagus nerve is in the form of extrinsic and intrinsic plexuses.

◆ The **adventitia/serosa** is the outer covering of oesophagus. Serosa is present in intra-abdominal part of oesophagus only, while elsewhere the perioesophageal adventitia covers it.

The *major functions* of oesophagus are swallowing by peristaltic activity and to prevent the reflux of gastric contents into the oesophagus.

CONGENITAL ANOMALIES

Congenital anomalies of the oesophagus are uncommon and are detected soon after birth. These include a few rare anomalies such as *agenesis* (congenital absence of oesophagus) which is incompatible with life, *duplication of oesophagus* (double oesophagus) and *congenital stenosis* (i.e. fibrous thickening of the oesophageal wall and atrophy of the muscularis propria). However, oesophageal atresia and tracheo-oesophageal fistula are relatively more common.

OESOPHAGEAL ATRESIA AND TRACHEO-OESOPHAGEAL FISTULA

In about 85% of cases, congenital atresia of the oesophagus is associated with tracheo-oesophageal fistula, usually at the level of tracheal bifurcation. For survival, the condition must be recognised and corrected surgically within 48 hours of birth of the newborn. Clinically, the condition is characterised by regurgitation of every feed, hypersalivation, attacks of cough and cyanosis. Death usually results from asphyxia, aspiration pneumonia and fluid-electrolyte imbalance.

Morphologically, the condition is recognised by cord-like non-canalised segment of oesophagus having blind pouch at both ends.

MUSCULAR DYSFUNCTIONS

These are disorders in which there is motor dysfunction of the oesophagus, manifested clinically by dysphagia. These include achalasia, hiatus hernia, oesophageal diverticula, and webs and rings.

ACHALASIA (CARDIOSPASM)

Achalasia of the oesophagus is a neuromuscular dysfunction due to which the cardiac sphincter fails to relax during swallowing and results in progressive dysphagia and dilatation of the oesophagus (*mega-oesophagus*).

ETIOLOGY There is loss of intramural neurons in the wall of the oesophagus. Most cases are of primary idiopathic achalasia i.e. congenital. Secondary achalasia may occur from some other causes which includes: Chagas' disease (an epidemic parasitosis with *Trypanosoma cruzi*), infiltration into oesophagus by gastric carcinoma or lymphoma, certain viral infections, and neurodegenerative diseases.

MORPHOLOGIC FEATURES There is dilatation above the short contracted terminal segment of the oesophagus. Muscularis propria of the wall may be of normal thickness, hypertrophied as a result of obstruction, or thinned out due to dilatation. Secondary oesophagitis may supervene and cause oesophageal ulceration and haematemesis.

HIATUS HERNIA

Hiatus hernia is the herniation or protrusion of part of the stomach through the oesophageal hiatus of the diaphragm. Oesophageal hiatal hernia is the cause of diaphragmatic hernia in 98% of cases. The condition is diagnosed radiologically in about 5% of apparently normal asymptomatic individuals. In symptomatic cases, especially the elderly women, the clinical features are heartburn (retrosternal burning sensation) and regurgitation of gastric juice into the mouth, both of which

are worsened due to heavy work, lifting weights and excessive bending.

ETIOLOGY The basic defect is the failure of the muscle fibres of the diaphragm that form the margin of the oesophageal hiatus. This occurs due to shortening of the oesophagus which may be congenital or acquired.

◆ **Congenitally short oesophagus** may be the cause of hiatus hernia in a small proportion of cases.

◆ More commonly, it is **acquired** due to secondary factors which cause fibrous scarring of the oesophagus as follows:

- Degeneration of muscle due to ageing.
- Increased intra-abdominal pressure such as in pregnancy, abdominal tumours etc.
- Recurrent oesophageal regurgitation and spasm causing inflammation and fibrosis.
- Increase in fatty tissue in obese people causing decreased muscular elasticity of diaphragm.

MORPHOLOGIC FEATURES There are 3 patterns in hiatus hernia (Fig. 18.1):

i) **Sliding or oesophago-gastric hernia** is the most common, occurring in 85% of cases. The herniated part of the stomach appears as supradiaphragmatic bell due to sliding up on both sides of the oesophagus.

ii) **Rolling or para-oesophageal hernia** is seen in 10% of cases. This is a true hernia in which cardiac end of the stomach rolls up para-oesophageally, producing an intra-thoracic sac.

iii) **Mixed or transitional hernia** constitutes the remaining 5% cases in which there is combination of sliding and rolling hiatus hernia.

OESOPHAGEAL DIVERTICULA

Diverticula are the outpouchings of oesophageal wall at the point of weakness. They may be congenital or acquired.

◆ **Congenital diverticula** occur either at the upper end of the oesophagus or at the bifurcation of trachea.

◆ **Acquired diverticula** may be of 2 types:

a) **Pulsion (Zenker's) type**—It is seen in the region of hypopharynx and occurs due to oesophageal obstruction such as due to chronic oesophagitis, carcinoma etc. The mucosa and

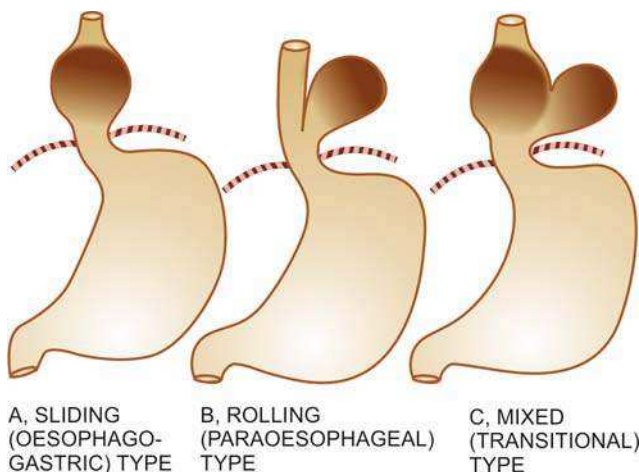

Figure 18.1 Patterns of hiatus hernia.

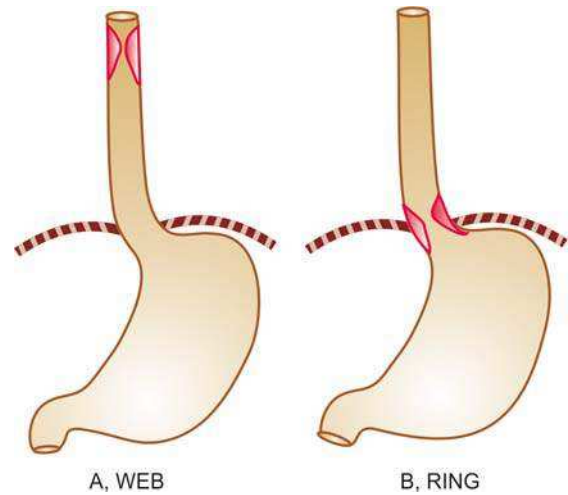

Figure 18.2 Oesophageal webs and rings.

submucosa herniate through the weakened area or through defect in the muscularis propria.

b) **Traction type**—It occurs in the lower third of oesophagus from contraction of fibrous tissue such as from pleural adhesions, scar tissue of healed tuberculous lesions in the hilum, silicosis etc.

Complications of diverticula include obstruction, infection, perforation, haemorrhage and carcinoma.

OESOPHAGEAL WEBS AND RINGS

Radiological shadows in the oesophagus resembling 'webs' and 'rings' are observed in some patients complaining of dysphagia.

WEBS These are located in the upper oesophagus, seen more commonly in adult women, and associated with dysphagia, iron deficiency anaemia and chronic atrophic glossitis (Plummer-Vinson syndrome).

RINGS Those located in the lower oesophagus, not associated with iron-deficiency anaemia, nor occurring in women alone, are referred to as 'Schatzki's rings'.

MORPHOLOGIC FEATURES The rings and webs are transverse folds of mucosa and submucosa encircling the entire circumference, or are localised annular thickenings of the muscle (Fig. 18.2). These give characteristic radiological shadows.

HAEMATEMESIS OF OESOPHAGEAL ORIGIN

Massive haematemesis (vomiting of blood) may occur due to vascular lesions in the oesophagus. These lesions are as under:

1. OESOPHAGEAL VARICES Oesophageal varices are tortuous, dilated and engorged oesophageal veins, seen along the longitudinal axis of oesophagus. They occur as a result of elevated pressure in the portal venous system, most commonly in cirrhosis of the liver (page 617). Less common causes are: portal vein thrombosis, hepatic vein thrombosis (Budd-Chiari syndrome) and pylephlebitis. The lesions occur as a result of bypassing of portal venous blood from the liver to the oesophageal venous plexus. The increased venous pressure in

the superficial veins of the oesophagus may result in ulceration and massive bleeding.

2. MALLORY-WEISS SYNDROME In this condition, there is lacerations of mucosa at the gastro-oesophageal junction following minor trauma such as by vomiting, retching or vigorous coughing. Patients present with upper gastro-oesophageal bleeding.

3. RUPTURE OF THE OESOPHAGUS Rupture of the oesophagus may occur following trauma, during oesophagoscopy, indirect injury (e.g. due to sudden acceleration and deceleration of the body) and spontaneous rupture (e.g. after overeating, extensive aerophagy etc).

4. OTHER CAUSES Oesophageal haematemesis may also occur in the following conditions:

- i) Bursting of aortic aneurysm into the lumen of oesophagus
- ii) Vascular erosion by malignant growth in the vicinity
- iii) Hiatus hernia
- iv) Oesophageal cancer
- v) Purpuras
- vi) Haemophilia.

INFLAMMATORY LESIONS

Inflammation of the oesophagus, oesophagitis, occurs most commonly from reflux, although a number of other clinical conditions and infections may also cause oesophagitis discussed below:

REFLUX (PEPTIC) OESOPHAGITIS

Reflux of the gastric juice is the commonest cause of oesophagitis.

PATHOGENESIS Gastro-oesophageal reflux, to an extent, may occur in normal healthy individuals after meals and in early pregnancy. However, in some clinical conditions, the gastro-oesophageal reflux is excessive, resulting in inflammation of the lower oesophagus. These conditions are as under:

- i) Sliding hiatus hernia
- ii) Chronic gastric and duodenal ulcers
- iii) Nasogastric intubation
- iv) Persistent vomiting
- v) Surgical vagotomy
- vi) Neuropathy in alcoholics, diabetics
- vii) Oesophagostomy.

MORPHOLOGIC FEATURES *Endoscopically*, the demarcation between normal squamous and columnar epithelium at the junctional mucosa is lost. The affected distal oesophageal mucosa is red, erythematous, friable and bleeds on touch. In advanced cases, there are features of chronic disease such as nodularity, strictures, ulcerations and erosions.

Microscopically, the reflux changes in the distal oesophagus include basal cell hyperplasia and deep elongation of the papillae touching close to the surface epithelium. Inflammatory changes vary according to the stage of the disease. *In early stage*, mucosa and submucosa are infiltrated by some polymorphs and eosinophils; *in chronic stage*, there is lymphocytic infiltration and fibrosis of all the layers of the oesophageal wall.

BARRETT'S OESOPHAGUS

This is a condition in which, following reflux oesophagitis, stratified squamous epithelium of the lower oesophagus is replaced by columnar epithelium (columnar metaplasia). The condition is seen more commonly in later age and is caused by factors producing gastro-oesophageal reflux disease (described above). Barrett's oesophagus is a premalignant condition evolving sequentially from Barrett's epithelium (columnar metaplasia with goblet cells) to dysplasia to carcinoma *in situ* and finally to oesophageal adenocarcinoma.

MORPHOLOGIC FEATURES Endoscopically, the affected area is red and velvety. Hiatus hernia and peptic ulcer at squamocolumnar junction (Barrett's ulcer) are frequently associated.

Microscopically, the changes are as under (**Fig. 18.3**):

1. The most common finding is the replacement of squamous epithelium by metaplastic columnar cells, along with goblet cells and Paneth cells (intestinal metaplasia). Based on length of oesophagus involved, it is further divided into long segment (≥ 3 cm) and short segment (< 3 cm) involvement.
2. Intestinal metaplasia may be accompanied by dysplastic changes of the columnar epithelium or glands ranging from low to high grade.
3. There may be changes of peptic ulcer due to presence of fundic gastric glands, or cardiac mucous glands.
4. Inflammatory changes, acute or chronic, are commonly accompanied.
5. There may be development of stricture in the long segment.

High-grade dysplasia may progress to invasive adenocarcinoma of the oesophagus in up to 20% cases: the reported risk of development of adenocarcinoma in Barrett's oesophagus is at the rate of 0.5% per year after diagnosis. Therefore, surveillance endoscopic biopsies are advised.

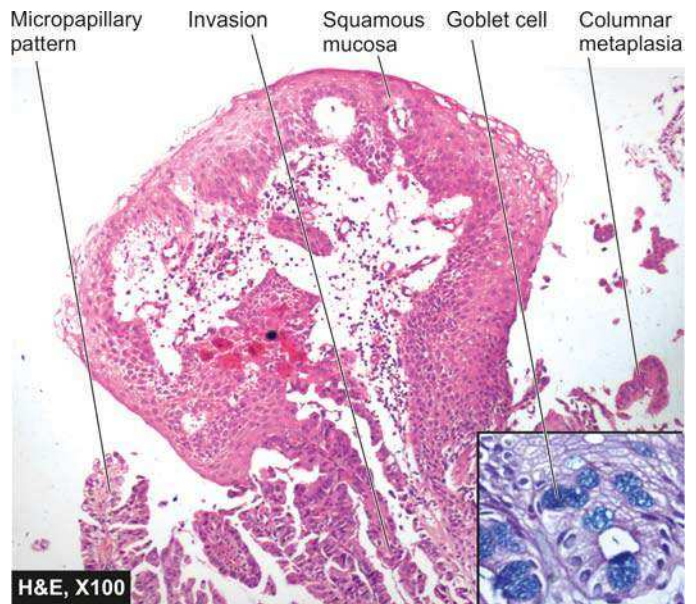

Figure 18.3 Barrett's oesophagus. The central part of the image shows squamous mucosa bounded on either side by metaplastic columnar mucosa showing anaplastic change and micropapillary pattern of adenocarcinoma. In box shows goblet cells in the metaplastic columnar epithelium stained positive for alcian blue.

OTHER CAUSES OF OESOPHAGITIS

These include infective and non-infective causes.

Infective Causes

A number of opportunistic infections in immunosuppressed individuals can cause oesophagitis. Some of these agents are as follows:

- i) Candida (Monilial) oesophagitis
- ii) Herpes simplex (Herpetic) oesophagitis
- iii) Cytomegalovirus
- iv) Tuberculosis.

Non-Infective Causes

- i) Eosinophilic oesophagitis caused by radiation, corrosives
- ii) Intake of certain drugs (anticholinergic drugs, doxycycline, tetracycline)
- iii) Ingestion of hot, irritating fluids
- iv) Crohn's disease
- v) Various vesiculobullous skin diseases.

TUMOURS OF OESOPHAGUS

Benign tumours of the oesophagus are uncommon and small in size (less than 3 cm). The epithelial benign tumours project as intraluminal masses arising from squamous epithelium (squamous cell papilloma), or from columnar epithelium (adenoma). The stromal or mesenchymal benign tumours are intramural masses such as leiomyoma and others like lipoma, fibroma, neurofibroma, rhabdomyoma, lymphangioma and haemangioma.

For all practical purposes, malignant tumours of the oesophagus are carcinomas because sarcomas such as leiomyosarcoma and fibrosarcoma occur with extreme rarity.

CARCINOMA OF OESOPHAGUS

Carcinoma of the oesophagus is diagnosed late, after symptomatic oesophageal obstruction (dysphagia) has developed and the tumour has transgressed the anatomical limits of the organ. The tumour occurs more commonly in men over 50 years of age. Prognosis is dismal: with standard methods of therapy

(surgical resection and/or irradiation), 70% of the patients die within one year of diagnosis. Five-year survival rate is 5-10%.

ETIOLOGY Although exact etiology of carcinoma of the oesophagus is not known, a number of conditions and factors have been implicated as under:

1. Diet and personal habits:

- i) Heavy smoking
- ii) Alcohol consumption
- iii) Intake of foods contaminated with fungus
- iv) Nutritional deficiency of vitamins and trace elements.

2. Oesophageal disorders:

- i) Oesophagitis (especially Barrett's oesophagus in adenocarcinoma)
- ii) Achalasia
- iii) Hiatus hernia
- iv) Diverticula
- v) Plummer-Vinson syndrome.

3. Other factors:

- i) *Race*—more common in the Chinese and Japanese than in Western races; more frequent in blacks than whites.
- ii) *Family history*—association with tylosis (keratosis palmaris et plantaris).
- iii) *Genetic factors*—predisposition with coeliac disease, epidermolysis bullosa, tylosis.
- iv) *HPV infection*—is a recent addition in etiologic factors.

At molecular level, abnormality of *p53* tumour suppressor gene has been found associated with a number of above risk factors, notably with consumption of tobacco and alcohol, and in cases having proven Barrett's oesophagus.

MORPHOLOGIC FEATURES Carcinoma of the oesophagus is mainly of 2 types—squamous cell (epidermoid) and adenocarcinoma. The sites of predilection for each of these 2 forms is shown in **Fig. 18.4,A**.

SQUAMOUS CELL (EPIDERMOID) CARCINOMA

Squamous cell or epidermoid carcinoma comprises 90% of primary oesophageal cancers. It is exceeded in incidence by carcinoma colon, rectum and stomach amongst all the

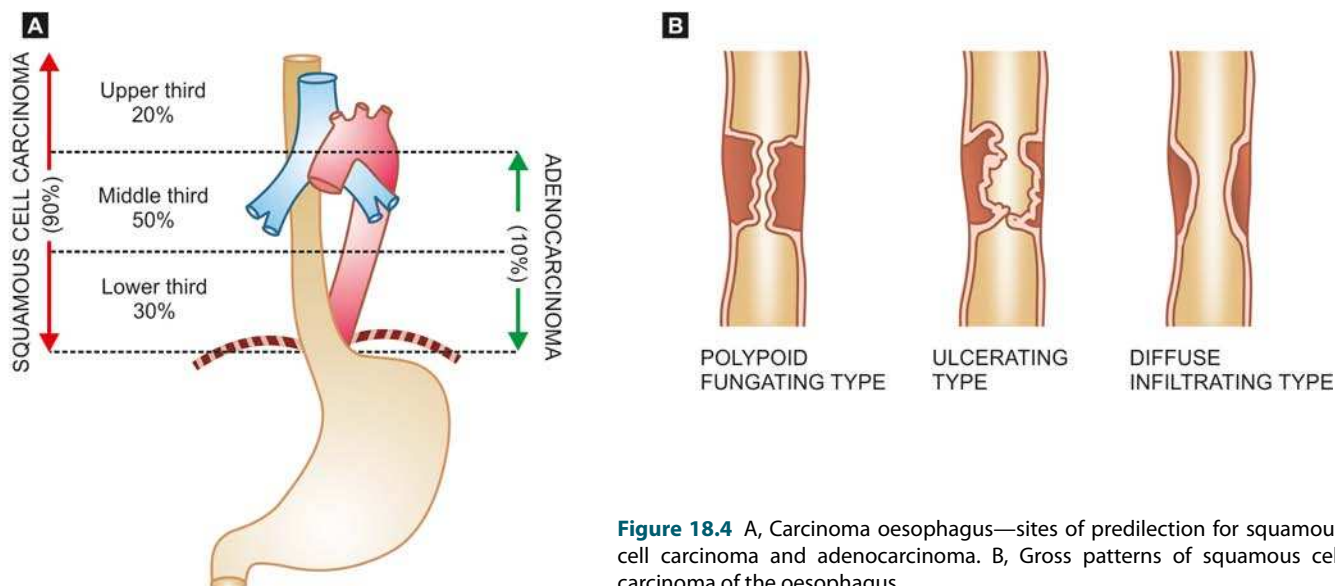

Figure 18.4 A, Carcinoma oesophagus—sites of predilection for squamous cell carcinoma and adenocarcinoma. B, Gross patterns of squamous cell carcinoma of the oesophagus.

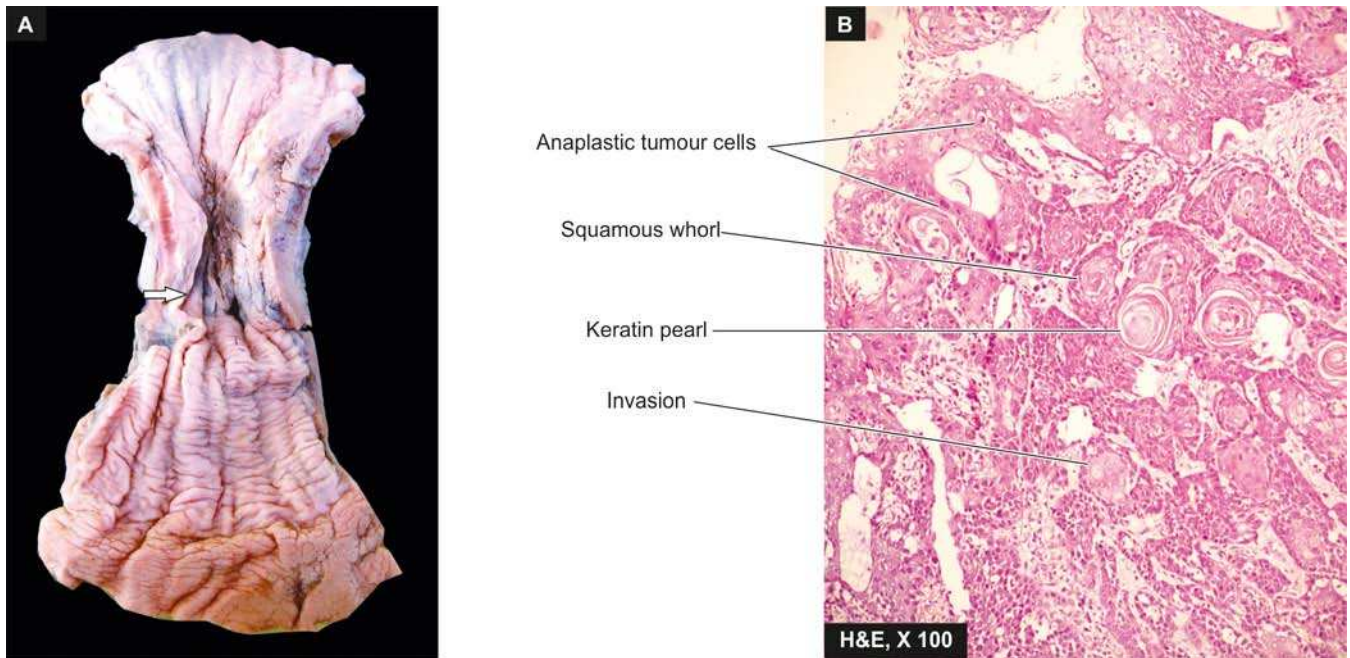

Figure 18.5 Squamous cell carcinoma oesophagus. A, Gross appearance. The tubular structure has thick muscle in its wall and has longitudinal mucosal folds. There is a concentric circumferential thickening in the middle (arrow) causing narrowing of the lumen (arrow). The mucosal surface is ulcerated. B, Photomicrograph shows whorls of anaplastic squamous cells invading the underlying soft tissues.

gastrointestinal cancers. The disease occurs in 6th to 7th decades of life and is more common in men than women. The sites of predilection are the three areas of oesophageal constrictions. Half of the squamous cell carcinomas of oesophagus occur in the middle third, followed by lower third, and the upper third of oesophagus in that order of frequency.

Grossly, 3 types of patterns are recognised (**Fig. 18.4,B**):

- i) *Polypoid fungating type*—is the most common form. It appears as a cauliflower-like friable mass protruding into the lumen.
- ii) *Ulcerating type*—is the next common form. It looks grossly like a necrotic ulcer with everted edges (**Fig. 18.5, A**).
- iii) *Diffuse infiltrating type*—appears as an annular, stenosing narrowing of the lumen due to infiltration into the wall of oesophagus.

Microscopically, majority of the squamous cell carcinomas of the oesophagus are well-differentiated or moderately-differentiated (**Fig. 18.5, B**). Prickle cells, keratin formation and epithelial pearls are commonly seen. However, non-keratinising and anaplastic growth patterns can also occur. An exophytic, slow-growing, extremely well-differentiated variant, *verrucous squamous cell carcinoma*, has also been reported in the oesophagus.

ADENOCARCINOMA Adenocarcinoma of the oesophagus constitutes less than 10% of primary oesophageal cancer. It occurs predominantly in men in their 4th to 5th decades. The common locations are lower and middle third of the oesophagus. These tumours have a strong and definite association with Barrett's oesophagus in which there are foci of gastric or intestinal type of epithelium.

Grossly, oesophageal adenocarcinoma appears as nodular, elevated mass in the lower oesophagus.

Microscopically, adenocarcinoma of the oesophagus can have 3 patterns:

- i) *Intestinal type*—is the adenocarcinoma with a pattern similar to that seen in adenocarcinoma of intestine or stomach.
- ii) *Adenosquamous type*—is the pattern in which there is an irregular admixture of adenocarcinoma and squamous cell carcinoma.
- iii) *Adenoid cystic type*—is an uncommon variety and is akin to similar growth in salivary gland i.e. a cribriform appearance in an epithelial tumour.

Adenocarcinoma of the oesophagus must be distinguished from adenocarcinoma of the gastric cardia. This is done by identifying normal oesophageal mucosa on distal as well as proximal margin of the tumour.

OTHER CARCINOMAS Besides the two main histological types of oesophageal cancer, a few other varieties are occasionally encountered. These are as follow:

- i) *Mucoepidermoid carcinoma* is a tumour having characteristics of squamous cell as well as mucus-secreting carcinomas.
- ii) *Malignant melanoma* is derived from melanoblasts in the epithelium of the oesophagus.
- iii) *Small cell carcinoma* arises from argyrophil cells in the basal layer of the epithelium.
- iv) *Undifferentiated carcinoma* is an anaplastic carcinoma which cannot be classified into any recognisable type of carcinoma.
- v) *Carcinosarcoma* consists of malignant epithelial as well as sarcomatous components.
- vi) *Secondary tumours* rarely occur in the oesophagus from carcinomas of the breast, kidney and adrenals.

SPREAD The oesophageal cancer spreads locally as well as to distant sites.

i) Local spread This is the most important mode of spread and is of great importance for surgical treatment. Local spread may occur in the transverse as well as longitudinal direction. The tumour may invade below into the stomach, above into the hypopharynx, into the trachea resulting in tracheo-oesophageal fistula, and may involve larynx causing hoarseness. The tumour may invade the muscular wall of the oesophagus and involve the mediastinum, lungs, bronchi, pleura and aorta.

ii) Lymphatic spread Submucosal lymphatic permeation may lead to multiple satellite nodules away from the main tumour. Besides, the lymphatic spread may result in metastases to the cervical, para-oesophageal, tracheo-bronchial and subdiaphragmatic lymph nodes.

iii) Haematogenous spread Blood-borne metastases from the oesophageal cancer are rare, probably because the death occurs early due to invasion of important structures by other modes of spread. However, metastatic deposits by haematogenous route can occur in the lungs, liver and adrenals.

GIST BOX 18.1 Diseases of Oesophagus

- ▣ Oesophageal atresia and tracheo-oesophageal fistula are more common congenital anomalies of oesophagus.
- ▣ Achalasia (or cardiospasm) and hiatus hernia are muscular dysfunctions of oesophagus.
- ▣ Barrett's oesophagus is the intestinal metaplasia along with presence of goblet cells in squamous-lined oesophagus and may be associated with dysplastic changes which may progress to adenocarcinoma.
- ▣ Common cancer of oesophagus is squamous cell type, most common in the middle third of oesophagus.

STOMACH

NORMAL STRUCTURE

The stomach is 'gland with cavity', extending from its junction with lower end of the oesophagus (cardia) to its junction with the duodenum (pylorus). The *lesser curvature* is inner concavity on the right, while the *greater curvature* is the outer convexity on the left side of the stomach.

The stomach has 5 anatomical regions (**Fig. 18.6**):

1. **Cardia** is the oesophagogastric junction and lacks the sphincter.
2. **Fundus** is the portion above the horizontal line drawn across the oesophagogastric junction.
3. **Body** is the middle portion of the stomach between the fundus and the pyloric antrum.
4. **Pyloric antrum** is the distal third of the stomach.
5. **Pylorus** is the junction of distal end of the stomach with the duodenum. It has powerful sphincter muscle.

The mucosal folds in the region of the body and the fundus are loose (*rugae*), while the antral mucosa is somewhat flattened. *Gastric canal* is the relatively fixed portion of the pyloric antrum and the adjoining lesser curvature; it is the site for numerous pathological changes such as gastritis, peptic ulcer and gastric carcinoma.

The stomach receives its blood supply from the left gastric artery and the branches of the hepatic and splenic arteries with widespread anastomoses. Numerous gastric lymphatics which communicate freely with each other are also present. The innervation of the stomach is by the vagi and branches of the sympathetic which are connected with ganglia in the muscular and submucous layers.

Histologically, the wall of the stomach consists of 4 layers—serosa, muscularis, submucosa and mucosa.

1. **Serosa** is derived from the peritoneum which is deficient in the region of lesser and greater curvatures.

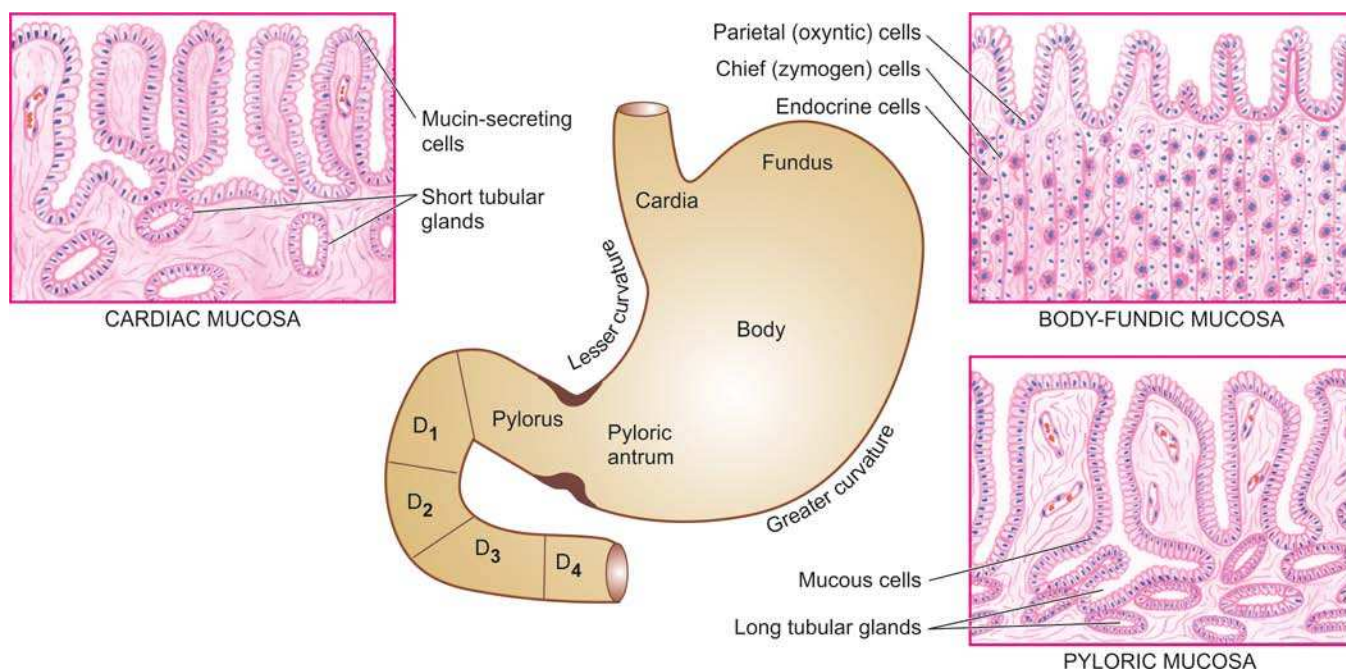

Figure 18.6 Anatomical subdivisions of the stomach correlated with histological appearance of gastric mucosa in different regions. D₁, D₂, D₃ and D₄ are the first to fourth parts of the duodenum.

2. Muscularis consists of 3 layers of smooth muscle fibres—the outer longitudinal, the middle circular and the inner oblique. Nerve plexuses and ganglion cells are present between the longitudinal and circular layers of muscle. The pyloric sphincter is the thickened circular muscle layer at the gastroduodenal junction.

3. Submucosa is a layer of loose fibroconnective tissue binding the mucosa to the muscularis loosely and contains branches of blood vessels, lymphatics and nerve plexuses and ganglion cells.

4. Mucosa consists of 2 layers—superficial and deep. Between the two layers is the lamina propria composed of network of fibrocollagenic tissue with a few lymphocytes, plasma cells, macrophages and eosinophils. The mucosa is externally bounded by muscularis mucosae:

i) Superficial layer: It consists of a single layer of surface epithelium composed of regular, mucin-secreting, tall columnar cells with basal nuclei. There is a rapid turnover of these cells. These dip down at places to form crypts (or pits or foveolae).

a) *Cardiac mucosa* is the transition zone between the oesophageal squamous mucosa and the oxyntic mucosa of the fundus and body with which it gradually merges.

b) *Oxyntic mucosa* lines both gastric fundus and body.

c) *Antral mucosa* lines the pyloric antrum.

ii) Deep layer: It consists of glands that open into the bottom of the crypts. Depending upon the structure, these glands are of 3 types:

a) *Glands of the cardia* are simple tubular or compound tubulo-racemose, lined by mucin secreting cells. A few endocrine cells and occasional parietal and chief cells are also present.

b) *Glands of the body-fundus* are long, tubular and tightly packed which may be coiled or dilated. There are 4 types of cells present in the glands of body-fundic mucosa:

◆ Parietal (Oxyntic) cells—are the most numerous and line the superficial (upper) part of the glands. Parietal cells are triangular in shape, have dark-staining nuclei and eosinophilic cytoplasm. These cells are responsible for production of hydrochloric acid of the gastric juice and the blood group substances.

◆ Chief (Peptic) cells—are the dominant cells in the deeper (lower) parts of the glands. Their basal nuclei are large with prominent nucleoli and the cytoplasm is coarsely granular and basophilic. These cells secrete pepsin of the gastric juice.

◆ Mucin-secreting neck cells—are small and fewer. These cells are present in the region of the narrow neck of the gastric glands i.e. at the junction of the glands with the pits.

◆ Endocrine (Kulchitsky or Enterochromaffin) cells—are widely distributed in the mucosa of all parts of the alimentary tract and are described later (page 544).

c) *Glands of the pylorus* are much longer than the body-fundic glands. These are simple tubular glands which are often coiled. They are lined mainly by small, granular, mucin-secreting cells resembling neck cells and occasional parietal cells but no chief cells. Gastrin-producing G-cells are present predominantly in the region of antropyloric mucosa, with a small number of these cells in the crypts and Brunner's glands of the proximal duodenum.

The secretory products of the gastric mucosa are the *gastric juice* and the *intrinsic factor*, required for absorption

of vitamin B₁₂. Gastric juice consists of hydrochloric acid, pepsin, mucin and electrolytes like Na⁺, K⁺, HCO₃⁻ and Cl⁻. Hydrochloric acid is produced by the parietal (oxyntic) cells by the interaction of Cl⁻ ions of the arterial blood with water and carbon dioxide in the presence of the enzyme, carbonic anhydrase. The degree of gastric activity is correlated with the 'total parietal cell mass'. Injection of histamine can stimulate the production of acid component of the gastric juice, while the pepsin-secreting chief cells do not respond to histamine. Physiologically, the gastric secretions are stimulated by the food itself.

The *control of gastric secretions* chiefly occurs in one of the following 3 ways:

1. Cephalic phase It is stimulated by the sight, smell, taste or even thought of food. A neural reflex is initiated via branches of the vagus nerve that promotes the release of hydrochloric acid, pepsinogen and mucus.

2. Gastric phase It is triggered by the mechanical and chemical stimuli.

i) *Mechanical stimulation* comes from stretching of the wall of the stomach and conveying neural messages to the medulla for gastric secretion.

ii) *Chemical stimulation* It is by digested proteins, amino acids, bile salts and alcohol which act on gastrin-producing G cells. Gastrin then passes into the blood stream and on return to the stomach promotes the release of gastric juice.

3. Intestinal phase It is triggered by the entry of protein-rich food in the small intestine. An intestinal hormone capable of stimulating gastric secretion is probably released into the blood stream.

GASTRIC ANALYSIS

In various diseases of the stomach, the laboratory tests to measure gastric secretions (consisting of gastric acid, pepsin, mucus and intrinsic factor) and serum gastrin are of particular significance (**Table 18.1**).

A. TESTS FOR GASTRIC SECRETIONS

1. Tests for Gastric Acid Secretions

The conventional fractional test meal (FTM) has been totally superseded by newer tests. These tests are based on the principle of measuring basal acid output (BAO) and maximal acid output (MAO) produced by the stomach under the influence of a variety of stimulants, and then comparing the readings of BAO and MAO with the normal values.

Quantitative analysis is performed after an overnight fast. The stomach is intubated and gastric secretion collected in 4 consecutive 15-minute intervals. This unstimulated, one-hour collection after titration for the acid concentration in it, is called BAO, expressed in mEq 1-hour. Subsequently, the stomach is stimulated to secrete maximal acid which is similarly collected for one hour and the acid content called as MAO, expressed in mEq-1-hour. Two highest 15-minute acid outputs are added and then multiplied by 2; this gives the peak acid output (PAO).

The tests for gastric acid secretion are named after the stimulants used for MAO. Some of the commonly used substances are as under:

Table 18.1 Gastric analysis.

| | |
|------|---|
| A. | TESTS FOR GASTRIC SECRETIONS |
| 1. | Tests for gastric acid secretions |
| i) | Histamine stimulation |
| ii) | Histalog stimulation |
| iii) | Pentagastrin (peptavlon) stimulation |
| iv) | Insulin meal (Hollander test) |
| v) | Tubeless analysis |
| 2. | Tests for pepsin Pepsin inhibitors |
| 3. | Tests for mucus Protein content of mucus |
| 4. | Tests for intrinsic factor |
| B. | TESTS FOR GASTRIN |
| 1. | Serum gastrin |
| 2. | Gastrin provocation tests |
| i) | Secretin test |
| ii) | Calcium infusion test |

i) HISTAMINE Histamine was the first standard stimulant used for gastric acid secretion test. Subcutaneous injection of histamine phosphate (0.04 mg/kg body weight) is given with simultaneous administration of antihistaminic agent to prevent the untoward side-effects of histamine.

ii) HISTALOG (BETAZOLE) Subcutaneous injection of histalog (1-15 mg/kg body weight) is preferable over histamine due to fewer undesired side-effects and no need for administration of antihistaminic agent.

iii) PENTAGASTRIN (PEPTAVLON) Pentagastrin is currently the most preferred agent administered in the dose of 6 mg/kg body weight. Its activity is similar to gastrin.

iv) INSULIN MEAL (HOLLANDER TEST) This test is based on the fact that in a state of hypoglycaemia, direct vagal action on the parietal cell mass is responsible for acid secretion. Hypoglycaemia induced by intravenous insulin (15 IU soluble insulin) can be used as a test for evaluating the completeness of vagotomy. No increase in acid production should occur if the vagal resection is complete.

v) TUBELESS ANALYSIS A resin-bound dye, diagnex blue, is given orally. The release of dye by the action of gastric acid and its appearance in the urine indicates the presence of gastric acid. The test can be repeated after giving stimulant of gastric secretion.

SIGNIFICANCE

Normal value for BAO is 1.5-2.0 mEq 1-hour and for MAO is 12-40 mEq 1-hour. In gastric ulcer, the values of BAO and MAO are usually normal or slightly below normal.

Higher values are found in:

- i) duodenal ulcer;
- ii) Zollinger-Ellison syndrome (gastrinoma); and
- iii) anastomotic ulcer.

Low value or achlorhydria are observed in:

- i) pernicious anaemia (atrophic gastritis); and
- ii) achlorhydria in the presence of gastric ulcer is highly suggestive of gastric malignancy.

2. Tests for Pepsin

Pepsin inhibitors are used for analysis of pepsin derived from pepsinogen for research purposes. The levels of pepsin are low in atrophic gastritis.

3. Tests for Mucus

Protein content of gastric mucus is measured, normal value being 1.8 mg/ml. The level is increased in chronic hypertrophic gastritis (Ménétrier's disease).

4. Test for Intrinsic Factor

Intrinsic factor (IF) is essential for vitamin B₁₂ absorption from the small intestine. In its absence, the absorption of vitamin B₁₂ is impaired as occurs in chronic atrophic gastritis and gastric atrophy. *Schilling test* is used for evaluation of patients with suspected pernicious anaemia but can also be used as a diagnostic test for pancreatic insufficiency resulting in impaired absorption of vitamin B₁₂ since gastric R-binder protein is not cleared from intrinsic factor due to reduced pancreatic proteolytic activity. Schilling test is discussed on page 284.

B. TESTS FOR GASTRIN

Circulating gastrin secreted by G-cells present in the antropyloric and proximal duodenal mucosa is normally 0-200 pg/ml. It can be tested by the following methods:

1. Serum Gastrin Levels

Radioimmunoassay (RIA) is the commonly used method of measurement of serum gastrin levels. Normal fasting values are 20-150 pg/ml. The levels are high in:

- i) atrophic gastritis (with low gastric acid secretion);
- ii) Zollinger-Ellison syndrome or gastrinoma (with high gastric acid secretion); and
- iii) following surgery on the stomach.

2. Gastrin Provocation Tests

These tests are used to differentiate between hypergastrinaemia and gastric acid hypersecretion as follows:

i) SECRETIN TEST An intravenous injection of secretin (1 unit/kg body weight) is given. If the serum gastrin levels rise by more than 50% of basal value in 5-15 minutes, it is diagnostic of Zollinger-Ellison syndrome (gastrinoma). This rise does not occur in other conditions.

ii) CALCIUM INFUSION TEST Intravenous infusion of calcium (5 mg/kg per hour) is given for 3 hour. Rise in serum gastrin levels by more than 50% of basal value is diagnostic of Zollinger-Ellison syndrome (gastrinoma).

GIST BOX 18.2 Gastric Analysis

- ☐ Tests for gastric acid secretion are named after the stimulants used for MAO e.g. histamine, histalog, pentagastrin etc.
- ☐ Tests for other gastric secretory products are done for pepsin, mucus and intrinsic factor.
- ☐ Circulating gastrin can be estimated in serum and by provocative tests.

CONGENITAL AND MISCELLANEOUS ACQUIRED CONDITIONS

PANCREATIC HETEROTOPIA

Heterotopic pancreatic tissue may present clinically as a gastric mass or may be an incidental finding. Symptomatic cases may present in newborn or later in life.

Grossly, it is seen as a mass projecting into the gastric lumen, generally in the region of submucosa and less often in the muscular layer. In most cases, the mass is located in the region of antrum or pylorus.

Microscopically, both normal mature pancreatic acinar and ductal tissue are seen. Islets are seen in about a third of cases.

PYLORIC STENOSIS

Hypertrophy and narrowing of the pyloric lumen occurs predominantly in male children as a congenital defect (*infantile pyloric stenosis*). The *adult form* is rarely seen, either as a result of late manifestation of mild congenital anomaly or may be acquired type due to inflammatory fibrosis or invasion by tumours.

ETIOLOGY The exact cause of *congenital (infantile)* pyloric stenosis is not known but it appears to have familial clustering and recessive genetic origin. The *acquired (adult)* pyloric stenosis is related to antral gastritis, and tumours in the region (gastric carcinoma, lymphoma, pancreatic carcinoma).

MORPHOLOGIC FEATURES *Grossly and microscopically*, there is hypertrophy as well as hyperplasia of the circular layer of muscularis in the pyloric sphincter accompanied by mild degree of fibrosis (Fig. 18.7).

CLINICAL FEATURES The patient, usually a first born male infant 3 to 6 weeks old, presents with the following clinical features:

1. Vomiting, which may be projectile and occasionally contains bile or blood.
2. Visible peristalsis, usually noticed from left to right side of the upper abdomen.
3. Palpable lump, better felt after an episode of vomiting.
4. Constipation.
5. Loss of weight.

OTHER ACQUIRED CONDITIONS

BEZOARS Bezoars are foreign bodies in the stomach, usually in patients with mental illness who chew these substances. Some of the common bezoars are as follows:

- i) *Trichobezoars* composed of a ball of hair.
- ii) *Phytobezoars* composed of vegetable fibres, seeds or fruit skin.
- iii) *Trichophytobezoars* combining both hair and vegetable matter.

ACUTE DILATATION Sudden and enormous dilatation of the stomach by gas or fluids due to paralysis of the gastric musculature may occur after abdominal operations, generalised peritonitis, and, in pyloric stenosis.

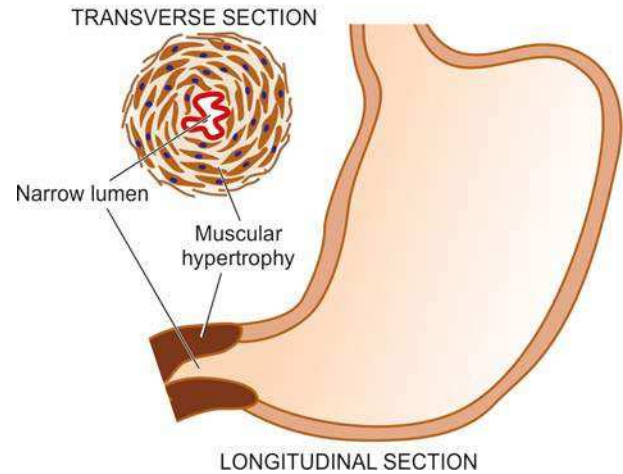

Figure 18.7 Pyloric stenosis, infantile type. Longitudinal and transverse section of the stomach showing hypertrophy of the circular layer of the muscularis in the pyloric sphincter.

GASTRIC RUPTURE The stomach may rupture rarely and prove fatal e.g. due to blunt trauma, external cardiac massage, ingestion of heavy meal or large quantity of liquid intake like beer.

GIST BOX 18.3

Congenital and Miscellaneous Acquired Conditions

- Important congenital anomalies causing obstructive features are pancreatic heterotopia and pyloric stenosis.
- Some uncommon acquired conditions are bezoars, acute dilatation and rupture.

INFLAMMATORY CONDITIONS

The two important inflammatory conditions of the stomach are *gastritis* and *peptic ulcer*. Rarely, stomach may be involved in tuberculosis, sarcoidosis and Crohn's disease.

GASTRITIS

The term 'gastritis' is commonly employed for any clinical condition with upper abdominal discomfort like indigestion or dyspepsia in which the specific clinical signs and radiological abnormalities are absent. The condition is of great importance due to its relationship with peptic ulcer and gastric cancer. Broadly speaking, gastritis may be of 2 types—acute and chronic. Chronic gastritis can further be of various types.

A simple classification of various types of gastritis is presented in **Table 18.2**.

Acute Gastritis

Acute gastritis is a transient acute inflammatory involvement of the stomach, mainly mucosa.

ETIOPATHOGENESIS A variety of etiologic agents have been implicated in the causation of acute gastritis. These are as follows:

1. **Diet and personal habits:**
 - i) Highly spiced food
 - ii) Excessive alcohol consumption

Table 18.2 Classification of gastritis.

| | |
|--|---------------------------|
| A. ACUTE GASTRITIS | |
| 1. Acute <i>H. pylori</i> gastritis | |
| 2. Other acute infective gastritis (bacteria, viruses, fungi, parasites) | |
| 3. Acute non-infective gastritis | |
| B. CHRONIC GASTRITIS | |
| 1. Type A (autoimmune) gastritis | : Body-fundic predominant |
| 2. Type B (<i>H. pylori</i> -related) gastritis | : Antral-predominant |
| 3. Type AB (mixed environmental) gastritis | : Antral-body gastritis |
| 4. Chemical (reflux) gastritis | : Antral-body predominant |
| 5. Miscellaneous forms of gastritis | |

- iii) Malnutrition
- iv) Heavy smoking.

2. Infections:

- i) *Bacterial infections* e.g. *Helicobacter pylori*, diphtheria, salmonellosis, pneumonia, staphylococcal food poisoning.
- ii) *Viral infections* e.g. viral hepatitis, influenza, infectious mononucleosis.

3. Drugs:

Intake of drugs like non-steroidal anti-inflammatory drugs (NSAIDs), aspirin, cortisone, phenylbutazone, indomethacin, preparations of iron, chemotherapeutic agents.

4. Chemical and physical agents:

- i) Intake of corrosive chemicals such as caustic soda, phenol, lysol
- ii) Gastric irradiation
- iii) Freezing.

5. Severe stress:

- i) Emotional factors like shock, anger, resentment etc.
- ii) Extensive burns
- iii) Trauma
- iv) Surgery.

In acute gastritis, the mucosal injury by any of the above agents causes acute inflammation by one of the following mechanisms:

1. *Reduced blood flow*, resulting in mucosal hypoperfusion due to ischaemia.
2. *Increased acid secretion* and its accumulation due to *H. pylori* infection resulting in damage to epithelial barrier.
3. *Decreased production of bicarbonate buffer*.

MORPHOLOGIC FEATURES *Grossly*, the gastric mucosa is oedematous with abundant mucus and haemorrhagic spots.

Microscopically, depending upon the stage, there is variable amount of oedema and infiltration by neutrophils in the lamina propria. In acute haemorrhagic and erosive gastritis, the mucosa is sloughed off and there are haemorrhages on the surface.

Chronic Gastritis

Chronic gastritis is the commonest histological change observed in biopsies from the stomach. The microscopic change is usually poorly correlated to the symptomatology, as the change is observed in about 35% of endoscopically normal mucosal biopsies. The condition occurs more frequently with advancing age; average age for symptomatic chronic gastritis being 45 years which corresponds well with the age incidence of gastric ulcer.

ETIOPATHOGENESIS In the absence of clear etiology of chronic gastritis, a number of etiologic factors have been implicated. All the causative factors of acute gastritis described above may result in chronic gastritis too. Recurrent attacks of acute gastritis may result in chronic gastritis. Some additional causes are as under:

1. *Reflux of duodenal contents into the stomach*, especially in cases which have undergone surgical intervention in the region of pylorus.
2. Infection with *H. pylori* is strongly implicated in the etiology of chronic gastritis and is more common.
3. *Associated disease of the stomach and duodenum*, such as gastric or duodenal ulcer, gastric carcinoma.
4. *Chronic hypochromic anaemia*, especially associated with atrophic gastritis.
5. *Immunological factors* such as autoantibodies to gastric parietal cells in atrophic gastritis and autoantibodies against intrinsic factor.

The *mechanism* of chronic gastric injury by any of the etiologic agents is by cytotoxic effect of the injurious agent on the gastric mucosal epithelium, thus breaking the barrier and then inciting the inflammatory response.

CLASSIFICATION Based on the type of mucosa affected (i.e. cardiac, body, pyloric, antral or transitional), a clinicopathologic classification has been proposed (Table 18.2).

1. Type A gastritis (Autoimmune gastritis) Type A gastritis involves mainly the body-fundic mucosa. It is also called autoimmune gastritis due to the presence of circulating antibodies and is sometimes associated with other autoimmune diseases such as Hashimoto's thyroiditis and Addison's disease. As a result of the antibodies against parietal cells and intrinsic factor, there is depletion of parietal cells and impaired secretion of intrinsic factor. These changes may lead to significant gastric atrophy where intestinal metaplasia may occur, and a small proportion of these patients may develop pernicious anaemia. Due to depletion of gastric acid-producing mucosal area, there is hypo- or achlorhydria, and hyperplasia of gastrin-producing G cells in the antrum resulting in hypergastrinaemia.

2. Type B gastritis (*H. pylori*-related) Type B gastritis mainly involves the region of antral mucosa and is more common. It is also called hypersecretory gastritis due to excessive secretion of acid, commonly due to infection with *H. pylori*. These patients may have associated peptic ulcer. Unlike type A gastritis, this form of gastritis has no autoimmune basis nor has association with other autoimmune diseases.

3. Type AB gastritis (Mixed gastritis, Environmental gastritis, Chronic atrophic gastritis) Type AB gastritis affects the mucosal region of A as well as B types (body-fundic and antral mucosa). This is the most common type of gastritis in

all age groups. It is also called environmental gastritis because a number of unidentified environmental factors have been implicated in its etiopathogenesis. Chronic atrophic gastritis is also used synonymously with type AB gastritis because in advanced stage, there is progression from chronic superficial gastritis to chronic atrophic gastritis, characterised by mucosal atrophy and metaplasia of intestinal or pseudopyloric type.

MORPHOLOGIC FEATURES *Grossly*, the features of all forms of gastritis are inconclusive. The gastric mucosa may be normal, atrophied, or oedematous.

Histologically, criteria for categorisation are based on the following:

- i) Extent of inflammatory changes in the mucosa (i.e. superficial or deep).
- ii) Activity of inflammation (i.e. quiescent or active; acute or chronic).
- iii) Presence of and type of metaplasia (i.e. intestinal or pseudopyloric).

Based on above, following simple morphologic classification has been proposed:

1. Chronic superficial gastritis
2. Chronic atrophic gastritis
3. Gastric atrophy
4. Chronic hypertrophic gastritis (Ménétrier's disease)
5. Uncommon forms of chronic gastritis.

However, *Sydney system* of recording of histologic changes in gastritis is more acceptable since it takes into account following multiple parameters as well:

- i) *Etiology* (*H. pylori*, autoimmune, NSAIDs, infections).
- ii) *Location* (pangastritis, predominant antral, predominant body-fundic).
- iii) *Morphology* (depth of inflammation—superficial or deep, severity of inflammation, type of inflammation, atrophy, metaplasia).
- iv) *Some special features* (e.g. granulomas, eosinophilic gastritis, erosions, necrosis, haemorrhages).

1. CHRONIC SUPERFICIAL GASTRITIS As the name suggests there is an inflammatory infiltrate consisting of plasma cells and lymphocytes in the superficial layer of the gastric mucosa, *but there are no histological changes in the deep layer of mucosa containing gastric glands*. Chronic superficial gastritis may resolve completely or may progress to chronic gastric atrophy.

Its most common etiologic agents *H. pylori*, a spiral-shaped bacteria, was first reported by Warren and Marshall in Australia in 1984 as inhabitant of the acid environment of the stomach causing gastritis. After initial skepticism, numerous workers subsequently verified its association with gastritis and peptic ulcer (Warren and Marshall shared Nobel Prize in medicine in 2005 for their discovery). It is now known that *H. pylori* is causative for almost all active cases of chronic superficial gastritis and about 65% of quiescent cases. The organism is identified on the epithelial layer on the luminal surface and does not invade the mucosa (**Fig. 18.8**). It is not seen on areas with intestinal metaplasia. *H. pylori* gastritis can be diagnosed by the following techniques:

i) *Invasive tests (Endoscopic biopsy)*:

- a) histologic examination combined with special stains for identification of microorganism: Giemsa, Steiner silver or Warthin-Starry stains;
- b) biopsy urease test which is quick and simple but not fully sensitive; and
- c) culture of the microorganism that helps in determining specific antibiotic sensitivity.

ii) *Non-invasive tests*:

- a) serologic tests (Immunoblot, ELISA) which are cheap and convenient but may not be helpful in early follow-up cases; and
- b) ¹⁴C urea breath test.

Although most patients of chronic superficial gastritis due to *H. pylori* remain asymptomatic, they may develop chronic atrophic gastritis, gastric atrophy, peptic ulcer disease.

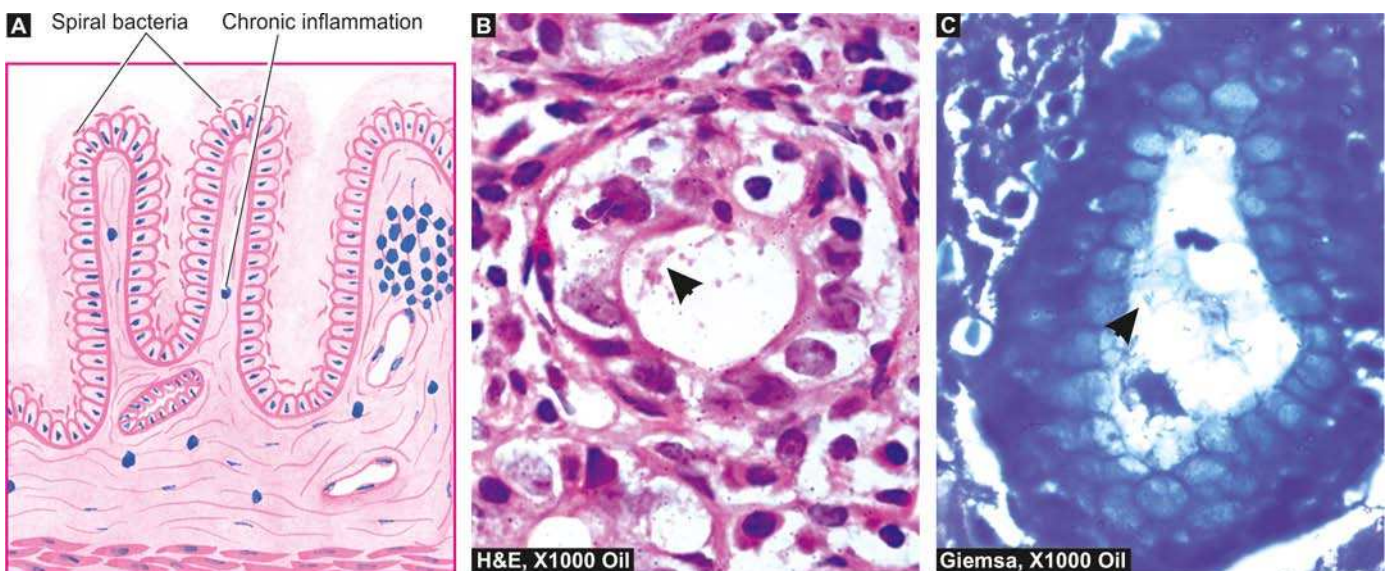

Figure 18.8 Histologic appearance of *H. pylori* chronic gastritis. A, Diagrammatic representation. B, H&E stained section. C, Demonstration of *H. pylori* in Giemsa stain.

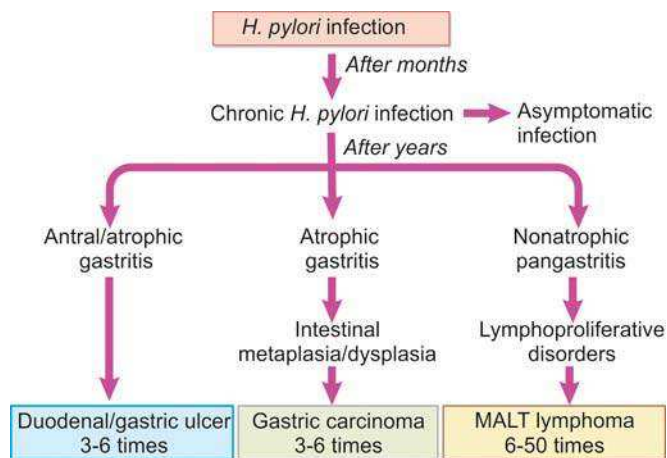

Figure 18.9 Consequences of long-term *H. pylori* gastritis.

H. pylori infection is now considered an independent risk factor for gastric cancer: 3-6 fold increased risk for gastric adenocarcinoma and 6-50 times risk of MALT lymphoma (Fig. 18.9).

2. CHRONIC ATROPHIC GASTRITIS In this stage, *there is inflammatory cell infiltrate in the deeper layer of the mucosa and atrophy of the epithelial elements including destruction of the glands.* Two types of metaplasia are commonly associated with atrophic gastritis:

i) Intestinal metaplasia Intestinal metaplasia is more common and involves antral mucosa more frequently. Characteristic histologic feature is the presence of intestinal type mucus-goblet cells; Paneth cells and endocrine cells may also be present. Parietal cells are very few or absent (Fig. 18.10). Intestinal metaplasia, focal or extensive, in atrophic gastritis is significant because its incidence is high in populations having high prevalence rate of gastric cancer like in Japan. However, areas of intestinal metaplasia are not colonised by *H. pylori*.

ii) Pseudopyloric metaplasia It involves the body glands which are replaced by proliferated mucus neck cells, conforming in appearance to normal pyloric glands. Its significance is not known.

3. GASTRIC ATROPHY In this, there is thinning of the gastric mucosa with loss of glands but no inflammation though lymphoid aggregates may be present.

4. CHRONIC HYPERTROPHIC GASTRITIS (MÉNÉTRIER'S DISEASE) This is an uncommon condition characterised pathologically by enormous thickening of gastric rugal folds resembling cerebral convolutions, affecting mainly the region of fundic-body mucosa and characteristically sparing antral mucosa. The patients present with dyspepsia, haematemesis, melaena or protein-losing enteropathy.

Histologically, the gastric pits are elongated and are tortuous. The mucosa is markedly thickened and parts of muscularis mucosae may extend into the thickened folds. Epithelium-lined cysts are commonly seen in the glandular layer. Inflammatory infiltrate is usually mild but lymphoid follicles may be present. The condition is considered significant in view of the risk of developing cancer.

5. MISCELLANEOUS FORMS OF CHRONIC GASTRITIS

A few other types of gastritis which do not fit into the description of the types of gastritis described above are as under:

i) Eosinophilic gastritis This condition is characterised by diffuse thickening of the pyloric antrum due to oedema and extensive infiltration by eosinophils in all the layers of the wall of antrum. Eosinophilic gastritis probably has an allergic basis.

ii) Chronic follicular gastritis This is a variant of chronic atrophic gastritis in which numerous lymphoid follicles are present in the mucosa and submucosa of the stomach.

iii) Haemorrhagic (Erosive) gastritis In this condition, there are superficial erosions and mucosal haemorrhages, usually following severe haematemesis. The causes for such erosions and haemorrhages are duodenal-gastric reflux, administration of non-steroidal anti-inflammatory drugs (NSAIDs), portal hypertension.

iv) Granulomatous gastritis Rarely, granulomas may be present in the gastric mucosa such as in tuberculosis, sarcoidosis, Crohn's disease, syphilis, various mycoses, and as a reaction to endogenous substance or foreign material.

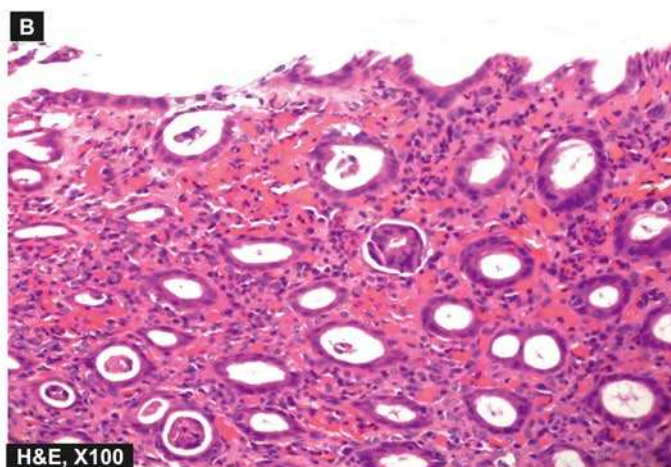

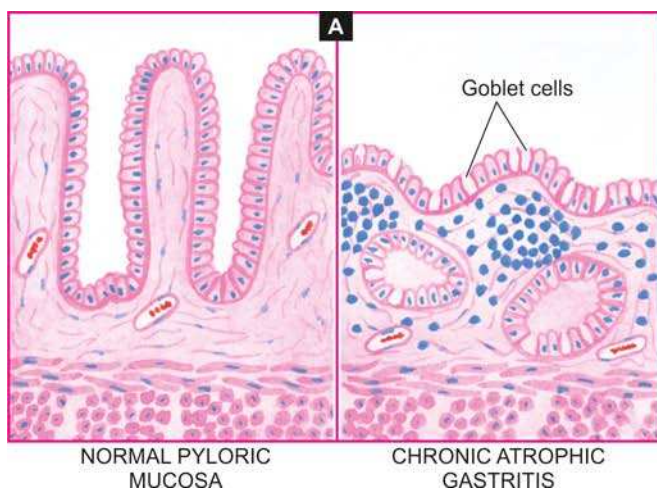

Figure 18.10 A, Chronic atrophic gastritis (right) contrasted with normal pyloric mucosa (left). There is marked gastric atrophy with disappearance of gastric glands and appearance of goblet cells (intestinal metaplasia). B, Photomicrograph showing chronic atrophic gastritis with intestinal metaplasia.

GIST BOX 18.4 Gastritis

- ▣ Gastritis may be acute or chronic.
- ▣ Acute gastritis is caused by a variety of injurious agents in diet, chemicals, certain drugs, chemicals and physical agents and severe burns.
- ▣ Chronic gastritis may be due to reflux, *H. pylori* infection, or due to other diseases of stomach and duodenum.
- ▣ Based on microscopy, chronic gastritis is classified into superficial, atrophic, hypertrophic and specific types.

some inflammatory reaction depending upon the duration of the ulcers. These ulcers commonly heal by complete re-epithelialisation without leaving any scars. Complications such as haemorrhage and perforation may occur.

PEPTIC ULCERS

Peptic ulcers are the areas of degeneration and necrosis of gastrointestinal mucosa exposed to acid-peptic secretions. Though they can occur at any level of the alimentary tract that is exposed to hydrochloric acid and pepsin, they occur most commonly (98-99%) in either the duodenum or the stomach in the ratio of 4:1. Each of the two main types may be acute or chronic.

Acute Peptic (Stress) Ulcers

Acute peptic ulcers or stress ulcers are multiple, small mucosal erosions, seen most commonly in the stomach but occasionally involving the duodenum.

ETIOLOGY These ulcers occur following severe stress. The causes are as follows:

1. *Psychological stress*
2. *Physiological stress* as in the following:
 - i) Shock
 - ii) Severe trauma
 - iii) Septicaemia
 - iv) Extensive burns (Curling's ulcers in the posterior aspect of the first part of the duodenum).
 - v) Intracranial lesions (Cushing's ulcers developing from hyperacidity following excessive vagal stimulation).
 - vi) Drug intake (e.g. aspirin, steroids, butazolidine, indomethacin).
 - vii) Local irritants (e.g. alcohol, smoking, coffee etc).

PATHOGENESIS It is not clear how the mucosal erosions occur in stress ulcers because actual hypersecretion of gastric acid is demonstrable in only Cushing's ulcers occurring from intracranial conditions such as due to brain trauma, intracranial surgery and brain tumours. In all other etiologic factors, gastric acid secretion is normal or below normal. In these conditions, the possible hypotheses for genesis of stress ulcers are as under:

1. Ischaemic hypoxic injury to the mucosal cells.
2. Depletion of the gastric mucus 'barrier' rendering the mucosa susceptible to attack by acid-peptic secretions.

MORPHOLOGIC FEATURES *Grossly*, acute stress ulcers are multiple (more than three ulcers in 75% of cases). They are more common anywhere in the stomach, followed in decreasing frequency by occurrence in the first part of duodenum. They may be oval or circular in shape, usually less than 1 cm in diameter.

Microscopically, the stress ulcers are shallow and do not invade the muscular layer. The margins and base may show

Chronic Peptic Ulcers (Gastric and Duodenal Ulcers)

If not specified, chronic peptic ulcers would mean gastric and duodenal ulcers, the two major forms of 'peptic ulcer disease' of the upper GI tract in which the acid-pepsin secretions are implicated in their pathogenesis. Peptic ulcers are common in the present-day life of the industrialised and civilised world.

Gastric and duodenal ulcers represent two distinct diseases as far as their etiology, pathogenesis and clinical features are concerned. However, morphological findings in both are similar and quite diagnostic. The features of gastric and duodenal peptic ulcers are described together below while their contrasting features are presented in **Table 18.3**.

INCIDENCE Peptic ulcers are more frequent in middle-aged adults. The peak incidence for duodenal ulcer is 5th decade, while for gastric ulcer it is a decade later (6th decade). Duodenal as well as gastric ulcers are more common in males than in females. Duodenal ulcer is almost four times more common than gastric ulcer; the overall incidence of gastroduodenal ulcers being approximately 10% of the male population.

ETIOLOGY The immediate cause of peptic ulcer disease is disturbance in normal protective mucosal 'barrier' by acid-pepsin, resulting in digestion of the mucosa. However, in contrast to duodenal ulcers, *the patients of gastric ulcer have low-to-normal gastric acid secretions, though true achlorhydria in response to stimulants never occurs in benign gastric ulcer*. Besides, 10-20% patients of gastric ulcer may have coexistent duodenal ulcer as well. Thus, the etiology of peptic ulcers possibly may not be explained on the basis of a single factor but is multifactorial. These factors are discussed below but the first two—*H. pylori* gastritis and NSAIDs-induced injury are considered most important.

1. Helicobacter pylori gastritis About 15-20% cases infected with *H. pylori* in the antrum develop duodenal ulcer in their life time while gastric colonisation by *H. pylori* never develops ulceration and remain asymptomatic. *H. pylori* can be identified in mucosal samples by histologic examination, culture and serology as discussed on page 531.

2. NSAIDs-induced mucosal injury Non-steroidal anti-inflammatory drugs are most commonly used medications in the developed countries and are responsible for direct toxicity, endothelial damage and epithelial injury to both gastric as well as duodenal mucosa.

3. Acid-pepsin secretions There is conclusive evidence that some level of acid-pepsin secretion is essential for the development of duodenal as well as gastric ulcer. Peptic ulcers never occur in association with pernicious anaemia in which there are no acid and pepsin-secreting parietal and chief cells respectively.

4. Gastritis Some degree of gastritis is always present in the region of gastric ulcer, though it is not clear whether it is the cause or the effect of ulcer. Besides, the population distribution pattern of gastric ulcer is similar to that of chronic gastritis.

Table 18.3 Distinguishing features of two major forms of peptic ulcers.

| FEATURE | DUODENAL ULCER | GASTRIC ULCER |
|-----------------------|---|---|
| 1. Incidence | i) Four times more common than gastric ulcers ii) Usual age 25-50 years iii) More common in males than in females (4:1) | Less common than duodenal ulcers Usually beyond 6th decade More common in males than in females (3.5:1) |
| 2. Etiology | Most commonly as a result of <i>H. pylori</i> infection Other factors—hypersecretion of acid-pepsin, association with alcoholic cirrhosis, tobacco, hyperparathyroidism, chronic pancreatitis, blood group O, genetic factors | Gastric colonisation with <i>H. pylori</i> asymptomatic but higher chances of development of duodenal ulcer. Disruption of mucus barrier most important factor. Association with gastritis, bile reflux, drugs, alcohol, tobacco |
| 3. Pathogenesis | i) Mucosal digestion from hyperacidity most significant factor ii) Protective gastric mucus barrier may be damaged | Usually normal-to-low acid levels; hyperacidity if present is due to high serum gastrin Damage to mucus barrier significant factor |
| 4. Pathologic changes | i) Most common in the first part of duodenum ii) Often solitary, 1-2.5 cm in size, round to oval, punched out iii) Histologically, composed of 4 layers—necrotic, superficial exudative, granulation tissue and cicatrisation | Most common along the lesser curvature and pyloric antrum Grossly similar to duodenal ulcer Histologically, indistinguishable from duodenal ulcer |
| 5. Complications | Commonly haemorrhage, perforation, sometimes obstruction; malignant transformation never occurs | Perforation, haemorrhage and at times obstruction; malignant transformation in less than 1% cases |
| 6. Clinical features | i) Pain-food-relief pattern ii) Night pain common iii) No vomiting iv) Melaena more common than haematemesis v) No loss of weight vi) No particular choice of diet vii) Deep tenderness in the right hypochondrium viii) Marked seasonal variation ix) Occurs more commonly in people at greater stress | Food-pain pattern No night pain Vomiting common Haematemesis more common Significant loss of weight Patients choose bland diet devoid of fried foods, curries etc. Deep tenderness in the midline in epigastrium No seasonal variation More often in labouring groups |

5. Other local irritants Pyloric antrum and lesser curvature of the stomach are the sites most exposed for longer periods to local irritants and thus are the common sites for occurrence of gastric ulcers. Some of the local irritating substances implicated in the etiology of peptic ulcers are heavily spiced foods, alcohol, cigarette smoking, unbuffered aspirin.

6. Dietary factors Nutritional deficiencies have been regarded as etiologic factors in peptic ulcers e.g. occurrence of gastric ulcer in poor socioeconomic strata, higher incidence of duodenal ulcer in parts of South India. However, malnutrition does not appear to have any causative role in peptic ulceration in European countries and the U.S.

7. Psychological factors Psychological stress, anxiety, fatigue and ulcer-type personality may exacerbate as well as predispose to peptic ulcer disease.

8. Genetic factors People with blood group O appear to be more prone to develop peptic ulcers than those with other blood groups. Genetic influences appear to have greater role in duodenal ulcers as evidenced by their occurrence in families, monozygotic twins and association with HLA-B5 antigen.

9. Hormonal factors Secretion of certain hormones by tumours is associated with peptic ulceration e.g. elaboration of gastrin by islet-cell tumour in Zollinger-Ellison syndrome, endocrine secretions in hyperplasia and adenomas of parathyroid glands, adrenal cortex and anterior pituitary.

10. Miscellaneous Duodenal ulcers have been observed to occur in association with various other conditions such as alcoholic cirrhosis, chronic renal failure, hyperparathyroidism, chronic obstructive pulmonary disease, and chronic pancreatitis.

PATHOGENESIS There are distinct differences in the pathogenetic mechanisms involved in duodenal and gastric ulcers as under:

Duodenal ulcer There is conclusive evidence to support the role of high acid-pepsin secretions in the causation of duodenal ulcers. Besides this, a few other noteworthy features in the pathogenesis of duodenal ulcers are as follows:

1. There is generally *hypersecretion of gastric acid* into the fasting stomach at night which takes place under the influence

of vagal stimulation. There is high basal as well as maximal acid output (BAO and MAO) in response to various stimuli.

2. Patients of duodenal ulcer have *rapid emptying* of the stomach so that the food which normally buffers and neutralises the gastric acid, passes down into the small intestine, leaving the duodenal mucosa exposed to the aggressive action of gastric acid.

3. *Helicobacter gastritis* caused by *H. pylori* is seen in 95-100% cases of duodenal ulcers. The underlying mechanisms are as under:

i) Gastric mucosal defense is broken by bacterial elaboration of urease, protease, catalase and phospholipase.

ii) *Host factors*: *H. pylori*-infected mucosal epithelium releases *proinflammatory cytokines* such as IL-1, IL-6, IL-8 and tumour necrosis factor- α , all of which incite intense inflammatory reaction.

iii) *Bacterial factors*: Epithelial injury is also induced by cytotoxin-associated gene protein (*CagA*), while vacuolating cytotoxin (*VacA*) induces elaboration of cytokines.

Gastric ulcer The pathogenesis of gastric ulcer is mainly explained on the basis of impaired gastric mucosal defenses against acid-pepsin secretions. Some other features in the pathogenesis of gastric ulcer are as follows:

1. Hyperacidity may occur in gastric ulcer due to *increased serum gastrin* levels in response to ingested food in an atonic stomach.

2. However, many patients of gastric ulcer have low-to-normal gastric acid levels. Ulcerogenesis in such patients is explained on the basis of damaging influence of *other factors* such as gastritis, bile reflux, cigarette smoke etc.

3. The normally protective *gastric mucus 'barrier'* against acid-pepsin is deranged in gastric ulcer. There is depletion in the quantity as well as quality of gastric mucus. One of the mechanisms for its depletion is colonisation of the gastric mucosa by *H. pylori* seen in 75-80% patients of gastric ulcer.

MORPHOLOGIC FEATURES Gross and microscopic changes in gastric and duodenal ulcers are similar and quite characteristic. *Gastric ulcers* are found predominantly along the lesser curvature in the region of pyloric antrum, more

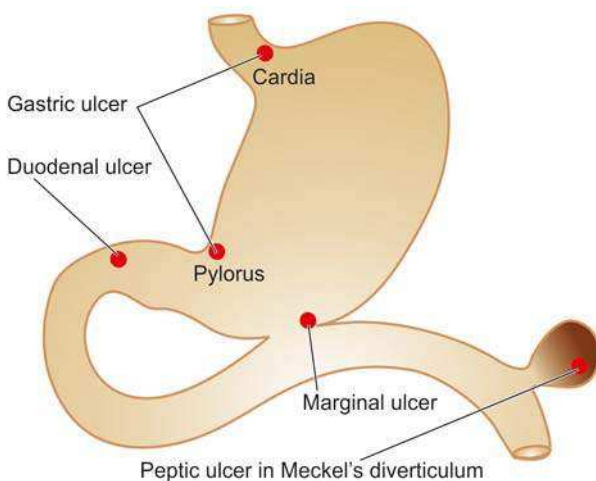

Figure 18.11 Distribution of peptic ulcers.

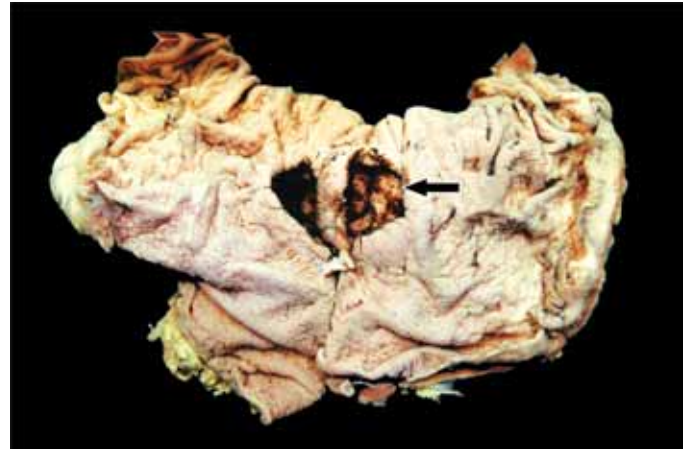

Figure 18.12 Benign chronic peptic ulcer. Partial gastrectomy specimen showing a punched out round to oval ulcer on the mucosa, about 1 cm in diameter (arrow) and penetrating into muscularis layer.

commonly on the posterior than the anterior wall. Most *duodenal ulcers* are found in the first part of the duodenum, usually immediate post-pyloric, more commonly on the anterior than the posterior wall. Uncommon locations include ulcer in the cardia, marginal ulcer and in the Meckel's diverticulum (**Fig. 18.11**).

Grossly, typical peptic ulcers are commonly solitary (80%), small (1-2.5 cm in diameter), round to oval and characteristically 'punched out'. Benign ulcers usually have flat margins in level with the surrounding mucosa. The mucosal folds converge towards the ulcer. The ulcers may vary in depth from being superficial (confined to mucosa) to deep ulcers (penetrating into the muscular layer) (**Fig. 18.12**). In about 10-20% of cases, gastric and duodenal ulcers are coexistent. Vast majority of the peptic ulcers are benign. *Chronic duodenal ulcer never turns malignant*, while chronic gastric ulcer may develop carcinoma in less than 1% of cases. Malignant gastric ulcers are larger, bowl-shaped with elevated and indurated mucosa at the margin (**Fig. 18.13**).

Microscopically, chronic peptic ulcers have 4 histological zones. From within outside, these are as under (**Fig. 18.14**): 1. *Necrotic zone*—lies in the floor of the ulcer and is composed of fibrinous exudate containing necrotic debris and a few leucocytes.

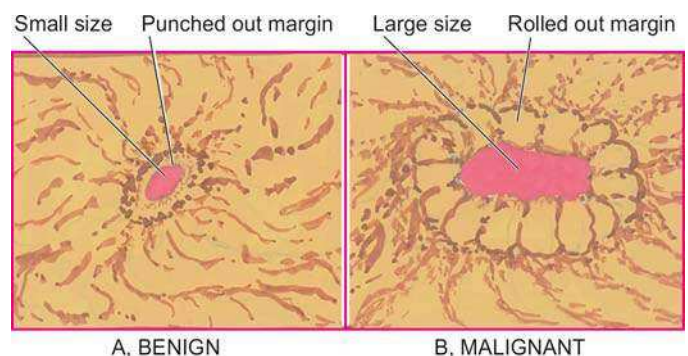

Figure 18.13 Chronic gastric ulcer (A) contrasted with malignant gastric ulcer (B).

2. **Superficial exudative zone**—lies underneath the necrotic zone. The tissue elements here show coagulative necrosis giving eosinophilic, smudgy appearance with nuclear debris.
3. **Granulation tissue zone**—is seen merging into the necrotic zone. It is composed of nonspecific inflammatory infiltrate and proliferating capillaries.
4. **Zone of cicatrisation**—is seen merging into thick layer of granulation tissue. It is composed of dense fibrocollagenic scar tissue over which granulation tissue rests. Thrombosed or sclerotic arteries may cross the ulcer which on erosion may result in haemorrhage.

COMPLICATIONS Acute and subacute peptic ulcers usually heal without leaving any visible scar. However, healing of chronic, larger and deeper ulcers may result in complications. These are as follows:

1. **Obstruction** Development of fibrous scar at or near the pylorus results in pyloric stenosis. Healed duodenal ulcers cause duodenal stenosis. Healed gastric ulcers along the lesser curvatures may produce 'hourglass' deformity due to fibrosis and contraction.
2. **Haemorrhage** Minor bleeding by erosion of small blood vessels in the base of an ulcer occurs in all the ulcers and can be detected by testing the stool for occult blood. Chronic blood loss may result in iron deficiency anaemia. Severe bleeding may cause 'coffee ground' vomitus or melaena. A penetrating chronic ulcer may erode a major artery (e.g. left gastric, gastroduodenal or splenic artery) and cause a massive and severe haematemesis and sometimes death.
3. **Perforation** A perforated peptic ulcer is an acute abdominal emergency. Perforation occurs more commonly in chronic duodenal ulcers than chronic gastric ulcers. Following sequelae may result:
 - i) On perforation the contents escape into the lesser sac or into the peritoneal cavity, causing *acute peritonitis*.
 - ii) Air escapes from the stomach and lies between the liver and the diaphragm giving the characteristic radiological appearance of *air under the diaphragm*.
 - iii) *Subphrenic abscess* between the liver and the diaphragm may develop due to infection.
 - iv) Perforation may extend to involve the *adjacent organs* e.g. the liver and pancreas.

4. **Malignant transformation** The dictum '*cancers ulcerate but ulcers rarely cancerate*' holds true for most peptic ulcers. A chronic duodenal ulcer never turns malignant, while less than 1% of chronic gastric ulcers may transform into carcinoma.

CLINICAL FEATURES Peptic ulcers are remitting and relapsing lesions. Their chronic and recurrent behaviour is summed up the saying: '*once a peptic ulcer patient, always a peptic ulcer patient*.' The two major forms of chronic peptic ulcers show variations in clinical features which are as follows:

1. **Age** The peak incidence of duodenal ulcer is in 5th decade while that for gastric ulcer is a decade later.
2. **People at risk** Duodenal ulcer occurs more commonly in people faced with more stress and strain of life (e.g. executives, leaders), while gastric ulcer is seen more often in labouring groups.
3. **Periodicity** The attacks in gastric ulcers last from 2-6 weeks, with interval of freedom from 1-6 months. The attacks of duodenal ulcer, are classically worsened by '*work, worry and weather*.'
4. **Pain** In gastric ulcer, epigastric pain occurs immediately or within 2 hours after food and never occurs at night. In duodenal ulcer, pain is severe, occurs late at night ('hunger pain') and is usually relieved by food.
5. **Vomiting** Vomiting which relieves the pain is a conspicuous feature in patients of gastric ulcer. Duodenal ulcer patients rarely have vomiting but instead get heart-burn (retrosternal pain) and 'water brash' (burning fluid into the mouth).

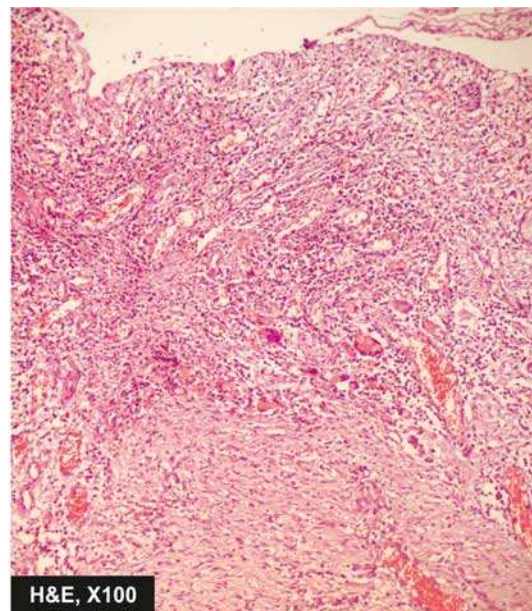

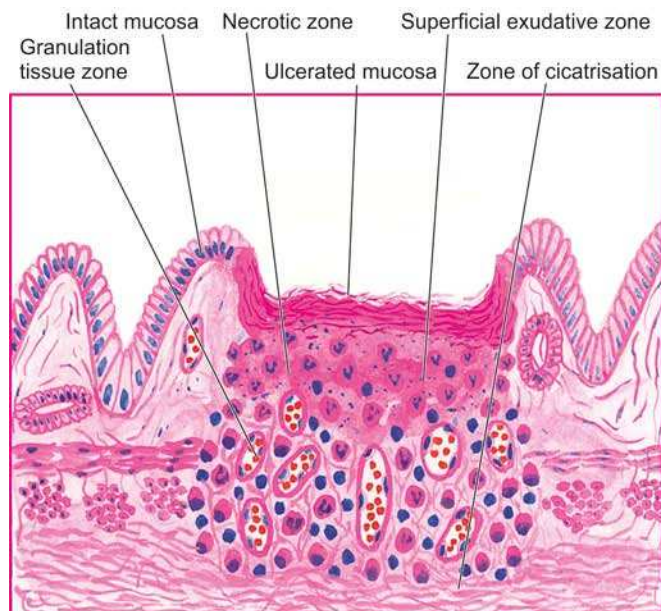

Figure 18.14 Chronic peptic ulcer. Histologic zones of the ulcer are illustrated in the diagram. The photomicrograph on right shows necrotic debris, ulceration and inflammation on the mucosal surface.

6. Haematemesis and melaena Haematemesis and melaena occur in gastric ulcers in the ratio of 60:40, while in duodenal ulcers in the ratio of 40:60. Both may occur together more commonly in duodenal ulcer than in gastric ulcer patients.

7. Appetite The gastric ulcer patients, though have good appetite but are afraid to eat, while duodenal ulcer patients have very good appetite.

8. Diet Patients of gastric ulcer commonly get used to a bland diet consisting of milk, eggs etc and avoid taking fried foods, curries and heavily spiced foods. In contrast, duodenal ulcer patients usually take all kinds of diets.

9. Weight Loss of weight is a common finding in gastric ulcer patients while patients of duodenal ulcer tend to gain weight due to frequent ingestion of milk to avoid pain.

10. Deep tenderness Deep tenderness is demonstrable in both types of peptic ulcers. In the case of gastric ulcer it is in the midline of the epigastrium, while in the duodenal ulcer it is in the right hypochondrium.

HAEMATEMESIS AND MELAENA OF GASTRIC ORIGIN

In continuity with the discussion on peptic ulcers which are the commonest cause of haematemesis and melaena, it is worthwhile listing various causes of haematemesis of gastric origin (causes of haematemesis of oesophageal origin are already given on page 522).

- i) Chronic peptic ulcers (gastric as well as duodenal)
- ii) Acute peptic ulcers (stress ulcers)
- iii) Multiple gastric and duodenal erosions
- iv) Carcinoma of the stomach
- v) Peptic ulcer in Meckel's diverticulum
- vi) Mallory-Weiss syndrome
- vii) Anaemias
- viii) Purpuras
- ix) Haemophilia.

GIST BOX 18.5 Peptic Ulcers

- ▣ Peptic ulcers are the areas of degeneration and necrosis in the duodenum or the stomach. Each of the two main types may be acute or chronic.
- ▣ The immediate cause of peptic ulcer disease is disturbance in normal protective mucosal 'barrier' by acid-pepsin.
- ▣ Etiology of peptic ulcers is multifactorial but *H. pylori* gastritis and NSAIDs-induced injury are two most important factors.
- ▣ In the pathogenesis of duodenal ulcers, there is role of high acid-pepsin secretions, while in gastric ulcers gastric mucosal defenses against acid-pepsin secretions are impaired.
- ▣ Typical peptic ulcers are commonly solitary, small, round to oval and punched out.
- ▣ Microscopically, chronic peptic ulcers have 4 histological zones: necrotic zone, superficial exudative, granulation tissue, and zone of cicatrization.
- ▣ Important complications of peptic ulcers are obstruction, haemorrhage, perforation and, rarely malignant change.

TUMOURS AND TUMOUR-LIKE LESIONS

The various types of tumour-like lesions (polyps) and benign and malignant tumours of the stomach are given in **Table 18.4**.

A. TUMOUR-LIKE LESIONS (POLYPS)

Hyperplastic (Inflammatory) Polyps

Hyperplastic or inflammatory polyps are regenerative, non-neoplastic lesions which are the most common type (90%). They may be single or multiple and are more often located in the pyloric antrum.

Grossly, the lesions may be sessile or pedunculated, 1 cm or larger in size, smooth and soft. The surface may be ulcerated or haemorrhagic.

Microscopically, they are composed of irregular hyperplastic glands, which may show cystic change. The lining epithelium is mostly superficial gastric type but antral glands, chief cells and parietal cells may be present. These lesions do not have cellular atypia and do not have malignant potential.

Hamartomatous Polyps

Hamartomatous polyps are not true neoplasms but are malformations. They are of various types such as gastric polyps of the Peutz-Jeghers syndrome (page 566), juvenile polyp, pancreatic heterotopia, heterotopia of Brunner's glands and inflammatory fibroid polyps (eosinophilic granulomatous polyps).

B. BENIGN TUMOURS

Adenomas (Adenomatous or Neoplastic Polyps)

Adenomas, also, referred to as adenomatous or neoplastic polyps, are true benign epithelial neoplasms and are much rare in the stomach than in the large intestine. They are also found more often in the region of pyloric antrum. They are

Table 18.4 Gastric tumours and tumour-like lesions.

| | |
|----|--|
| A. | TUMOUR-LIKE LESIONS (POLYPS) |
| | 1. Hyperplastic (inflammatory) polyps |
| | 2. Hamartomatous polyps |
| B. | BENIGN TUMOURS |
| | 1. <i>Epithelial</i> |
| | Adenomas (adenomatous or neoplastic polyps) |
| | 2. <i>Non-epithelial</i> |
| | Gastrointestinal spindle cell (stromal) tumours (GIST) |
| C. | MALIGNANT TUMOURS |
| | 1. <i>Epithelial (90%)</i> |
| | (i) Adenocarcinoma |
| | (ii) Others |
| | 2. <i>Non-epithelial (2%)</i> |
| | (i) Leiomyosarcoma |
| | (ii) Leiomyoblastoma |
| | (epithelioid leiomyoma) |
| | 3. <i>Carcinoid tumour (3%)</i> |
| | 4. <i>Lymphoma (4%)</i> |

commonly associated with atrophic gastritis and pernicious anaemia. Morphologically, adenomatous polyps of the stomach resemble their counterparts in the large bowel and are described on page 568.

Stromal Tumours

Stomach may be the site for occurrence of various uncommon benign tumours of stromal cell origin e.g. leiomyomas (being the most common); others are neurofibromas, schwannomas and lipomas. They are usually firm, circumscribed nodules, less than 4 cm in size and appear as submucosal nodules. They resemble in gross and microscopic appearance with their counterparts in other parts of the body.

The term *gastrointestinal stromal tumours (GISTs)* is used for a group of uncommon benign tumours composed of spindle cells or stromal cells but lacking the true phenotypic features of smooth muscle cells, neural cells or Schwann cells. They are uncommon but as compared to other sites in the GIT, are most common in the stomach. Their behaviour is generally benign but may be recurrent, aggressive or even metastasis may occur.

C. MALIGNANT TUMOURS

Gastric Carcinoma

INCIDENCE Carcinoma of the stomach comprises more than 90% of all gastric malignancies and is the leading cause of cancer-related deaths in countries where its incidence is high. The highest incidence is between 4th to 6th decades of life and is twice more common in men than in women.

ETIOLOGY A number of etiologic factors have been implicated in causation of gastric cancer. These are as under:

1. *H. pylori* infection *H. pylori* infection of the stomach is an important risk factor for the development of gastric cancer. Epidemiologic studies throughout world have shown that a seropositivity with *H. pylori* is associated with 3 to 6 times higher risk of development of gastric cancer. It may be mentioned here that similar association of *H. pylori* infection exists with gastric lymphomas (MALT type) as well.

2. Dietary factors Epidemiological studies suggest that dietary factors are most significant in the etiology of gastric cancer. The evidences in support of this are multifold:

- Occurrence of gastric cancer in the region of gastric canal (i.e. along the lesser curvature and the pyloric antrum) where irritating foods exert their maximum effect.
- Populations consuming certain foodstuffs have high risk of developing gastric cancer e.g. ingestion of smoked foods, high intake of salt, pickled raw vegetables, high intake of carcinogens as nitrates in foods and drinking water, nitrites as preservatives for certain meats etc. However, intake of green leafy vegetables, citrus fruits and animal fats has been reported to have protective role in gastric cancer.
- Tobacco smoke, tobacco juice and consumption of alcohol have all been shown to have carcinogenic effect on gastric mucosa.

3. Geographical factors There are geographic variations in the incidence of gastric cancer. Japan, Chile and Italy have the highest recorded death rate from gastric cancer, while the incidence is considerably low in the US, UK and Canada. The higher incidence in certain geographic regions is the result

of environmental influences as observed from the finding of incidence of gastric cancer in the next generation of Japanese immigrants to the US which is comparable to that of native Americans.

4. Racial factors Within the country, different ethnic groups may have variations in incidence of gastric cancer e.g. incidence is higher in Blacks, American Indians, Chinese in Indonesia, North Wales than other parts of Wales.

5. Genetic factors Genetic influences have some role in the etiology of gastric cancer. Not more than 4% of patients of gastric cancer have a family history of this disease. Individuals with blood group A have higher tendency to develop gastric cancer (Recall that the peptic ulcer is more common in individuals with blood group O). A germ line mutation in E-cadherin gene inherited as an autosomal dominant pattern has been linked to higher incidence of occult gastric cancer in younger individuals.

6. Pre-malignant changes in the gastric mucosa There are some conditions of gastric mucosa which have increased risk to development of gastric cancer:

- Hypo- or achlorhydria in atrophic gastritis of gastric mucosa with intestinal metaplasia.
- Adenomatous (neoplastic) polyps of the stomach.
- Chronic gastric ulcer (ulcer-cancer), and its association with achlorhydria.
- Stump carcinoma in patients who have undergone partial gastrectomy.

MORPHOLOGIC FEATURES Gastric carcinoma is most commonly located in the region of gastric canal (prepyloric region) formed by lesser curvature, pylorus and antrum. Other less common locations are the body, cardia and fundus (Fig. 18.15).

Pathogenetically, a sequential evolution of all gastric carcinomas from an initial stage of *in situ* carcinoma confined to mucosal layers called early gastric carcinoma (EGC) has been found. EGC eventually penetrates the muscularis or beyond, resulting in advanced gastric

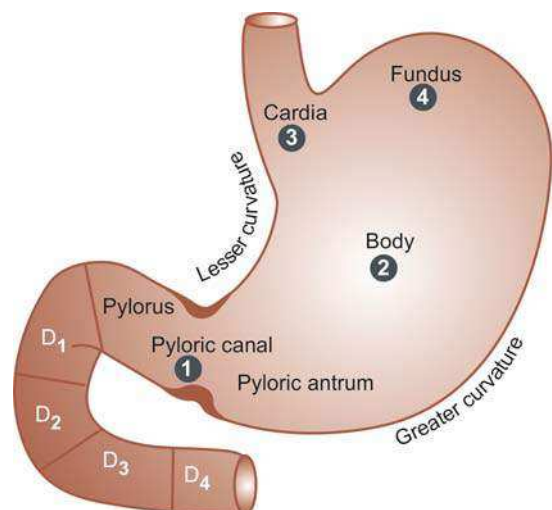

Figure 18.15 Distribution of gastric carcinoma in the anatomical subdivisions of the stomach. The serial numbers in the figure indicate the order of frequency of occurrence of gastric cancer.

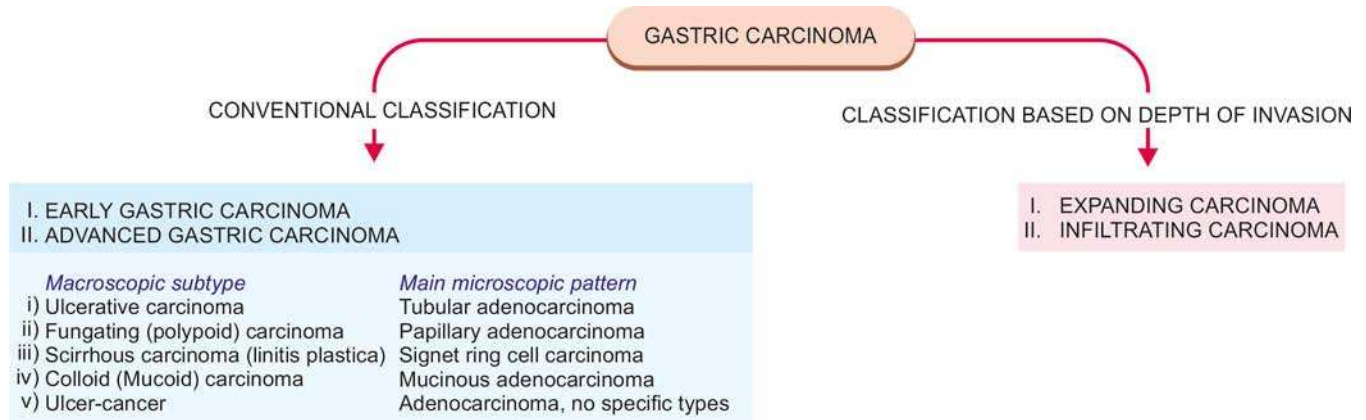

Figure 18.16 Classifications of gastric carcinomas. A, Conventional classification, showing correlation of the macroscopic subtypes with the main histological patterns. B, Classification based on the depth of invasion by the tumour.

carcinoma. Accordingly, gastric carcinomas are broadly classified into 2 main groups:

- I. *Early gastric carcinoma (EGC).*
- II. *Advanced gastric carcinoma*, which has 5 further major gross subtypes:
 - i) Ulcerative carcinoma
 - ii) Fungating (Polypoid) carcinoma
 - iii) Scirrhus carcinoma (Linitis plastica)
 - iv) Colloid (Mucoïd) carcinoma
 - v) Ulcer-cancer

In addition to the above classification, gastric carcinomas have been classified, *on the basis of extent of invasion*, into 2 groups:

- I. *Expanding (formerly intestinal type) carcinomas* that grow laterally by an invasive margin. The tumour cells are in the form of cohesive clusters.
- II. *Infiltrating (formerly diffuse type) carcinomas* have poorly-defined invasive border. The tumour cells are loose and invade singly or in small group.

These classifications are summarised in **Fig. 18.16** and comparative morphology of various types is shown diagrammatically in **Fig. 18.18**.

I. EARLY GASTRIC CARCINOMA (EGC) (Fig. 18.18,A)

EGC is the term used to describe cancer limited to the mucosa and submucosa. The diagnosis of this condition has been made possible by extensive work on histogenesis

of gastric cancer by Japanese pathologists by the use of fiberoptic endoscope and gastrocamera. In Japan, EGC comprises 35% of newly-diagnosed cases of gastric cancer.

Grossly, the lesion of EGC may have 3 patterns—polypoid (protruded), superficial and ulcerated (**Fig. 18.17**):

- | | | |
|----------|---|-----------------------|
| Type I | : | Polypoid type |
| Type IIa | : | Superficial elevated |
| Type IIb | : | Superficial flat |
| Type IIc | : | Superficial depressed |
| Type III | : | Ulcerated type |

Histologically, EGC is a typical glandular adenocarcinoma, usually well-differentiated type.

Prognosis of EGC after surgical resection is quite good; 5-year survival rate being 93-99%.

Early gastric carcinoma must be distinguished from certain related terms as under:

- ◆ *Epithelial dysplasia* is cellular atypia seen in intestinal metaplasia such as in atrophic gastritis and pernicious anaemia.
- ◆ *Carcinoma in situ* in the stomach is a state of severe cellular atypia or dysplasia, without invasion across the basement membrane of the glands.

II. ADVANCED GASTRIC CARCINOMA When the carcinoma crosses the basement membrane into the muscularis propria or beyond, it is referred to as advanced gastric

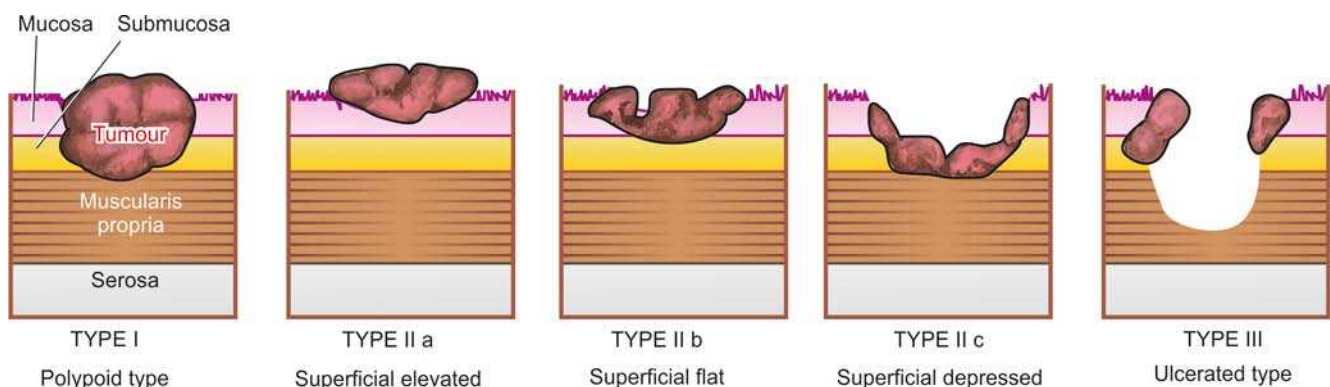

Figure 18.17 Diagrammatic representation of gross patterns of early gastric carcinoma.

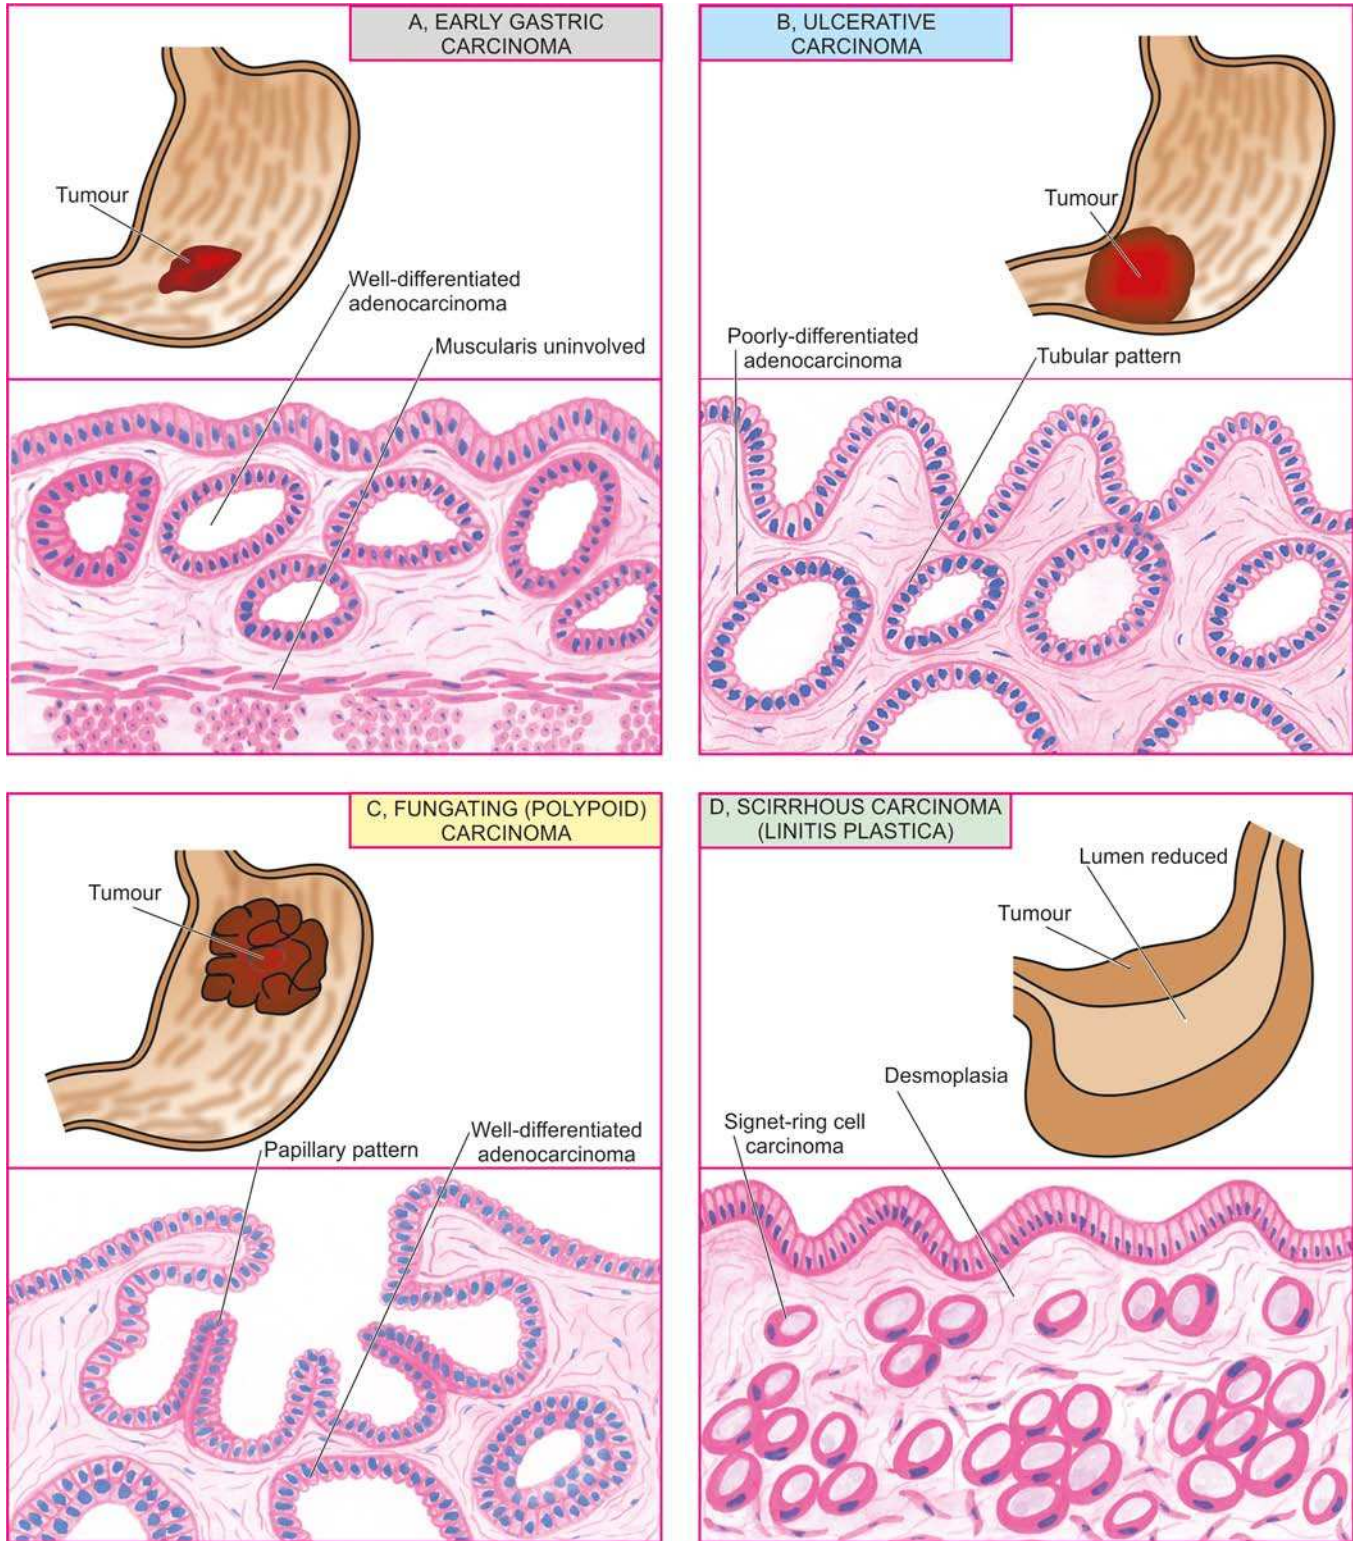

Figure 18.18 Gastric carcinoma, gross appearance of subtypes and their corresponding dominant histological patterns.

carcinoma. Advanced gastric carcinoma has following 5 patterns:

i) Ulcerative carcinoma (Fig. 18.18,B) This is the most common pattern. The tumour appears as a flat, infiltrating and ulcerative growth with irregular necrotic base and raised margin. It is seen more commonly in the region of gastric canal (Fig. 18.19,A).

Histologically, ulcerative carcinomas are poorly-differentiated adenocarcinomas, which invade deeply into the stomach wall. Tubular and acinar patterns are seen more commonly (Fig. 18.19, B).

ii) Fungating (polypoid) carcinoma (Fig. 18.18,C) The second common pattern is a cauliflower growth projecting into the lumen, similar to what is commonly seen in the

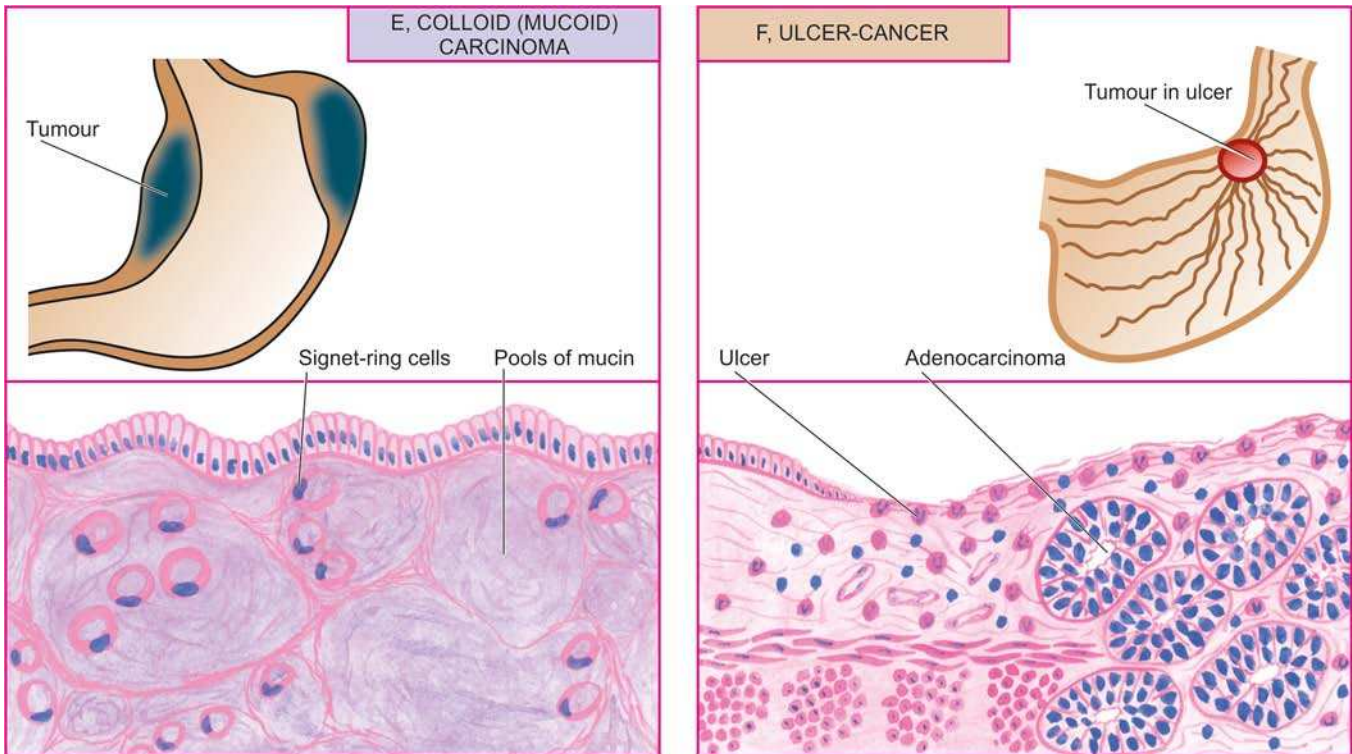

Figure 18.18 contd... Gastric carcinoma, gross appearance of subtypes and their corresponding dominant histological patterns.

large intestine. It is seen more often in the fundus. The tumour undergoes necrosis and infection commonly.

Histologically, fungating or polypoid carcinomas are well-differentiated adenocarcinomas, commonly papillary type.

iii) Scirrhous carcinoma (Linitis plastica) (Fig. 18.18,D) In this pattern, the stomach wall is thickened due to extensive desmoplasia giving the appearance as 'leather-bottle stomach' or 'linitis plastica'. The involvement may be localised to pyloric antrum, or diffuse affecting whole of the stomach from the cardia to pylorus. The lumen of the stomach is reduced. There are no ulcers but rugae are prominent (Fig. 18.19,C).

Histologically, it may be an adenocarcinoma or signet-ring cell carcinoma, extensively infiltrating the stomach wall, but due to marked desmoplasia cancer cells may be difficult to find (Fig. 18.19,D).

iv) Colloid (Mucoïd) carcinoma (Fig. 18.18,E) This pattern is usually seen in the fundus. The tumour grows like masses having gelatinous appearance due to secretion of large quantities of mucus.

Histologically, mucoïd carcinoma contains abundant pools of mucin in which are seen a small number of tumour cells, sometimes having signet-ring appearance.

v) Ulcer-cancer (Fig. 18.18,F) Development of cancer in chronic gastric ulcer is a rare occurrence (less than 1%). Majority of ulcer-cancers are malignant lesions from the beginning. For confirmation of cancer in a pre-existing gastric ulcer, the characteristic microscopic appearance of peptic ulcer should be demonstrable with one portion of the base or the margin of the ulcer showing carcinomatous changes.

Histologically, ulcer-cancers are adenocarcinomas without any specific features. The differences between a benign and malignant gastric ulcer are summarised in Table 18.5 (also see Fig. 18.13).

SPREAD Carcinoma of the stomach may spread by the following routes:

1. Direct spread Direct spread by local extension is the most common feature of gastric carcinoma. The spread occurs mainly from the loose submucosal layer but eventually muscularis and serosa are also invaded. After the peritoneal covering of the stomach has been invaded, transcoelomic dissemination may occur in any other part of the peritoneal cavity but ovarian masses (one sided or both-sided) occur more commonly, referred to as *Krukenberg tumours* (page 740). Submucosal spread occurs more often upwards into the oesophagus due to continuity of the layers of stomach with those of oesophagus, while the spread downwards into the duodenum occurs less often due to the presence of pyloric sphincter and submucosal Brunner's glands. The tumour may directly involve other neighbouring structures and organs like lesser and greater omentum, pancreas, liver, common bile duct, diaphragm, spleen and transverse colon.

2. Lymphatic spread Metastases to regional lymph nodes occur early, especially in the scirrhous carcinoma. The groups of lymph nodes involved are along the lesser and greater curvature around the cardia and suprapancreatic lymph nodes. Involvement of left supraclavicular lymph node, *Virchow* or *Troisier's sign*, is sometimes the presenting feature of gastric carcinoma.

3. Haematogenous spread Blood spread of gastric carcinoma may occur to the liver, lungs, brain, bones, kidneys

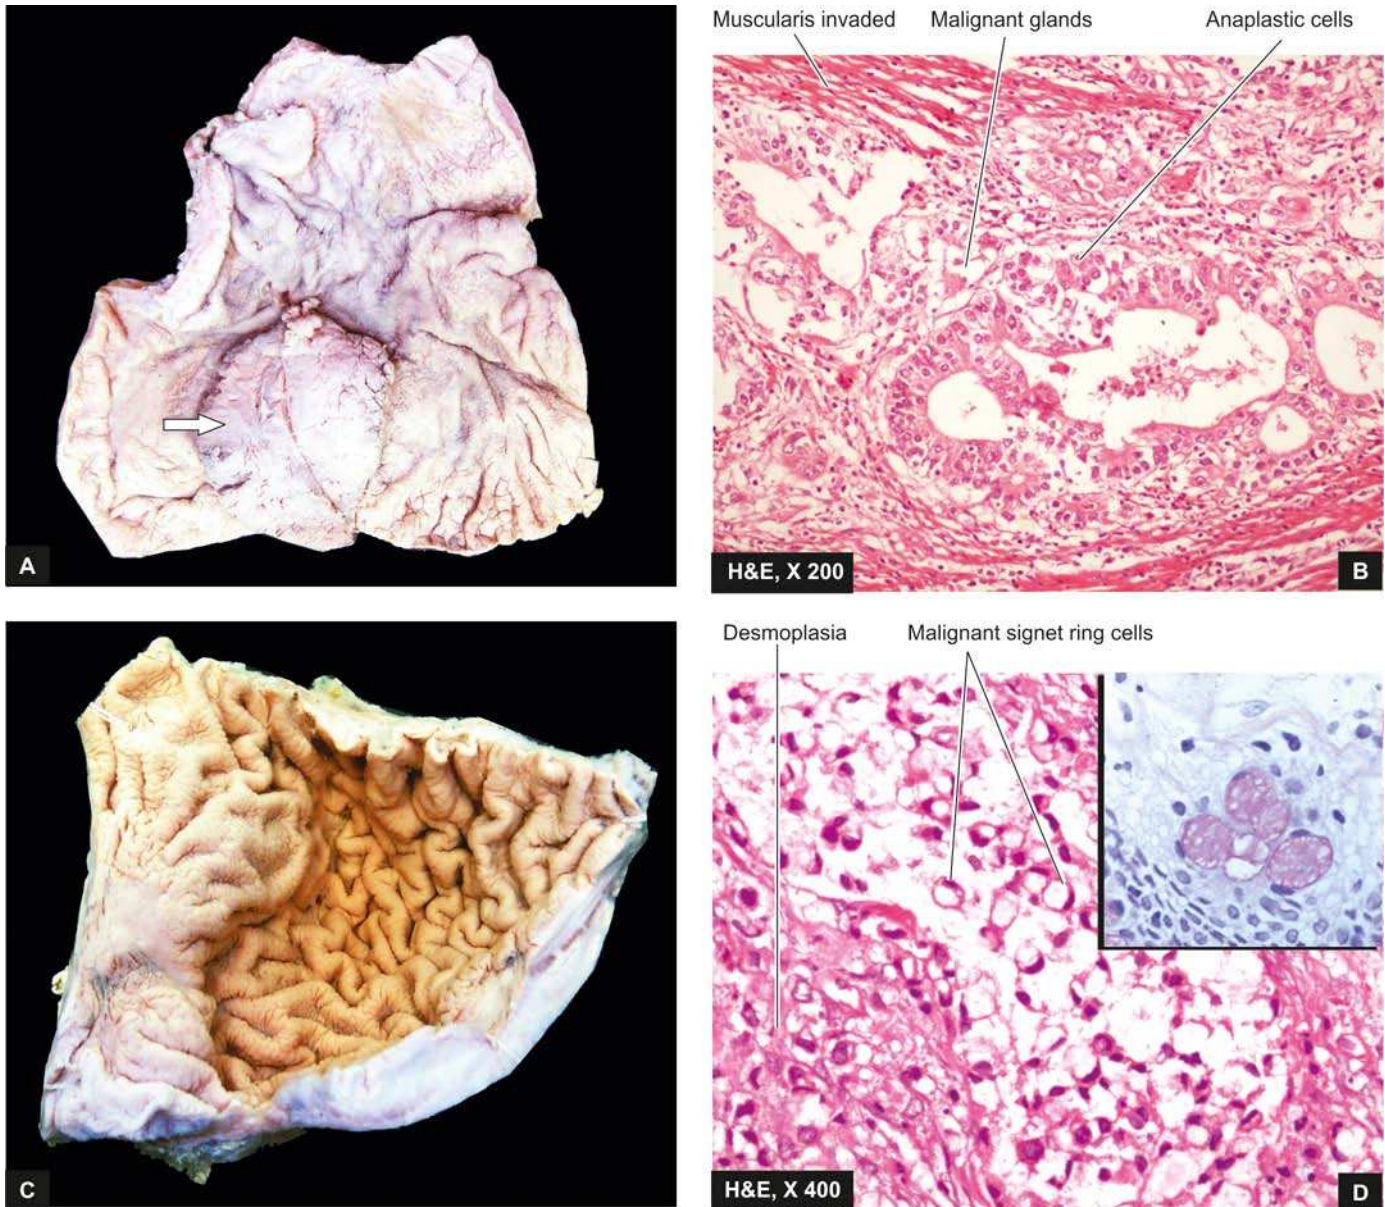

Figure 18.19 A, *Ulcerative carcinoma stomach*. The luminal surface of the stomach in the region of pyloric canal shows an elevated irregular growth with ulcerated surface and raised margins. B, Malignant cells forming irregular glands with stratification are seen invading the layers of the stomach wall. C, *Linitis plastica*. The wall of the stomach in the region of pyloric canal is markedly thickened and fibrotic while the mucosal folds are lost. D, Microscopy shows characteristic signet ring tumour cells having abundant mucinous cytoplasm positive for mucicarmine (in box). The stroma is desmoplastic.

and adrenals. It occurs more commonly with the poorly-differentiated carcinoma.

The American Joint Committee on Cancer has developed *TNM staging* system for gastric carcinoma based on tumour invasion (T), lymph node involvement (N) and distant metastasis (M) into earliest stage $T_{is} N_0 M_0$ (intraepithelial tumour) to most advanced stage $T_{any} N_{any} M_1$.

CLINICAL FEATURES Gastric carcinoma may have diverse presentations. The usual clinical features are as under:

- i) Persistent abdominal pain
- ii) Gastric distension and vomiting
- iii) Loss of weight (cachexia)
- iv) Loss of appetite (anorexia)
- v) Anaemia, weakness, malaise.

The most common complication of gastric cancer is haemorrhage (in the form of haematemesis and/or melaena); others are obstruction, perforation and jaundice.

Gastric carcinoma remains undiagnosed until late when the symptoms appear. Therefore, the prognosis is generally poor; 5-year survival rate being 5-15% from the time of diagnosis of advanced gastric carcinoma. However, 5-year survival rate for early gastric carcinoma is far higher (93-99%) and hence the need for early diagnosis of the condition.

Other Carcinomas

Besides the various morphologic patterns of adenocarcinoma just described, other carcinomas that occur rarely in the stomach are: adenosquamous carcinoma, squamous cell carcinoma and undifferentiated carcinoma, all of which are morphologically similar to such tumours elsewhere.

Leiomyosarcoma

Leiomyosarcoma, though rare, is the commonest soft tissue sarcoma, the stomach being the more common site in the gastrointestinal tract.

Table 18.5 Differences between benign and malignant gastric ulcers.

| FEATURE | BENIGN ULCER | MALIGNANT ULCER |
|-------------------------|---|--|
| 1. Age | Younger age | Older age |
| 2. Sex | Markedly common in males | Slightly common in males |
| 3. Duration of symptoms | Weeks to years | Weeks to months |
| 4. Location | Commonly lesser curvature of pylorus and antrum | Commonly greater curvature of pylorus and antrum |
| 5. Gross features | | |
| a) Size | Small | Large |
| b) Shape | Regular | Irregular |
| c) Mucosal folds | Radiating | Interrupted |
| d) Ulcer bed | Haemorrhagic | Necrotic |
| 6. Barium studies | Punched out ulcer | Irregular filling defect |
| 7. Acidity | Usually normal-to-low | May be normal-to-even achlorhydria |
| 8. Therapy | Responds well to medical therapy | Usually does not respond to medical therapy |

Grossly, the tumour may be of variable size but is usually quite large, pedunculated and lobulated mass into the lumen.

Microscopically, leiomyosarcoma is characterised by high cellularity and presence of mitotic figures. Tumour is usually well-differentiated.

Leiomyoblastoma (Epithelioid Leiomyoma)

This is a rare tumour, the behaviour of which is intermediate between clearly benign and malignant tumour.

Grossly, the tumour is large, circumscribed and projects into the lumen.

Microscopically, it is characterised by round to polygonal cells with clear perinuclear halos. The number of mitoses determines the biological behaviour of the tumour.

Carcinoid Tumour

Carcinoid tumours are rare in the stomach and are usually non-argentaffin type but argentaffinomas also occur. Their behaviour is usually malignant; they are described on page 559.

Lymphomas of Gut

Primary gastrointestinal lymphomas are defined as lymphomas arising in the gut without any evidence of systemic involvement at the time of presentation.

Secondary gastrointestinal lymphomas, on the other hand, appear in the gut after dissemination from other primary site.

Gastric lymphomas constitute over 50% of all bowel lymphomas; other sites being small and large bowel in decreasing order of frequency. Prognosis of primary gastric lymphoma is better than for intestinal lymphomas. Primary lymphoma of stomach is the most common malignant gastric tumour (4%) next to carcinoma.

Clinical manifestations of gastric lymphomas may be similar to gastric carcinoma. Age incidence for lymphomas of the gastrointestinal tract is usually lower than that for carcinoma (30-40 years as compared to 40-60 years in gastric carcinoma) and may occur even in childhood. Relationship

with long-standing chronic *H. pylori* gastritis with lymphoid hyperplasia has been strongly suggested.

Grossly, gastric lymphomas have 2 types of appearances:

1. *Diffusely infiltrating type*, producing thickening of the affected gut wall, obliteration of mucosal folds and ulcerations. Cut section shows lesions in the mucosa and submucosa but in late stage whole thickness of the gut wall may be affected.
2. *Polypoid type*, which produces large protruding mass into the lumen with ulcerated surface.

Lymph node involvement may occur in either of the two patterns.

Microscopically, gastric lymphomas are most often non-Hodgkin's lymphomas of the following types:

- ◆ *High-grade* large cell immunoblastic lymphoma being the most common.
- ◆ *Low-grade* small lymphocytic well-differentiated B-cell lymphoma referred to as *MALToma* is the next in frequency (arising from Mucosa Associated Lymphoid Tissue).

GIST BOX 18.6 Tumours and Tumour-like Lesions of Stomach

- ☐ Tumour-like gastric lesions are polyps e.g. hyperplastic (inflammatory), hamartomatous.
- ☐ Benign tumours are adenomas and rare stromal tumours.
- ☐ Gastric carcinoma is etiologically linked to *H. pylori* infection.
- ☐ Most common location is the region of pyloric canal.
- ☐ Early gastric carcinoma is an initial *in situ* stage.
- ☐ Advanced gastric carcinoma has several morphologic types: ulcerative, fungating, scirrhous, colloid, and ulcer-cancer.
- ☐ Common histologic type is adenocarcinoma of varying grades. Signet ring type and colloid carcinoma are mucinous variants.
- ☐ Gastric cancer may spread directly to adjacent structures and to distant sites by haematogenous and lymphatic route.
- ☐ Other cancers in stomach are lymphoma and carcinoid tumour.

NORMAL STRUCTURE

Anatomically, the small bowel having a length of 550-650 cm, includes the duodenum, jejunum and ileum and tends to become narrower throughout its course.

Histologically, the small bowel is identified by recognition of villi. The wall of the small intestine consists of 4 layers:

1. The **serosa** is the outer covering of the small bowel which is complete except over a part of the duodenum.

2. The **muscularis propria** is composed of 2 layers of smooth muscle tissue—outer thinner longitudinal and inner thicker circular layer. These muscles are functionally important for peristalsis. Between the two layers of muscle lie ganglionated plexus, myenteric plexus of Auerbach.

3. The **submucosa** is composed of loose fibrous tissue with blood vessels and lacteals in it. It contains a gangliated plexus, Meissner's plexus, having fewer and smaller cells than the Auerbach's plexus.

4. The **mucosa** consists of glandular epithelium overlying the lamina propria composed of loose connective tissue and contains phagocytic cells and abundance of lymphoid cells (Peyer's patches in the ileum) and plasma cells. It is supported externally by thin layer of smooth muscle fibres, *muscularis mucosae*. The mucous membrane is thrown into folds or *plicae* which are more in the jejunum and less in the ileum, thus increasing the absorptive surface enormously. The absorptive surface is further increased by the intestinal villi. *Villi* are finger-like or leaf-like projections which contain 3 types of cells:

i) **Simple columnar cells** They perform absorptive function due to the presence of brush border consisting of large number of microvilli.

ii) **Goblet cells** These are mucus-secreting cells and are interspersed between the columnar cells.

iii) **Endocrine cells** These are scattered in the villi as well as are widely distributed throughout the gastrointestinal tract. These cells have various synonyms as under:

a) *Kulchitsky cells*, after the name of its discoverer.

b) *Enterochromaffin cells*, due to their resemblance to chromaffin cells of the adrenal medulla.

c) *Argentaffin cells*, as the intracytoplasmic granules stain positively with silver salts by reduction reaction (argyrophil cells, on the other hand, require the addition of exogenous reducing substance for staining).

d) *Endocrine cells*, as these specialised cells are considered to be part of APUD cell system (having common properties as Amine content, amine Precursor Uptake and Decarboxylation). APUD cells are considered to be endodermal in origin, while previously they were thought to be neural crest derivative. Other endocrine cells belonging to the APUD cell system are C-cells of the thyroid, chromaffin cells of the adrenal medulla, certain cells of the carotid body, bronchi, hypothalamus, pituitary and sympathetic ganglia.

Endocrine cells are heavily populated in the proximal small bowel as this is the most active site for absorption and secretory activities. They are sparse in the colon which is less active site for such functions.

The duodenum contains distinctively branched *Brunner's glands* present in the submucosa and going up to muscularis mucosae. The deeper layer of the mucosa of the small intestine elsewhere contains intestinal glands or *crypts of Lieberkuhn*. They are lined by columnar cells, goblet cells, endocrine cells and Paneth cells. Paneth cells are normally exclusively found in the small intestine and occasionally in the caecum. These cells are characterised by the presence of supranuclear granules rich in lysozyme.

The blood supply of the whole of small intestine, except the first part of the duodenum, is by the superior mesenteric artery which supplies blood by mesenteric arterial arcades and the straight arteries.

The main *functions* of the small intestine are digestion and absorption so that ultimately nutrients passing into the blood stream are utilised by the cells in metabolism. The mucosal layer of the small intestine has remarkable capacity for regeneration and new lining is laid every 3-4 days.

CONGENITAL ANOMALIES AND INTESTINAL OBSTRUCTION**MECKEL'S DIVERTICULUM**

Meckel's diverticulum is the most common congenital anomaly of the gastrointestinal tract, occurring in 2% of population. It is more common in males. The anomaly is commonly situated on the antimesenteric border of the ileum, about 1 meter above the ileocaecal valve. Like other true diverticula, Meckel's diverticulum is an outpouching containing all the layers of the intestinal wall in their normal orientation (**Fig. 18.20**). It is almost always lined by small intestinal type of epithelium; rarely it may contain islands of gastric mucosa and ectopic pancreatic tissue. Embryologic origin of Meckel's diverticulum is from incomplete obliteration of vitellointestinal duct (Other anomalies resulting from the remnants of vitellointestinal duct are vitelline sinus and vitelline cyst).

The common *complications* of Meckel's diverticulum are perforation, haemorrhage and diverticulitis.

In addition to congenital Meckel's diverticulum, *acquired diverticula* also occur in the small intestine. These are commonly multiple (diverticulosis), frequently located on the mesenteric border, and are sometimes associated with malabsorption.

OTHER ANOMALIES

There are a few uncommon anomalies of small intestine:

Intestinal atresia is congenital absence of lumen, most commonly affecting the ileum or duodenum. The proximal segment has a blind end which is separated from distal segment freely, or the two segments are joined by a fibrous cord. The condition must be recognised early and treated surgically, as otherwise it is incompatible with life.

Intestinal stenosis is congenital narrowing of the lumen affecting a segment of the small intestine. Intestinal segment above the level of obstruction is dilated and that below it is collapsed.

Intestinal malrotation is a developmental abnormality of the midgut (i.e. the portion of intestine between the duodenojejunal

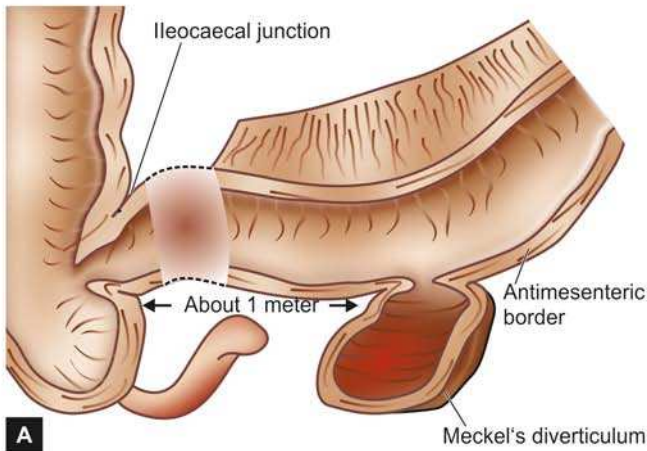

Figure 18.20 Meckel's diverticulum. A, Common location and gross appearance. B, Resected segment of the small intestine shows an outpouching which on section is seen communicating with the intestinal lumen. The lumen contains necrotic debris.

flexure and the middle of transverse colon). Due to failure of normal rotation of midgut, the following consequences can occur:

- i) Exomphalos i.e. intestinal eventration at the umbilicus.
- ii) Misplacement of the caecum, appendix and ascending colon.
- iii) Mobile caecum.

INTESTINAL OBSTRUCTION

Conditions which interfere with the propulsion of contents in the intestine are considered under the heading of intestinal obstruction. The causes of intestinal obstruction can be classified under the following 3 broad groups:

1. Mechanical obstruction It can occur as a result of the following causes:

- i) *Internal obstruction (intramural and intraluminal):*
 - a) Inflammatory strictures (e.g. Crohn's disease)
 - b) Congenital stenosis, atresia, imperforate anus
 - c) Tumours
 - d) Meconium in mucoviscidosis
 - e) Roundworms
 - f) Gallstones, faecoliths, foreign bodies
 - g) Ulceration induced by potassium chloride tablets prescribed to counter hypokalaemia.
- ii) *External compression:*
 - a) Peritoneal adhesions and bands
 - b) Strangulated hernias
 - c) Intussusception
 - d) Volvulus
 - e) Intra-abdominal tumour.

2. Neurogenic obstruction It occurs due to paralytic ileus i.e. paralysis of muscularis of the intestine as a result of shock after abdominal operation or by acute peritonitis.

3. Vascular obstruction Obstruction of the superior mesenteric artery or its branches may result in infarction causing paralysis. The causes are as under:

- i) Thrombosis
- ii) Embolism
- iii) Accidental ligation.

Out of the various causes listed above, conditions producing external compression on the bowel wall are the most common causes of intestinal obstruction (80%). Some of these are described below.

PERITONEAL ADHESIONS AND BANDS Adhesions and bands in the peritoneum composed of fibrous tissue result following healing in peritonitis. Rarely, such fibrous adhesions and bands may be without any preceding peritoneal inflammation and are of congenital origin. In either case, peritoneal bands and adhesions result in partial or complete intestinal obstruction by outside pressure on the bowel wall.

HERNIA Hernia is protrusion of portion of a viscus through an abnormal opening in the wall of its natural cavity.

◆ **External hernia** is the protrusion of the bowel through a defect or weakness in the peritoneum.

◆ **Internal hernia** is the term applied for herniation that does not present on the external surface.

Two major factors involved in the formation of a hernia are as under:

- i) *Local weakness* which may be congenital e.g. at the umbilicus, inguinal and femoral canals, and in surgical scars called 'incisional hernia'.
- ii) *Increased intra-abdominal pressure* that is produced by coughing, straining and exertion.

Inguinal hernias are more common, followed in decreasing frequency, by femoral and umbilical hernias. Inguinal hernias may be of 2 types:

◆ **Direct** when hernia passes medial to the inferior epigastric artery and it appears through the external abdominal ring.

◆ **Indirect** when it follows the inguinal canal lateral to the inferior epigastric artery.

When the contents of hernia such as loop of intestine can be returned to the abdominal cavity, it is called *reducible*. When it is not possible to reduce hernia due to large contents or due to adhesions in the hernial sac, it is referred to as *irreducible*.

When the blood flow in the hernial sac is obstructed, it results in *strangulated hernia*. Obstruction to the venous drainage and arterial supply may result in infarction or gangrene of the affected loop of intestine. The gross and

microscopic appearance of strangulated intestine is the same as that of infarction of intestine.

INTUSSUSCEPTION Intussusception is the telescoping of a segment of intestine into the segment below due to peristalsis. The telescoped segment is called the *intussusceptum* and lower receiving segment is called the *intussusciens*. The condition occurs more commonly in infants and young children, more often in the ileocaecal region when the portion of ileum invaginates into the ascending colon without affecting the position of the ileocaecal valve (Fig. 18.21). Less common forms are ileo-ileal and colo-colic intussusception.

In children, the cause is usually not known though enlargement of the lymphoid tissue in the terminal ileum has been suggested by some. In the case of adults, the usual causes are foreign bodies and tumours.

The main *complications* of intussusception are intestinal obstruction, infarction, gangrene, perforation and peritonitis.

VOLVULUS Volvulus is the twisting of loop of intestine upon itself through 180° or more. This leads to obstruction of the intestine as well as cutting off of the blood supply to the affected loop. The usual causes are bands and adhesions (congenital or acquired) and long mesenteric attachment. The condition is more common in the sigmoid colon than the small bowel.

GIST BOX 18.7

Congenital Anomalies and Intestinal Obstruction

- ☐ Meckel's diverticulum is a common anomaly and located in the ileum on anti-mesenteric border about 1 meter above ileocaecal valve.
- ☐ Intestinal atresia, stenosis and malrotation are uncommon anomalies.
- ☐ Intestinal obstruction may result from mechanical, neurogenic or vascular causes.
- ☐ Some of the common etiologies of intestinal obstruction are peritoneal bands, adhesions, intussusception and volvulus.

ISCHAEMIC BOWEL DISEASE (ISCHAEMIC ENTEROCOLITIS)

Ischaemic lesions of the gastrointestinal tract may occur in the small intestine and/or colon; the latter is called *ischaemic colitis* or *ischaemic enterocolitis* and is commonly referred to as ischaemic bowel disease. In either case, the cause of ischaemia is compromised mesenteric circulation, while ischaemic effect is less likely to occur in the stomach, duodenum and rectum due to abundant collateral blood supply.

Depending upon the extent and severity of ischaemia, 3 patterns of pathologic lesions can occur (Fig. 18.22):

1. *Transmural infarction*, characterised by full thickness involvement i.e. transmural ischaemic necrosis and gangrene of the bowel.
2. *Mural infarction*, characterised by haemorrhagic gastro-enteropathy (haemorrhage and necrosis). The ischaemic effect in mural infarction is limited to mucosa, submucosa and superficial muscularis, while *mucosal infarction* is confined to mucosal layers superficial to muscularis mucosae.
3. *Ischaemic colitis*, due to chronic colonic ischaemia causing fibrotic narrowing of the affected bowel.

These pathologic patterns are described here.

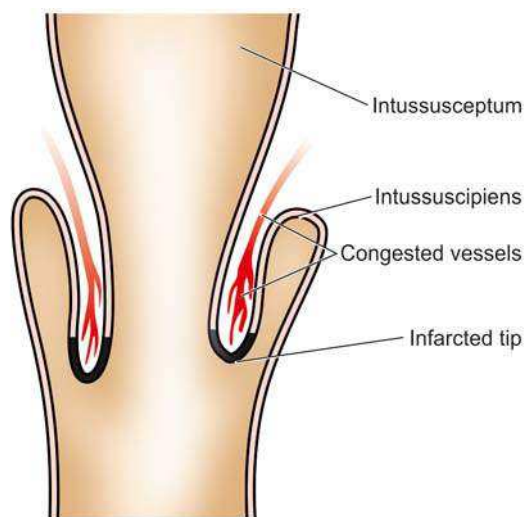

Figure 18.21 Ileocaecal intussusception.

TRANSMURAL INFARCTION

Ischaemic necrosis of the full-thickness of the bowel wall is more common in the small intestine than the large intestine.

ETIOPATHOGENESIS The common causes of transmural infarction of small bowel are as under:

1. *Mesenteric arterial thrombosis* such as due to the following:
 - i) Atherosclerosis (most common)
 - ii) Aortic aneurysm
 - iii) Vasospasm
 - iv) Fibromuscular hyperplasia
 - v) Invasion by the tumour
 - vi) Use of oral contraceptives
 - vii) Arteritis of various types
2. *Mesenteric arterial embolism* arising from the following causes:
 - i) Mural thrombi in the heart
 - ii) Endocarditis (infective and nonbacterial thrombotic)
 - iii) Atherosclerotic plaques
 - iv) Atrial myxoma
3. *Mesenteric venous occlusion* is less common cause of full-thickness infarction of the bowel. The causes are as under:
 - i) Intestinal sepsis e.g. appendicitis
 - ii) Portal venous thrombosis in cirrhosis of the liver
 - iii) Tumour invasion
 - iv) Use of oral contraceptives

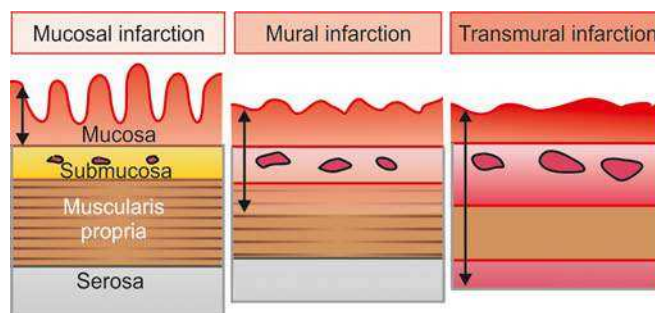

Figure 18.22 Schematic diagram to show the three types of ischaemic bowel disease depending upon the extent of involvement.

4. *Miscellaneous causes:*

- i) Strangulated hernia
- ii) Torsion
- iii) Fibrous bands and adhesions.

MORPHOLOGIC FEATURES *Grossly*, irrespective of the underlying etiology, infarction of the bowel is haemorrhagic (red) type (page 112). A varying length of the small bowel may be affected. In the case of colonic infarction, the distribution area of superior and inferior mesenteric arteries (i.e. *splenic flexure*) is more commonly involved. The affected areas become dark purple and markedly congested and the peritoneal surface is coated with fibrinous exudate. The wall is thickened, oedematous and haemorrhagic. The lumen is dilated and contains blood and mucus. In arterial occlusion, there is sharp line of demarcation between the infarcted bowel and the normal intestine, whereas in venous occlusion the infarcted area merges imperceptibly into the normal bowel (**Fig. 18.23**).

Microscopically, there is coagulative necrosis and ulceration of the mucosa and there are extensive submucosal haemorrhages. The muscularis is less severely affected by ischaemia. Subsequently, inflammatory cell infiltration and secondary infection occur, leading to gangrene of the bowel (**Fig. 18.24**).

The condition is clinically characterised by 'abdominal angina' in which the patient has acute abdominal pain, nausea, vomiting, and sometimes diarrhoea. The disease is rapidly fatal, with 50-70% mortality rate.

MURAL AND MUCOSAL INFARCTION (HAEMORRHAGIC GASTROENTEROPATHY)

Mural and mucosal infarctions are limited to superficial layers of the bowel wall, sparing the deeper layer of the muscularis and the serosa. The condition is also referred to as *haemorrhagic gastroenteropathy*, and in the case of colon as *membranous colitis*.

Figure 18.23 Haemorrhagic infarct of the small intestine. The infarcted area is swollen, dark in colour and coated with fibrinous exudate. A sharp line of demarcation separates infarcted area from the normal bowel (arrow).

ETIOPATHOGENESIS Haemorrhagic gastroenteropathy results from conditions causing non-occlusive hypoperfusion (compared from transmural infarction which occurs from occlusive causes). These are as under:

1. Shock
2. Cardiac failure
3. Infections
4. Intake of drugs causing vasoconstriction e.g. digitalis, norepinephrine.

MORPHOLOGIC FEATURES *Grossly*, the lesions affect variable length of the bowel. The affected segment of the bowel is red or purple but without haemorrhage and exudation on the serosal surface. The mucosa is oedematous at places, sloughed and ulcerated at other places. The lumen contains haemorrhagic fluid.

Microscopically, there is patchy ischaemic necrosis of mucosa, vascular congestion, haemorrhages and inflammatory cell infiltrate. The changes may extend into superficial muscularis but deeper layer of muscularis and serosa are spared. Secondary bacterial infection may supervene resulting in pseudomembranous enterocolitis.

Clinically, as in transmural infarction, the features of abdominal pain, nausea, vomiting and diarrhoea are present, but the changes are reversible and curable. With adequate therapy, normal morphology is completely restored in superficial lesions, while deeper lesions may heal by fibrosis leading to stricture formation.

ISCHAEMIC COLITIS

Although this condition affects primarily colon in the region of splenic flexure, it is described here due to its apparent pathogenetic relationship with ischaemic injury. Ischaemic colitis is characterised by chronic segmental colonic ischaemia followed by chronic inflammation and healing by fibrosis and scarring causing obstruction (ischaemic stricture).

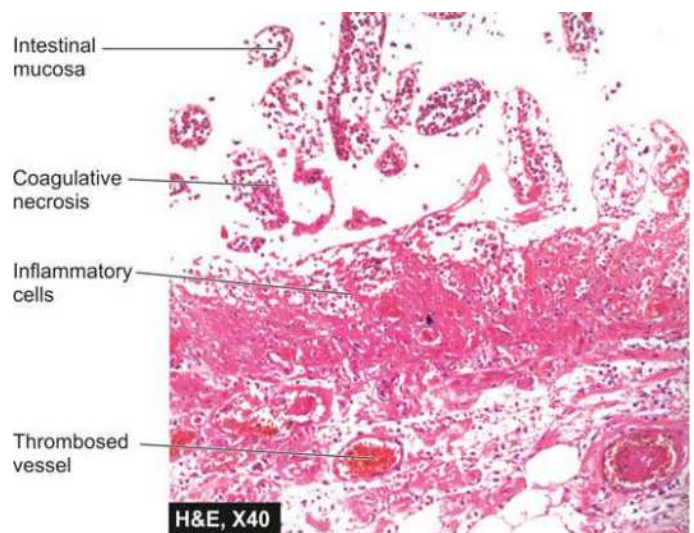

Figure 18.24 Infarct small intestine, microscopic appearance. The mucosa in the infarcted area shows coagulative necrosis and submucosal haemorrhages: muscularis is also partly affected. Inflammatory cell infiltration is marked at the line of demarcation between the infarcted and normal bowel.

Grossly, most frequently affected site is the splenic flexure; other site is rectum. Ischaemic colitis passes through 3 stages: infarct, transient ischaemia and ischaemic stricture. However, the surgical submitted specimens generally are of the ischaemic stricture. External surface of the affected area is fusiform or saccular. On cut section, there are patchy, segmental and longitudinal mucosal ulcers. Thus, the gross appearance can be confused with either of the two types of inflammatory bowel disease.

Microscopically, the ulcerated areas of the mucosa show granulation tissue. The submucosa is characteristically thickened due to inflammation and fibrosis. The muscularis may also show inflammatory changes and patchy replacement by fibrosis. The blood vessels may show atheromatous emboli, organising thrombi and endarteritis obliterans.

NECROTISING ENTEROCOLITIS

Necrotising enterocolitis is an acute inflammation of the terminal ileum and ascending colon, occurring primarily in premature and low-birth-weight infants within the first week of life and less commonly in full-term infants (page 172).

ETIOLOGY The condition has been considered as a variant of the spectrum of ischaemic bowel disease. Important factors in the etiology of this disorder, thus, are as follows:

1. Ischaemia
2. Hypoxia/anoxia of the bowel due to bypassing of blood from the affected area
3. Bacterial infection and endotoxins
4. Establishment of feeding
5. Infants fed on commercial formulae than breast-fed, implying the role of immunoprotective factors.

MORPHOLOGIC FEATURES **Grossly**, the affected segment of the bowel is dilated, necrotic, haemorrhagic and friable. Bowel wall may contain bubbles of air (pneumatosis intestinalis).

Microscopically, the changes are variable depending upon the stage. Initial changes are confined to mucosa and show oedema, haemorrhage and coagulative necrosis. A *pseudomembrane* composed of necrotic epithelium, fibrin and inflammatory cells may develop. As the ischaemic process extends to the subjacent layers, muscle layer is also involved and may lead to perforation and peritonitis.

In healed cases, stricture formation, malabsorption and short bowel syndrome are the usual complications.

GIST BOX 18.8 Ischaemic Bowel Disease

- Ischaemic lesions of the small intestine and/or colon are called ischaemic enterocolitis.
- Depending upon the extent and severity of ischaemia, there are 3 patterns of pathologic lesions: transmural infarction, haemorrhagic gastroenteropathy and chronic ischaemic colitis.
- The causes for ischaemia may be due to mesenteric arterial or venous occlusion.
- Necrotising enterocolitis is an acute inflammation of the terminal ileum and ascending colon, occurring primarily in premature and low-birth-weight infants.

INFLAMMATORY BOWEL DISEASE (CROHN'S DISEASE AND ULCERATIVE COLITIS)

DEFINITION The term 'inflammatory bowel disease (IBD)' is commonly used to include 2 idiopathic bowel diseases having many similarities but the conditions usually have distinctive morphological appearance. These 2 conditions are Crohn's disease (regional enteritis) and ulcerative colitis:

1. Crohn's disease or Regional enteritis is an idiopathic chronic ulcerative IBD, characterised by transmural, non-caseating granulomatous inflammation, affecting most commonly the segment of terminal ileum and/or colon, though any part of the gastrointestinal tract may be involved.

2. Ulcerative colitis is an idiopathic form of acute and chronic ulcero-inflammatory colitis affecting chiefly the mucosa and submucosa of the rectum and descending colon, though sometimes it may involve the entire length of the large bowel.

Both these disorders primarily affect the bowel but may have systemic involvement in the form of polyarthritis, uveitis, ankylosing spondylitis, skin lesions and hepatic involvement. Both diseases can occur at any age but are more frequent in 2nd and 3rd decades of life. Females are affected slightly more often.

ETIOPATHOGENESIS

The exact etiology of IBD remains unknown. However, multiple factors are implicated which can be considered under the following 3 groups:

1. Genetic factors Genetic factors are implicated in the etiopathogenesis of IBD is supported by the following evidences:

i) There is about 3 to 20 times higher incidence of occurrence of IBD in first-degree relatives. This is due to genetic defect causing diminished epithelial barrier function.

ii) Overall, there is approximately 50% chance of development of IBD (Crohn's disease about 60% concordance, ulcerative colitis about 6% concordance) in monozygotic twins.

iii) Although no specific and consistent gene association with IBD has been seen, genome-wide search has revealed that disease-predisposing loci are present in chromosomes 16q, 12p, 6p, 14q and 5q. In particular, *CARD15* (caspase-associated recruitment domain containing protein 15) on chromosome 16q is expressed by several cells in the intestinal mucosa which in mutated form results in loss of its function and renders an individual about 50-times higher risk to develop Crohn's disease.

iv) HLA studies show that ulcerative colitis is more common in HLA-DRB1-alleles while Crohn's disease is more common in HLA-DR7 and DQ4 alleles.

2. Immunologic factors Defective immunologic regulation in IBD has been shown to play significant role in the pathogenesis of IBD:

i) *Defective regulation of immune suppression* In a normal individual, there is lack of immune responsiveness to dietary antigens and commensal flora in the intestinal lumen. The mechanism responsible for this is by activation of CD4+ T cells secreting cytokines inhibitory to inflammation (IL-10, TGF- β) which suppress inflammation in the gut wall. In IBD, this immune mechanism of suppression of inflammation is defective and thus results in uncontrolled inflammation.

ii) *Transgenic mouse experimental model studies.* Gene 'knock out' studies on colitis in mice have revealed that multiple immune abnormalities may be responsible for IBD as under:

- a) Deletion of inflammation inhibitory cytokines (e.g. IL-2, IL-10, TGF- β) or their receptors.
- b) Deletion of molecules responsible for T cell recognition (e.g. T cell antigen receptors, MHC class II).
- c) Interference with normal epithelial barrier function in the intestine (e.g. blocking N-cadherin, deletion of multi-drug resistance MDR gene).

iii) *Type of inflammatory cells* In both types of IBD, activated CD4⁺ T cells are present in the lamina propria and in the peripheral blood. These cells either activate other inflammatory cells (e.g. macrophages and B cells), or recruit more inflammatory cells by stimulation of homing receptor on leucocytes and vascular endothelium. There are two main types of CD4⁺ T cells in IBD:

◆ *TH1 cells* secrete proinflammatory cytokines IFN- γ and TNF which induce transmural granulomatous inflammation seen in Crohn's disease. IL-12 initiates TH1 cytokine pathway.

◆ *TH2 cells* secrete IL-4, IL-5 and IL-13 which induce superficial mucosal inflammation characteristically seen in ulcerative colitis.

3. Exogenous factors In addition to role of genetic factors and deranged T-cell mediated immunity, a role for several exogenous and environmental factors has been assigned:

i) *Microbial factors*: At different times, role of a variety of microbes in initiation of inflammatory response by the body has been suspected. Accordingly, several microorganism species (bacteria, viruses, protozoa and fungi) have been suspect but without definite evidence: *Mycobacterium paratuberculosis*, *Salmonella*, *Shigella*, *Helicobacter*, *Clostridia*, *bacteroides*, *Escherichia*, *Measles virus* etc.

ii) *Psychosocial factors*: It has been observed that individuals who are unduly sensitive, dependent on others and unable to express themselves, or some major life events such as illness or death in the family, divorce, interpersonal conflicts etc, suffer from irritable colon or have exacerbation of symptoms.

Patients of IBD in the West have been found to suffer from greater functional impairment than the general population, as assessed by *sickness impact profile* which is a measure of overall psychological and physical functioning.

iii) *Smoking*: Role of smoking in causation of Crohn's disease has been reported.

iv) *Oral contraceptives*: An increased risk to develop Crohn's disease with long-term use of oral contraceptives has been found in some studies but there is no such increased risk for ulcerative colitis.

Consensus hypothesis in *pathogenesis* of IBD combines the role of above three major groups of etiologic factors i.e. in a *genetically predisposed individual*, the effects of exogenous and endogenous host factors result in dysregulation of mucosal immune function, which gets further modified by *certain environmental factors*.

MORPHOLOGIC FEATURES

The morphologic features of Crohn's disease and ulcerative colitis are sufficiently distinctive so as to be classified separately.

CROHN'S DISEASE Crohn's disease may involve any portion of the gastrointestinal tract but affects most commonly 15-25 cm of the terminal ileum which may extend into the caecum and sometimes into the ascending colon:

Grossly, characteristic feature is the multiple, well-demarcated segmental bowel involvement with intervening uninvolved 'skip areas'. The wall of the affected bowel segment is thick and hard, resembling a 'hose pipe'. Serosa may be studded with minute granulomas. The lumen of the affected segment is markedly narrowed. The mucosa shows 'serpiginous ulcers', while intervening surviving mucosa is swollen giving 'cobblestone appearance'. There may be deep fissuring into the bowel wall (**Fig. 18.25**).

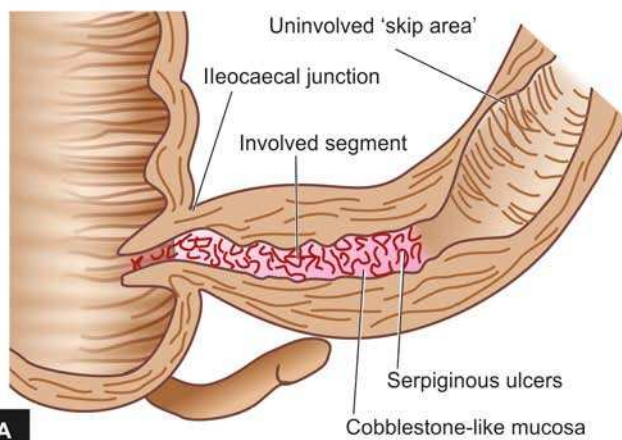

Figure 18.25 Crohn's disease of the terminal ileum. A, The lesions are characteristically segmental with intervening uninvolved 'skip areas'. The bowel wall is thickened and the lumen narrowed, giving hose-pipe appearance. Serpiginous ulcers, some deep fissures and swollen intervening surviving mucosa giving 'cobblestone appearance', are present. B, The specimen of small intestine is shown in longitudinal section along with a segment in cross-section. External surface shows increased mesenteric fat, thickened wall and narrow lumen. Luminal surface of longitudinal cut section shows segment of thickened wall with narrow lumen which is better appreciated in cross-section (arrow) while intervening areas of the bowel are uninvolved or skipped.

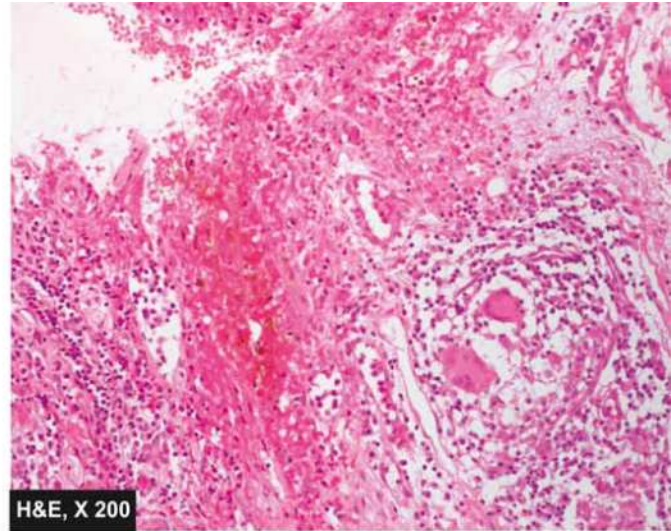

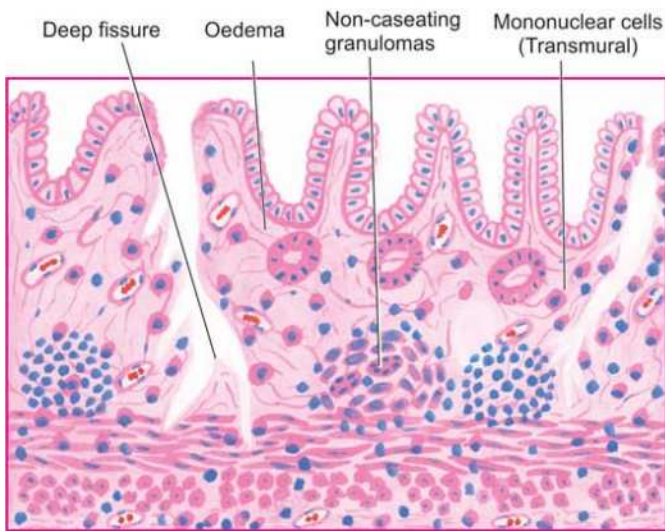

Figure 18.26 Crohn's disease of the ileum. The histological features present are: transmural chronic inflammatory cell infiltration, deep fissures into the bowel wall, submucosal widening due to oedema, some prominent lymphoid follicles and a few non-caseating epithelioid cell granulomas in the bowel wall.

Histologically, the characteristic features are as follows (**Fig. 18.26**):

1. *Transmural inflammatory cell infiltrate* consisting of chronic inflammatory cells (lymphocytes, plasma cells and macrophages) is the classical microscopic feature.
2. *Non-caseating, sarcoid-like granulomas* are present in all the layers of the affected bowel wall in 60% of cases and may even be seen in the regional lymph nodes.
3. There is *patchy ulceration* of the mucosa which may take the form of deep fissures, accompanied by inflammatory infiltrate of lymphocytes and plasma cells.
4. There is *widening of the submucosa* due to oedema and foci of lymphoid aggregates.
5. In more *chronic cases*, fibrosis becomes increasingly prominent in all the layers disrupting muscular layer.

ULCERATIVE COLITIS Classically, ulcerative colitis begins in the rectum, and in continuity extends upwards into the sigmoid colon, descending colon, transverse colon, and sometimes may involve the entire colon. The colonic contents may rarely backflow into the terminal ileum in continuity, causing '*back-wash ileitis*' in about 10% of cases.

Grossly, the characteristic feature is the continuous involvement of the rectum and colon without any uninvolved skip areas compared to Crohn's disease. The appearance of colon may vary depending upon the stage and intensity of the disease because of remissions and exacerbations. Mucosa shows linear and superficial ulcers, usually not penetrating the muscular layer. The intervening intact mucosa may form inflammatory 'pseudopolyps.' The muscle layer is thickened due to contraction, producing shortening and narrowing of the affected colon with loss of normal haustral folds giving 'garden-hose appearance' (**Fig. 18.27**).

Histologically, ulcerative colitis because of remission and exacerbations, is characterised by alternating 'active disease process' and 'resolving colitis.' The changes in the 'active disease process' are as under (**Fig. 18.28**):

1. *Crypt distortion, cryptitis* and focal accumulations of neutrophils forming *crypt abscesses*.
2. *Marked congestion, dilatation and haemorrhages* from mucosal capillaries.
3. *Superficial mucosal ulcerations*, usually not penetrating into the muscle coat, except in severe cases, and is accompanied by nonspecific inflammatory cell infiltrate of lymphocytes, plasma cells, neutrophils, some eosinophils and mast cells in the lamina propria.
4. *Goblet cells* are markedly *diminished* in cases of active disease.
5. Areas of *mucosal regeneration and mucodepletion* of lining cells.
6. In long-standing cases, epithelial *cytologic atypia* ranging from mild to marked dysplasia and sometimes developing into carcinoma *in situ* and frank adenocarcinoma.

COMPLICATIONS

Complications of Crohn's disease and ulcerative colitis are as under:

Crohn's disease:

1. *Malabsorption* due to impaired absorption of fat, vitamin B₁₂, proteins and electrolytes from the diseased small bowel.
2. *Fistula formation* may occur in long-standing cases. These may be internal fistulae between the loops of the intestine, or external fistulae such as enterocutaneous, rectal and anal fistulae.
3. *Stricture formation* may occur in chronic cases due to extensive fibrosis in the affected bowel wall.
4. *Development of malignancy* in the small intestine as a late complication of Crohn's disease is rarer than that in ulcerative colitis, but lymphoma may develop more often in Crohn's disease than adenocarcinoma (seen in some long-standing cases of ulcerative colitis).

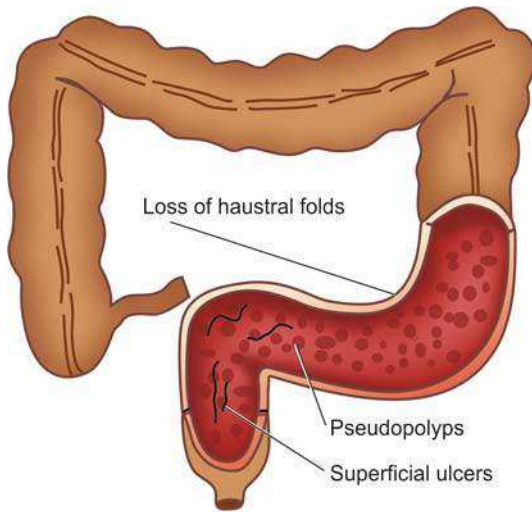

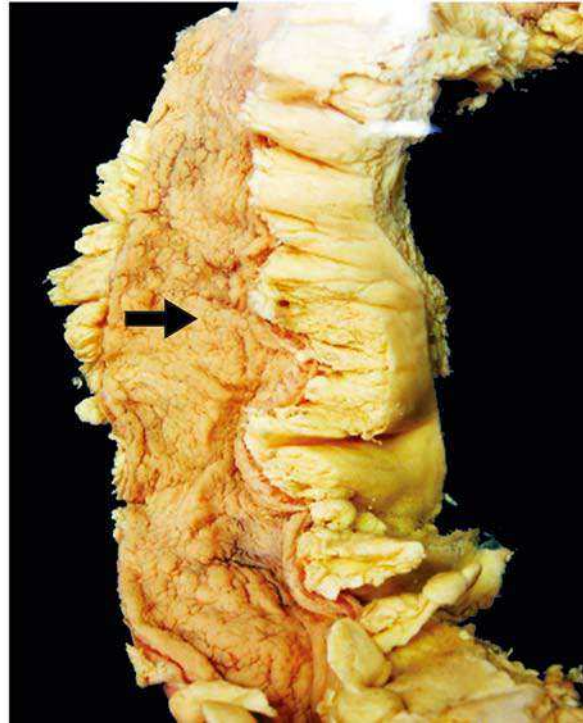

Figure 18.27 Ulcerative colitis. Continuous involvement of the rectum and colon without any uninvolved skip areas. The ulcers are superficial with intervening inflammatory pseudopolyps. The lumen is narrow and the haustral folds are lost giving 'garden-hose appearance'.

Ulcerative colitis:

1. *Toxic megacolon (Fulminant colitis)* is the acute fulminating colitis in which the affected colon is thin-walled and dilated and is prone to perforation and faecal peritonitis. There is deep penetration of the inflammatory cell infiltrate into muscle layer which is disrupted.
2. *Perianal fistula* formation may occur rarely.
3. *Carcinoma* may develop in long-standing cases of ulcerative colitis of more than 10 years duration.
4. *Stricture formation* almost never occurs in ulcerative colitis.

The distinguishing features of the two conditions are summarised in [Table 18.6](#).

GIST BOX 18.9 Inflammatory Bowel Disease

- Inflammatory bowel disease (IBD) includes 2 idiopathic bowel diseases: Crohn's disease (regional enteritis) and ulcerative colitis.
- Crohn's disease is an idiopathic chronic ulcerative IBD, characterised by transmural, non-caseating granulomatous inflammation, affecting most commonly the segment of terminal ileum and/or colon.

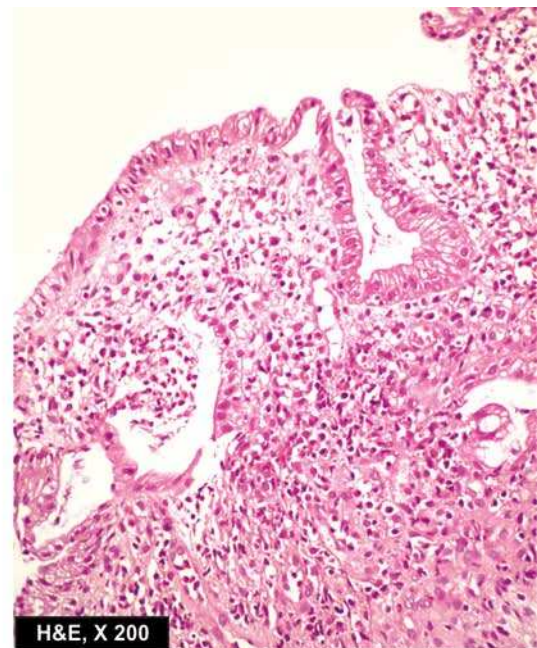

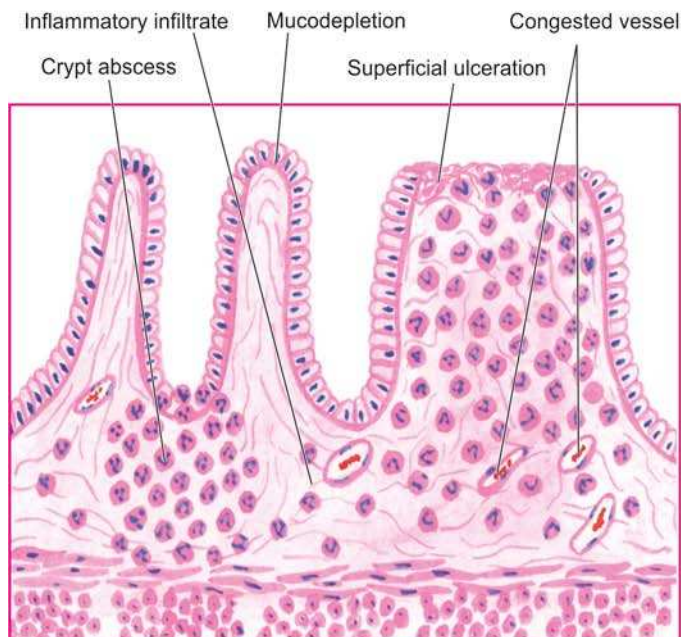

Figure 18.28 Ulcerative colitis in active phase. The microscopic features seen are superficial ulcerations, with mucosal infiltration by inflammatory cells and a 'crypt abscess'.

Table 18.6 Distinguishing features of Crohn's disease and ulcerative colitis.

| FEATURE | CROHN'S DISEASE | ULCERATIVE COLITIS |
|---------------------------------|--|---|
| A. MACROSCOPIC FEATURES | | |
| 1. <i>Distribution</i> | Segmental with skip areas | Continuous without skip areas |
| 2. <i>Location</i> | Commonly terminal ileum and/or ascending colon | Commonly rectum, sigmoid colon and extending upwards |
| 3. <i>Extent</i> | Usually involves the entire thickness of the affected segment of bowel wall | Usually superficial, confined to mucosal layers |
| 4. <i>Ulcers</i> | Serpiginous ulcers, may develop into deep fissures | Superficial mucosal ulcers without fissures |
| 5. <i>Pseudopolyps</i> | Rarely seen | Commonly present |
| 6. <i>Fibrosis</i> | Common | Rare |
| 7. <i>Shortening</i> | Due to fibrosis | Due to contraction of muscularis |
| B. MICROSCOPIC FEATURES | | |
| 1. <i>Depth of inflammation</i> | Typically transmural | Mucosal and submucosal |
| 2. <i>Type of inflammation</i> | Non-caseating granulomas and infiltrate of mononuclear cells (lymphocytes, plasma cells and macrophages) | Crypt abscess and non-specific acute and chronic inflammatory cells (lymphocytes, plasma cells, neutrophils, eosinophils, mast cells) |
| 3. <i>Mucosa</i> | Patchy ulceration | Haemorrhagic mucosa with ulceration |
| 4. <i>Submucosa</i> | Widened due to oedema and lymphoid aggregates | Normal or reduced in width |
| 5. <i>Muscularis</i> | Infiltrated by inflammatory cells | Usually spared except in cases of toxic megacolon |
| 6. <i>Fibrosis</i> | Present | Usually absent |
| C. IMMUNOLOGIC FEATURES | | |
| 1. <i>Lymphocyte type</i> | CD4+ TH1 | CD4+ TH2 |
| 2. <i>Cytokines</i> | INF- γ , TNF, IL-12 | TGF- β , IL-4, IL-5, IL-13 |
| 3. <i>ANCA-P antibodies</i> | Positive in a few | Positive in most |
| D. COMPLICATIONS | | |
| 1. <i>Fistula formation</i> | Internal and external fistulae in 10% cases | Extremely rare |
| 2. <i>Malignant changes</i> | Rare | May occur infrequently in disease of more than 10 years' duration |
| 3. <i>Type of malignancy</i> | Lymphoma more often than carcinoma | Carcinoma more often than lymphoma |
| 4. <i>Fibrous strictures</i> | Common | Never |

- ☐ Ulcerative colitis is an idiopathic acute and chronic ulceroinflammatory colitis affecting chiefly the mucosa and submucosa of the rectum and descending colon.
- ☐ Exact etiology of IBD is not known but genetic, immunologic and a few exogenous factors (microbes, psychology etc) are strongly implicated.
- ☐ Complications of IBD are malabsorption, formation of fistula and stricture, toxic megacolon and development of malignancy in late cases.

INFECTIVE AND OTHER ENTEROCOLITIS

Besides IBD, a variety of other acute and chronic inflammatory conditions affect small bowel (enteritis), large bowel (colitis), or both (enterocolitis); the last named being more common. Hence, all these conditions involving small bowel and/or large

bowel are described together here for better correlation of features.

The various forms of inflammations of the bowel after excluding IBD can be categorised broadly into *infective enterocolitis* and *pseudomembranous enterocolitis*.

INFECTIVE ENTEROCOLITIS

These are a group of acute and chronic inflammatory lesions of small intestine and/or colon caused by microorganisms (bacteria, viruses, fungi, protozoa and helminths). All these are characterised by diarrhoeal syndromes. Pathogenetically speaking, these microorganisms can cause enterocolitis by 2 mechanisms—by *enteroinvasive bacteria* producing ulcerative lesions, and by *enterotoxin-producing bacteria* resulting in non-ulcerative lesions.

A list of common microorganisms producing enterocolitis is presented in **Table 18.7**. A few important forms are described below.

Table 18.7 Micro-organisms causing infective enterocolitis.

| | |
|-------|-------------------------------------|
| A. | BACTERIAL ENTEROCOLITIS |
| 1. | Entero-invasive bacteria |
| (i) | Tuberculosis |
| (ii) | <i>Salmonella</i> |
| (iii) | <i>Campylobacter jejuni</i> |
| (iv) | <i>Shigella</i> |
| (v) | <i>Escherichia coli</i> |

Intestinal Tuberculosis

Intestinal tuberculosis can occur in 3 forms—primary, secondary and hyperplastic caecal tuberculosis.

1. PRIMARY INTESTINAL TUBERCULOSIS Though an uncommon disease in the developed countries of the world, primary tuberculosis of the ileocaecal region is quite common in developing countries including India. In the pre-pasteurisation era, it used to occur by ingestion of unpasteurised cow's milk infected with *Mycobacterium bovis*. But now-a-days due to control of tuberculosis in cattle and pasteurisation of milk, virtually all cases of intestinal tuberculosis are caused by *M. tuberculosis*. The predominant changes are in the mesenteric lymph nodes without any significant intestinal lesion.

Grossly, the affected lymph nodes are enlarged, matted and caseous (tabes mesenterica). Eventually, there is healing by fibrosis and calcification (Fig. 18.29,A).

Microscopically, in the initial stage, there is primary complex or Ghon's focus in the intestinal mucosa as occurs elsewhere in primary tuberculous infection (page 142). Subsequently, the mesenteric lymph nodes are affected which show typical tuberculous granulomatous inflammatory reaction with caseation necrosis. Tuberculous peritonitis may occur due to spread of the infection.

2. SECONDARY INTESTINAL TUBERCULOSIS Self-swallowing of sputum in patients with active pulmonary tuberculosis may cause secondary intestinal tuberculosis, most commonly in the terminal ileum and rarely in the colon.

Grossly, the intestinal lesions are prominent than the lesions in regional lymph nodes as in secondary pulmonary tuberculosis (Fig. 18.29,B). The lesions begin in the Peyer's patches or the lymphoid follicles with formation of small ulcers that spread through the lymphatics to form large ulcers which are *transverse to the long axis of the bowel*, (c.f. typhoid ulcers of small intestine, described below). These ulcers may be coated with caseous material. Serosa may be studded with visible tubercles. In advanced cases, transverse fibrous strictures and intestinal obstruction are seen (Fig. 18.30,A, B).

Histologically, the tuberculous lesions in the intestine are similar to those observed elsewhere i.e. presence of tubercles. Mucosa and submucosa show ulceration and the muscularis may be replaced by variable degree of fibrosis (Fig. 18.30,C). Tuberculous peritonitis may be observed.

3. HYPERPLASTIC ILEOCAECAL TUBERCULOSIS This is a variant of occurring secondary to pulmonary tuberculosis.

Grossly, the terminal ileum, caecum and/or ascending colon are thick-walled with mucosal ulceration. Clinically, the lesion is palpable and may be mistaken for carcinoma (Fig. 18.29,C).

Microscopically, the presence of caseating tubercles distinguishes the condition from Crohn's disease in which granulomas are non-caseating. Besides, bacteriological evidence by culture or animal inoculation and Mantoux test are helpful in differential diagnosis of the two conditions.

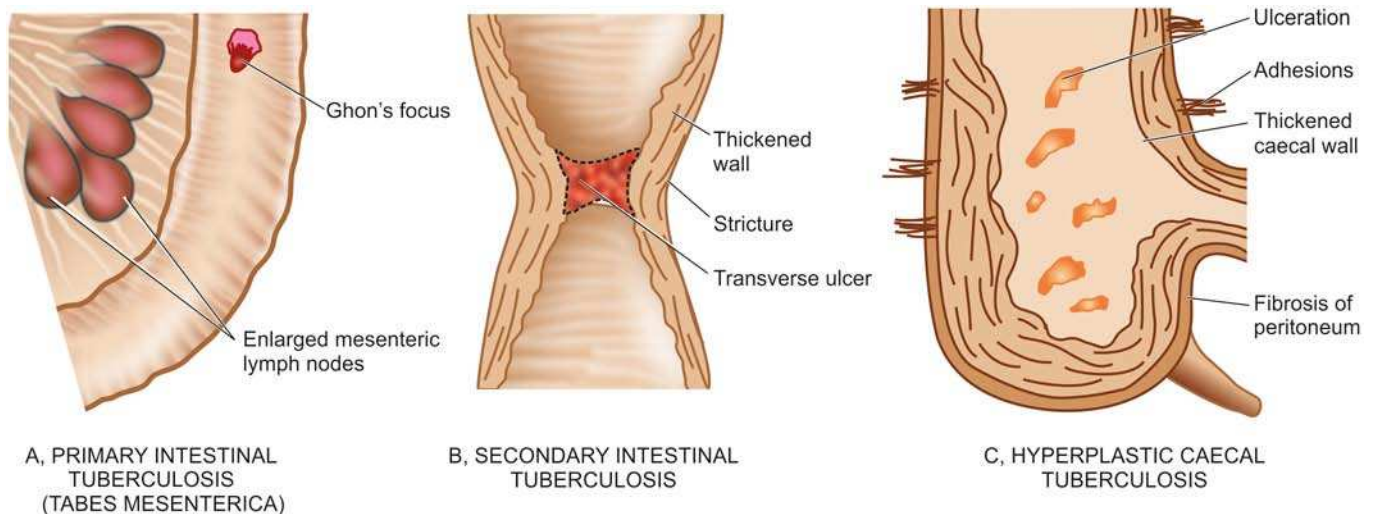

Figure 18.29 Intestinal tuberculosis, three patterns.

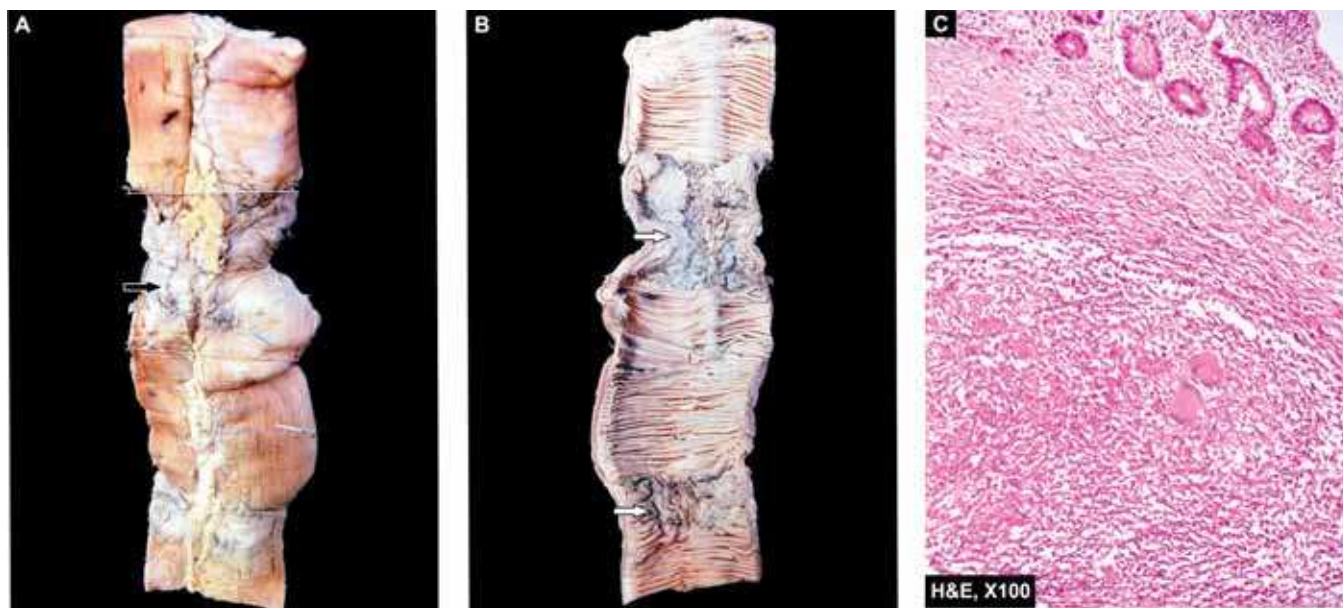

Figure 18.30 Intestinal tuberculosis. A, The external surface of small intestine shows stricture and a lymph node in section having caseation necrosis (arrow). B, The lumen shows characteristic transverse ulcers and two strictures (arrow). The wall of intestine in the area of narrowed lumen is thickened. C, Microscopy of intestine shows caseating epithelioid cell granulomas in the intestinal wall.

Enteric Fever

The term enteric fever is used to describe acute infection caused by *Salmonella typhi* (typhoid fever) or *Salmonella paratyphi* (paratyphoid fever). Besides these 2 salmonellae, *Salmonella typhimurium* causes food poisoning.

PATHOGENESIS The typhoid bacilli are ingested through contaminated food or water. During the initial asymptomatic incubation period of about 2 weeks, the bacilli invade the lymphoid follicles and Peyer's patches of the small intestine and proliferate. Following this, the bacilli invade the bloodstream causing bacteraemia, and the characteristic clinical features of the disease like continuous rise in temperature and 'rose spots' on the skin are observed. Immunological reactions (Widal's test) begin after about 10 days and peak titres are seen by the end of the third week. Eventually, the bacilli are localised in the intestinal lymphoid tissue (producing typhoid intestinal lesions), in the mesenteric lymph nodes (leading to haemorrhagic lymphadenitis), in the liver (causing foci of parenchymal necrosis), in the gallbladder (producing typhoid cholecystitis), and in the spleen (resulting in splenic reactive hyperplasia).

MORPHOLOGIC FEATURES The lesions are observed in the intestines as well as in other organs.

1. INTESTINAL LESIONS *Grossly*, terminal ileum is affected most often, but lesions may be seen in the jejunum and colon. Peyer's patches show oval typhoid ulcers with their *long axis along the length of the bowel* (c.f. tuberculous ulcers of small intestine, described above). The base of the ulcers is black due to sloughed mucosa. The margins of the ulcers are slightly raised due to inflammatory oedema and cellular proliferation. There is never significant fibrosis and hence fibrous stenosis seldom occurs in healed typhoid lesions. The regional lymph nodes are invariably enlarged (**Fig. 18.31,A**).

Microscopically, there is hyperaemia, oedema and cellular proliferation consisting of phagocytic histiocytes (showing characteristic erythrophagocytosis), lymphocytes and plasma cells. Though enteric fever is an example of acute inflammation, neutrophils are invariably absent from the cellular infiltrate and this is reflected in the leucopenia with neutropenia and relative lymphocytosis in the peripheral blood (**Fig. 18.31,B**).

The main **complications** of the intestinal lesions of typhoid are perforation of the ulcers and haemorrhage.

2. OTHER LESIONS Besides the intestinal involvement, various other organs and tissues showing pathological changes in enteric fever are as under:

- i) *Mesenteric lymph nodes*—haemorrhagic lymphadenitis.
- ii) *Liver*—foci of parenchymal necrosis.
- iii) *Gallbladder*—typhoid cholecystitis.
- iv) *Spleen*—splenomegaly with reactive hyperplasia.
- v) *Kidneys*—nephritis.
- vi) *Abdominal muscles*—Zenker's degeneration.
- vii) *Joints*—arthritis.
- viii) *Bones*—osteitis.
- ix) *Meninges*—Meningitis.
- x) *Testis*—Orchitis.

Persistence of organism in the gallbladder or urinary tract may result in passage of organisms in the faeces or urine creating a 'carrier state' which is a source of infection to others.

Bacterial Food Poisoning

This is a form of acute bacterial illness that occurs following ingestion of food or water contaminated with bacteria other than those that cause specific acute intestinal infections like typhoid, paratyphoid, cholera or dysentery bacilli. The illness results from either bacterial invasion or bacterial toxicogenic effect on the bowel.

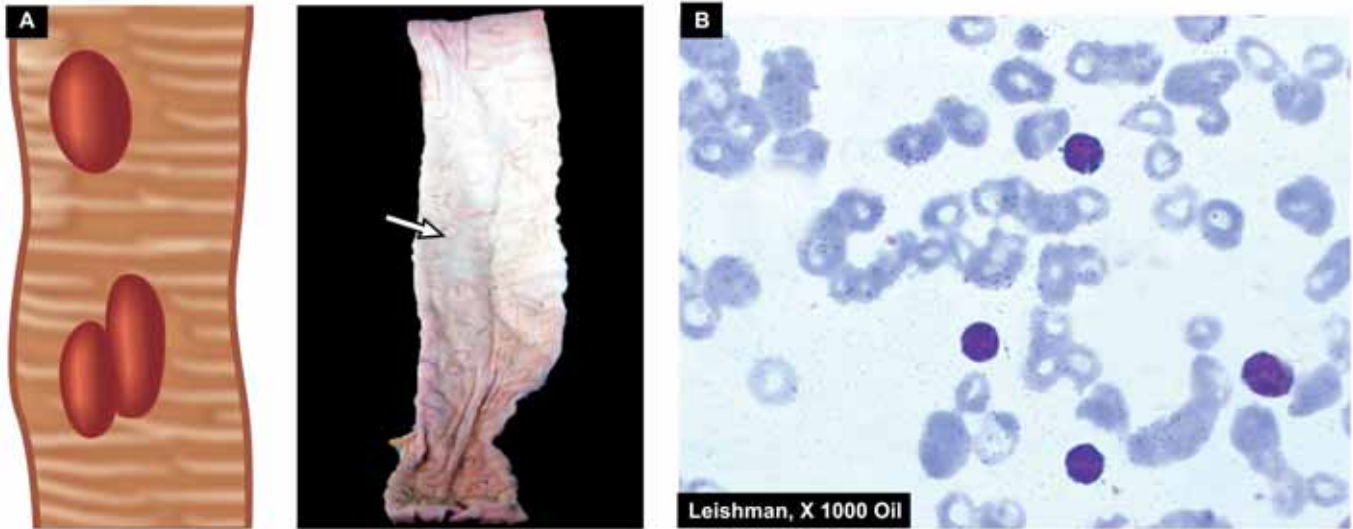

Figure 18.31 A, Typhoid ulcers in the small intestine appear characteristically oval with their long axis parallel to the long axis of the bowel. B, Blood picture in typhoid fever showing neutropenia and relative lymphocytosis.

The commonest causes of bacterial food poisoning resulting in enteritis or enterocolitis are as under:

- 1. Staphylococcal food poisoning** *Staphylococcus aureus* infection acquired from contaminated food produces either *mild food poisoning* by enterotoxins, or may cause more severe form of the illness called *pseudomembranous enterocolitis* described below. Staphylococcal food poisoning occurs due to liberation of enterotoxins by the bacteria.
- 2. Clostridial food poisoning** Infection with anaerobic organisms *Clostridium welchii*, following consumption of contaminated meat results in acute food poisoning (page 172). The illness occurs both by bacterial invasion as well as by toxins.
- 3. Botulism** This is a severe form of paralysing illness caused by ingestion of organism, *Clostridium botulinum*, which produces neurotoxin.
- 4. Salmonella food poisoning (Salmonellosis)** This is an infection (and not caused by toxins) occurring due to food contaminated by *S. typhimurium* or *S. enteritidis*. The condition manifests with fever, vomiting, and diarrhoea. Death may result from depletion of water and electrolytes.

Dysenteries

The term 'dysentery' is used to mean diarrhoea with abdominal cramps, tenesmus and passage of mucus in the stools. Based on etiology, there are 2 main forms of dysenteries—bacillary and amoebic.

1. BACILLARY DYSENTERY Bacillary dysentery is the term used for infection by *Shigella* species: *S. dysenteriae*, *S. flexneri*, *S. boydii* and *S. sonnei*. Infection occurs by faeco-oral route and is seen with poor personal hygiene, in densely populated areas, and with contaminated food and water. The common housefly plays a role in spread of infection.

Grossly, the lesions are mainly found in the colon and occasionally in the ileum. Superficial transverse ulcerations of mucosa of the bowel wall occur in the region of lymphoid

follicles but perforation is seldom seen. The intervening intact mucosa is hyperaemic and oedematous. Following recovery from the acute attack, complete healing usually takes place.

Microscopically, the mucosa overlying the lymphoid follicles is necrosed. The surrounding mucosa shows congestion, oedema and infiltration by neutrophils and lymphocytes. The mucosa may be covered by greyish-yellow '*pseudomembrane*' composed of fibrinosuppurative exudate.

The *complications* of bacillary dysentery are haemorrhage, perforation, stenosis, polyarthritides and iridocyclitis.

2. AMOEBIC DYSENTERY This is due to infection by *Entamoeba histolytica*. It is more prevalent in the tropical countries and primarily affects the large intestine. Infection occurs from ingestion of cyst form of the parasite. The cyst wall is dissolved in the small intestine from where the liberated amoebae pass into the large intestine. Here, they invade the epithelium of the mucosa, reach the submucosa and produce the characteristic flask-shaped ulcers (page 178).

Grossly, early intestinal lesions appear as small areas of elevation on the mucosal surface. In advanced cases, typical flask-shaped ulcers having narrow neck and broad base are seen. They are more conspicuous in the caecum, rectum and in the flexures (**Fig. 18.32**).

Microscopically, the ulcerated area shows chronic inflammatory reaction consisting of lymphocytes, plasma cells, macrophages and eosinophils. The trophozoites of *Entamoeba* are seen in the inflammatory exudate and are concentrated at the advancing margin of the lesion. Intestinal amoebae characteristically have ingested red cells in their cytoplasm. Oedema and vascular congestion are present in the area surrounding the ulcers.

Complications of intestinal amoebic ulcers are: amoebic liver abscess or amoebic hepatitis, perforation, haemorrhage and formation of amoeboma which is a tumour-like mass.

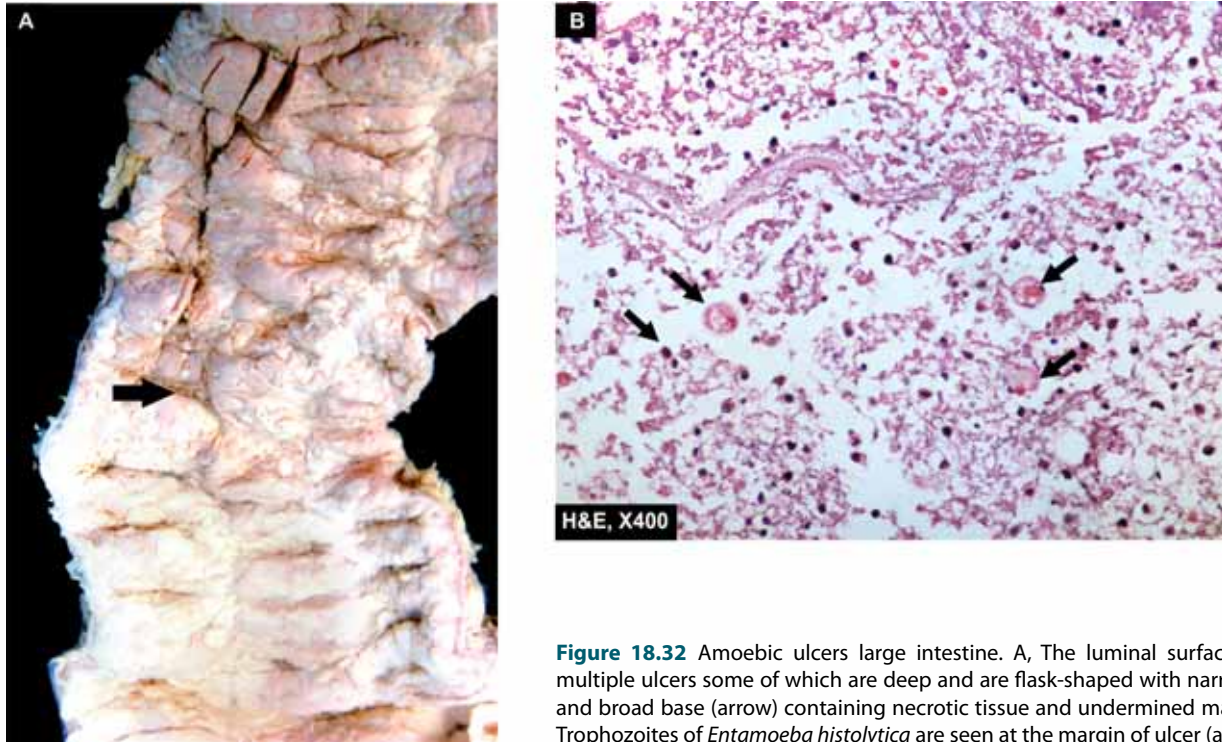

Figure 18.32 Amoebic ulcers large intestine. A, The luminal surface shows multiple ulcers some of which are deep and are flask-shaped with narrow neck and broad base (arrow) containing necrotic tissue and undermined margins. B, Trophozoites of *Entamoeba histolytica* are seen at the margin of ulcer (arrow).

PSEUDOMEMBRANOUS ENTEROCOLITIS (ANTIBIOTIC-ASSOCIATED DIARRHOEA)

Pseudomembranous enterocolitis is a form of acute inflammation of colon and/or small intestine characterised by formation of 'pseudomembrane' over the site of mucosal injury.

ETIOLOGY Numerous studies have established the overgrowth of *Clostridium difficile* with production of its toxin in the etiology of antibiotic-associated diarrhoea culminating in pseudomembranous colitis. Oral antibiotics such as clindamycin, ampicillin and the cephalosporins are more often (20%) associated with antibiotic-associated diarrhoea, while development of pseudomembranous colitis may occur in 1-10% cases.

Pseudomembrane formation may also occur in various other conditions as under:

1. Staphylococcal enterocolitis
2. Bacillary (*Shigella*) dysentery
3. *Candida* enterocolitis

MORPHOLOGIC FEATURES *Grossly*, the lesions may be confined, to the large intestine or small intestine, or both may be involved. The mucosa of the bowel is covered by patchy, raised yellow-white plaques. Elsewhere, the mucosa is congested and may show small mucosal ulcerations.

Microscopically, the 'pseudomembrane' is composed of network of fibrin and mucus, in which are entangled inflammatory cells and mucosal epithelial cells. There is focal necrosis of surface epithelial cells. The lamina propria contains inflammatory cell infiltrate, mainly neutrophils. The submucosa has congested capillaries and may show microthrombi. The inflammation spreads laterally rather than deeply.

GIST BOX 18.10 Infective and Other Enterocolitis

- ▣ Infective enterocolitis are caused by bacteria, viruses, fungi, protozoa and metazoa.
- ▣ Intestinal tuberculosis can occur as primary, secondary or hyperplastic ileocaecal type. In a classic case, there are multiple transverse ulcers and strictures causing intestinal obstruction.
- ▣ Enteric fever is acute infection caused by *Salmonella* (typhoid fever). There are oval ulcers along the long axis of the small intestine and may be complicated by perforation.
- ▣ Bacterial food poisoning may be caused by staphylococci, *Clostridia*, and *Salmonella*.
- ▣ Dysentery is diarrhoea with abdominal cramps, tenesmus and passage of mucus in the stools, and may be bacillary and amoebic.
- ▣ Pseudomembranous enterocolitis is the acute inflammation of colon and/or small intestine with formation of 'pseudomembrane'. There is often overgrowth of *Clostridium difficile*.

MALABSORPTION SYNDROME

DEFINITION AND CLASSIFICATION

The malabsorption syndrome (MAS) is characterised by impaired intestinal absorption of nutrients especially of fat; some other substances are proteins, carbohydrates, vitamins and minerals. MAS is subdivided into 2 broad groups:

- ◆ **Primary MAS**, which is due to primary deficiency of the absorptive mucosal surface and of the associated enzymes.

Table 18.8 Classification of malabsorption syndrome.

| | |
|-------|--|
| I. | PRIMARY MALABSORPTION |
| 1. | Coeliac sprue |
| 2. | Collagenous sprue |
| 3. | Tropical sprue |
| 4. | Whipple's disease |
| 5. | Disaccharidase deficiency |
| 6. | Allergic and eosinophilic gastroenteritis |
| II. | SECONDARY MALABSORPTION |
| 1. | <i>Impaired digestion</i> |
| (i) | Mucosal damage e.g. in tuberculosis, Crohn's disease, lymphoma, amyloidosis, radiation injury, systemic sclerosis |
| (ii) | Hepatic and pancreatic insufficiency |
| (iii) | Resection of bowel |
| (iv) | Drugs e.g. methotrexate, neomycin, phenindione etc. |
| 2. | <i>Impaired absorption</i> |
| (i) | Short or stagnant bowel (blind loop syndrome) from surgery or disease resulting in abnormal proliferation of microbial flora |
| (ii) | Acute infectious enteritis |
| (iii) | Parasitoses e.g. Giardia, Strongyloides, hookworms |
| 3. | <i>Impaired transport</i> |
| (i) | Lymphatic obstruction e.g. in lymphoma tuberculosis, lymph-angiectasia |
| (ii) | Abetalipoproteinaemia |

◆ **Secondary MAS**, in which mucosal changes result secondary to other factors such as diseases, surgery, trauma and drugs.

Each of the two main groups has a number of causes listed in **Table 18.8**.

CLINICAL FEATURES

The clinical manifestations of MAS vary according to the underlying cause. However, some common symptoms are as follows:

1. Steatorrhoea (pale, bulky, foul-smelling stools)
2. Chronic diarrhoea
3. Abdominal distension
4. Barborygmi and flatulence
5. Anorexia
6. Weight loss
7. Muscle wasting
8. Dehydration
9. Hypotension
10. Specific malnutrition and vitamin deficiencies depending upon the cause.

INVESTIGATIONS

When MAS is suspected on clinical grounds, the following investigations (laboratory tests and endoscopic biopsy) may be carried out to confirm it:

I. LABORATORY TESTS

1. Tests for fat malabsorption:

- i) Faecal analysis for fat content
- ii) Microscopic analysis for faecal fat
- iii) Blood lipid levels after a fatty meal
- iv) Tests based on absorption of radioactive-labelled fat.

2. Tests for protein malabsorption:

- i) Bile acid malabsorption
- ii) Radioactive-labelled glycine breath test.
- iii) Prothrombin time (vitamin K deficiency)
- iv) Secretin and other pancreatic tests.

3. Tests for carbohydrate malabsorption:

- i) D-xylose tolerance test
- ii) Lactose tolerance test
- iii) Hydrogen breath test
- iv) Bile acid breath test

4. Vitamin B₁₂ malabsorption:

- i) Schilling test (page 284).

II. INTESTINAL MUCOSAL BIOPSY

Mucosal biopsy of small intestine is essential for making the diagnosis of MAS and also evaluation of a patient on follow-up. The availability of endoscopes has enabled easy viewing of affected mucosa directly and taking mucosal biopsy under vision; this has largely replaced the earlier per-oral Crosby-Kugler capsule biopsy of small intestine. The biopsy should first be examined under dissecting microscope before histologic sectioning.

Normal villous (Fig. 18.33,A) Under the dissecting microscope, the normal jejunal mucosa has tall, slender, finger-shaped or leaf-shaped villi. It is lined by tall columnar absorptive epithelium and has scattered lymphocytes in the lamina propria.

Villous atrophy Variable degree of flattening of intestinal mucosa in MAS is the commonest pathological change in mucosal pattern and is referred to as villous atrophy. It may be of 2 types—partial and subtotal/total type.

◆ *Partial villous atrophy* is the mild form of the lesion in which villi fuse with each other and thus become short and broad, commonly called as convolutions and irregular ridges (**Fig. 18.33,B**). The epithelial cells show compensatory hyperplasia suggesting a turnover of these cells (**Fig. 18.34,A**). Lamina propria shows increased cellular infiltrate, predominantly of plasma cells.

Partial villous atrophy is commonly found in children and adults with diarrhoea, parasitic infestations, Crohn's disease, ulcerative colitis and malabsorption due to drugs and radiation injury.

◆ *Subtotal/Total villous atrophy* is the severe form of the lesion in which there is flattening of mucosa due to more advanced villous fusion (**Fig. 18.33,C**). The surface epithelium is cuboidal and there is increased plasma cell infiltrate in the lamina propria (**Fig. 18.34,B**).

Subtotal and total villous atrophy is exhibited by a number of conditions such as nontropical sprue, tropical sprue, intestinal lymphomas, carcinoma, protein-calorie malnutrition etc.

IMPORTANT TYPES OF MAS

Coeliac Sprue (Non-tropical Sprue, Gluten-Sensitive Enteropathy, Idiopathic Steatorrhoea)

This is the most important cause of primary malabsorption occurring in temperate climates. The condition is characterised by significant loss of villi in the small intestine and therefore

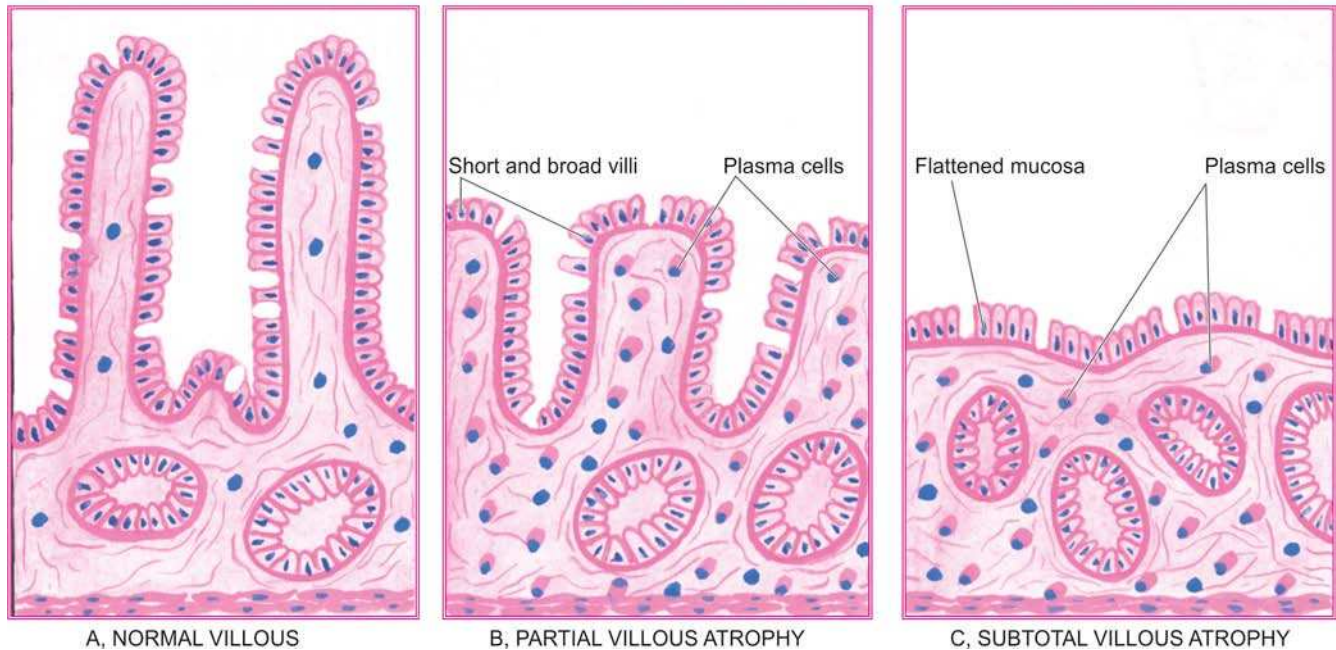

Figure 18.33 Jejunal biopsy diagrammatic appearance in malabsorption syndrome.

diminished absorptive surface area. The condition occurs in 2 forms:

Childhood form, seen in infants and children and is commonly referred to as *coeliac disease*.

Adult form, seen in adolescents and early adult life and used to be called *idiopathic steatorrhea*.

In either case, there is genetic abnormality resulting in sensitivity to gluten (a protein) and its derivative, gliadin, present in diets such as grains of wheat, barley and rye. Serum antibodies—IgA antigliadin and IgA antiendomysial, have been found but is not known whether these antibodies are primary or appear secondary to tissue damage.

The symptoms are usually relieved on elimination of gluten from the diet. The role of heredity is further supported by the observation of familial incidence and HLA association of the disease. Exact pathogenesis of the condition is not clear. However, following hypotheses have been proposed in causing mucosal cell damage:

1. *Hypersensitivity reaction* as seen by gluten-stimulated antibodies.
2. Toxic effect of gluten due to *inherited enzyme deficiency* in the mucosal cells.

Histologically, there are no differences in the pathological findings in children and adults. There is variable degree of flattening of the mucosa, particularly of the upper jejunum, and to some extent of the duodenum and ileum. The surface epithelial cells are cuboidal or low columnar type. There may be *partial villous atrophy* which is replacement of normal villous pattern by convolutions, or *subtotal villous atrophy* characterised by flat mucosal surface. Lamina propria shows increased number of plasma cells and lymphocytes (**Fig. 18.34**).

The major sequela of long-term coeliac sprue is increased incidence of intestinal carcinoma in these cases.

Collagenous Sprue

This entity is regarded as the end-result of coeliac sprue in which the villi are totally absent (*total villous atrophy*) and there are unique and diagnostic broad bands of collagen under the basal lamina of surface epithelium. The condition is refractory to any treatment and the course is generally fatal. Some workers consider collagenous sprue as a variant of coeliac sprue without classifying it separately.

Tropical Sprue

This disease, as the name suggests, occurs in individuals living in or visiting tropical areas such as Caribbean countries, South India, Sri Lanka and Hong Kong. Pathogenesis of the condition is not clear but there is evidence to support enterotoxin

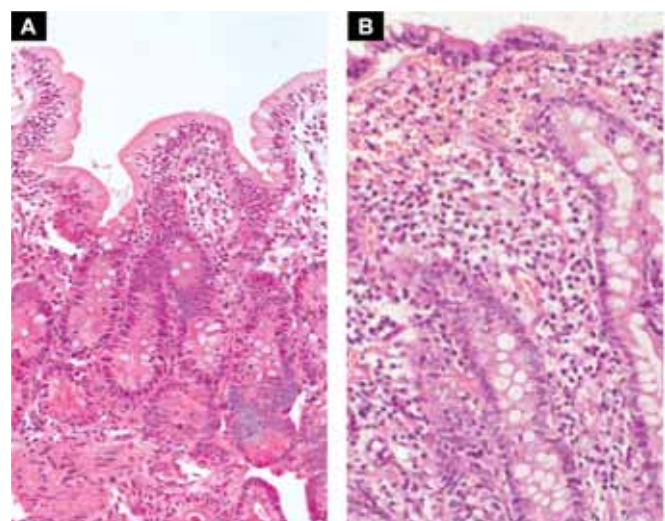

Figure 18.34 A, *Partial villous atrophy*. There is shortening and blunting of the villi with reduction in their height. There is crypt hyperplasia. B, *Subtotal villous atrophy*. There is near total flattening of the villi and crypt hyperplasia.

production by some strains of *E. coli* which causes the intestinal injury. Severe cases are characterised by additional features such as macrocytic anaemia, glossitis and emaciation due to intestinal malabsorption of vitamin B₁₂ and folate.

Histologically, there is usually *partial villous atrophy* and sometimes *subtotal atrophy*.

The lesions are relieved by removal of the patient from the tropical area and by oral administration of antibiotics but gluten-free diet has no role in improvement.

Whipple's Disease (Intestinal Lipodystrophy)

This is an uncommon bacterial disease involving not only the intestines but also various other systems such as central nervous system, heart, blood vessels, skin, joints, lungs, liver, spleen and kidneys. The disease is more common in males in 4th to 5th decades of life. Patients may present with features of malabsorption or may have atypical presentation in the form of migratory polyarthritides, neurological disturbances and focal hyperpigmentation of the skin.

Histologically, the affected tissues show presence of characteristic macrophages containing PAS-positive granules and rod-shaped micro-organisms (Whipple's bacilli). These macrophages are predominantly present in the lamina propria of the small intestine and mesenteric lymph nodes.

Patients respond very well to oral antibiotic therapy.

Protein-Losing Enteropathies

A number of disorders of the gastrointestinal tract are accompanied by excessive protein loss without concomitant increase in protein synthesis, thus resulting in hypoproteinaemia. These diseases are listed below:

- i) Whipple's disease
- ii) Crohn's disease
- iii) Ulcerative colitis
- iv) Sprue
- v) Intestinal lymphangiectasia
- vi) Ménétrier's disease (Hypertrophic gastritis).

GIST BOX 18.11 Malabsorption Syndrome (MAS)

- ▣ MAS is characterised by impaired intestinal absorption of fat; some other substances are proteins, carbohydrates, vitamins and minerals.
- ▣ Clinically, common symptom of MAS is steatorrhoea i.e. pale, bulky, foul-smelling stools.
- ▣ Mucosal biopsy of small intestine is essential for making the diagnosis of MAS. It shows presence of villous atrophy varying from partial to near total.
- ▣ Sprue of various types causes MAS e.g. celiac (gluten-sensitive), tropical, collagenous.

SMALL INTESTINAL TUMOURS

Although small intestine is about 6 meter long, but for obscure reasons, benign as well as malignant tumours in it are surprisingly rare.

◆ Most common *benign tumours*, in descending order of frequency, are: gastrointestinal stromal tumours (GIST) (page 538), leiomyomas, adenomas and vascular tumours (haemangioma, lymphangioma).

◆ Amongst the *malignant tumours*, the most frequently encountered, in descending frequency, are: carcinoid tumours, lymphomas and adenocarcinoma.

All these tumours are identical in morphology to those seen elsewhere in the alimentary tract. Carcinoid tumour, a peculiar neoplasm most common in the midgut, and lymphoma are described below.

CARCINOID TUMOUR (ARGENTAFFINOMA)

Carcinoid tumour or argentaffinoma is a generic term applied to tumours originating from endocrine cells (*synonyms*: argentaffin cells, Kulchitsky cells, enterochromaffin cells) belonging to APUD cell system and are therefore also called as apudomas (page 782). The endocrine cells are distributed throughout the mucosa of GI tract. These cells have secretory granules which stain positively with silver salts (argentaffin granules) or many stain after addition of exogenous reducing agent (non-argentaffin or argyrophil granules). Accordingly, carcinoid tumour may be argentaffin or argyrophil type. Depending upon the embryologic derivation of the tissues where the tumour is located, these are classified as foregut, midgut, and hindgut carcinoids.

◆ **Midgut carcinoids**, seen in terminal ileum and appendix are the most common (60-80%) and are more often argentaffin positive.

◆ **Hindgut carcinoids**, occurring in rectum and colon are more commonly argyrophil type, and comprise about 10-20% of carcinoids.

◆ **Foregut carcinoids**, located in the stomach, duodenum and oesophagus are also argyrophil type and are encountered as frequently as in the hindgut (10-20%).

Other uncommon locations are the bronchus, trachea, gallbladder, and Meckel's diverticulum.

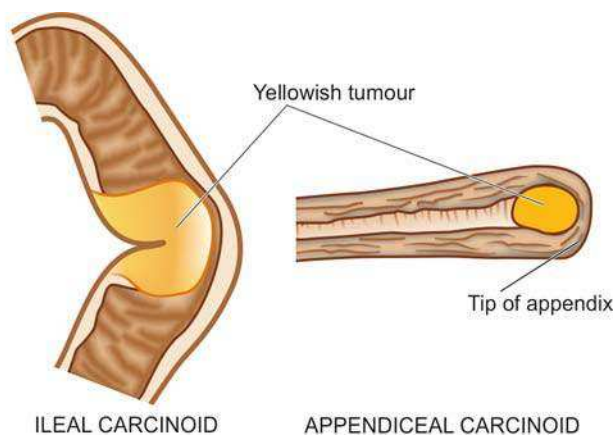

Appendix and terminal ileum, the two most common sites for carcinoids, depict variation in their age and sex incidence and biologic behaviour:

◆ **Appendiceal carcinoids**, occur more frequently in 3rd and 4th decades of life without any sex predilection, are often solitary and behave as locally malignant tumours.

◆ **Ileal carcinoids**, on the other hand, are seen more often in later age (7th decade) with female preponderance, are more commonly multiple and behave like metastasising carcinomas.

MORPHOLOGIC FEATURES *Grossly*, all carcinoids are small, button-like submucosal elevations with intact or ulcerated overlying mucosa. They are usually small; those larger than 2 cm are more often metastasising. Ileal and gastric carcinoids are commonly multiple, whereas appendiceal carcinoids commonly involve the tip of the organ and are solitary (**Fig. 18.35**). Cut section of all the carcinoids is bright yellow.

Histologically, the tumour cells may be arranged in a variety of patterns—solid nests, sheets, cords, trabeculae and clusters, all of which show characteristic palisading of the peripheral cells. Acinar arrangement and rosettes are rarely seen. The tumour cells are classically small, monotonous,

ILEAL CARCINOID

APPENDICEAL CARCINOID

Figure 18.35 Carcinoid tumour. Gross appearance at common locations in longitudinal section.

having uniform nuclei and poorly-defined cell boundaries (**Fig. 18.36**). The argentaffin carcinoids show eosinophilic granules in the cytoplasm which stain positively by the argentaffin reaction. Mitotic figures are rare. However, the cytologic features are a poor guide for distinguishing clinically benign from malignant behaviour of the tumour, but all carcinoids infiltrate the bowel wall.

CARCINOID SYNDROME Carcinoid tumours that metastasise, especially to the liver, are sometimes associated with the carcinoid syndrome. The syndrome consists of the following features:

1. Intermittent attacks of flushing of the skin of face
2. Episodes of watery diarrhoea
3. Abdominal pain
4. Attacks of dyspnoea due to bronchospasm
5. Right-sided heart failure due to involvement of tricuspid and pulmonary valves and endocardium (page 431).

A number of *secretory products* in a functioning carcinoid tumour have been demonstrated:

- i) 5-Hydroxytryptamine (5-HT, serotonin)
- ii) 5-Hydroxytryptophan

- iii) 5-Hydroxy-indole acetic acid (5-HIAA)
- iv) Histamine
- v) Kallikrein
- vi) Bradykinin

However, 5-HT and its degradation product, 5-HIAA, are particularly significant in the production of *carcinoid syndrome*. 5-HT, a potent vasodilator and smooth muscle stimulant, is normally synthesised in the endocrine cells of the gut from dietary tryptophan. Tryptophan is first hydroxylated to 5-hydroxytryptophan, then decarboxylated to 5-HT and further oxidised to 5-HIAA by the monoamine oxidase in the liver cells. It is then excreted in the urine. This capacity to synthesise 5-HT and 5-HIAA is markedly elevated in primary and hepatic metastatic carcinoids. Midgut carcinoids have rich decarboxylating enzymes and are thus able to produce large quantities of 5-HT and 5-HIAA, accounting for high frequency of carcinoid syndrome in them. Foregut and hindgut carcinoids, on the other hand, lack decarboxylating enzymes and, therefore, are less often associated with carcinoid syndrome.

LYMPHOMA

Malignant lymphoma of the small intestine has a few peculiarities:

1. *Presence and type of an underlying disorder*: e.g. long-term malabsorption syndrome, AIDS, Crohn's disease.
2. *Primary versus secondary lymphoma*: Extranodal lymphoma is more common in gastrointestinal tract than elsewhere, it is important to rule out spread of primary nodal lymphoma to the intestine.
3. *Type of lymphoma and its cell lineage*: NHL of various types, particularly B-cell type, are the only intestinal lymphomas because Hodgkin's disease in intestine is extremely rare. B-cell NHL in intestine include: immunoproliferative small intestinal disease (IPSID), low-grade B-cell NHL of MALT type, follicular lymphoma, diffuse large B-cell lymphoma (DLBCL), Burkitt's lymphoma, mantle zone lymphoma. T-cell NHL is rare and represents a complication of long-standing sprue.

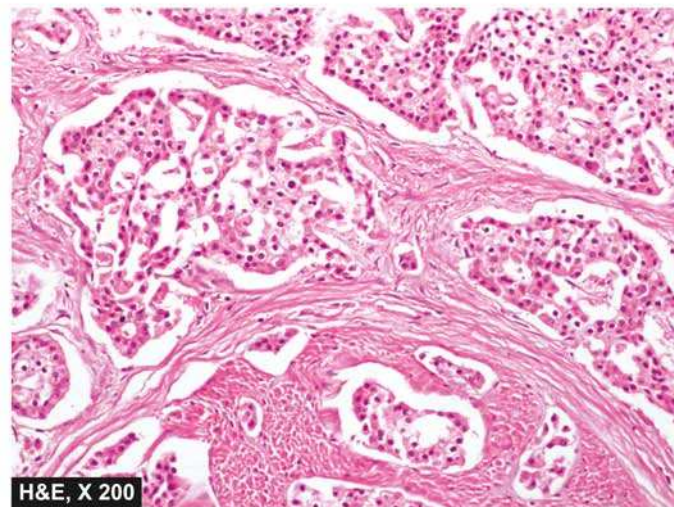

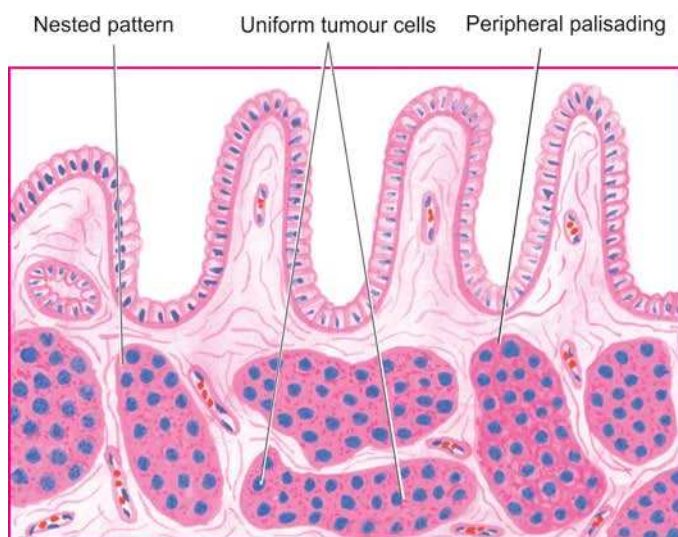

Figure 18.36 Microscopic appearance showing solid masses and trabeculae of uniform, monotonous, small cells with palisading of the peripheral cells.

Figure 18.37 Lymphoma small intestine. The polypoid growth is seen projecting into lumen while the covering mucosa is ulcerated.

Morphology of NHL is identical to its counterpart described in the stomach (page 543) (**Fig. 18.37**).

GIST BOX 18.12 Small Intestinal Tumours

- ▣ Leiomyoma and GIST are examples of benign tumours of small intestine.
- ▣ Carcinoid tumour originates from endocrine cells. It may occur in midgut, hindgut and foregut.
- ▣ Grossly, it is small button-like nodule over mucosa.
- ▣ Microscopically, the tumour cells are monomorphic and have typical endocrine pattern.
- ▣ Non-Hodgkin's lymphoma of B-cell type is another common malignant tumour in small intestine.

APPENDIX

NORMAL STRUCTURE

Appendix is a vestigial organ which serves no useful purpose in human beings but instead becomes the site of trouble at times. It is like a diverticulum of the caecum, usually lying behind the caecum and varies in length from 4 to 20 cm (average 7 cm).

Histologically, appendix has four layers in its wall—*mucosa*, *submucosa*, *muscularis* and *serosa*. The mucosa has patchy distribution of crypts and the submucosa has abundant lymphoid tissue. Argentaffin and non-argentaffin endocrine cells are present in the base of mucosal glands just as in the small intestine. The muscularis of the appendix has two layers (inner circular and outer longitudinal) as elsewhere in the alimentary tract.

Two important diseases involving the appendix are appendicitis and appendiceal carcinoids.

APPENDICITIS

Acute inflammation of the appendix, acute appendicitis, is the most common acute abdominal condition confronting the surgeon. The condition is seen more commonly in older children and young adults, and is uncommon at the extremes of age. The disease is seen more frequently in the West and in affluent societies which may be due to variation in diet—a diet with low bulk or cellulose and high protein intake more often causes appendicitis.

ETIOPATHOGENESIS The most common mechanism is obstruction of the lumen from various etiologic factors that leads to increased intraluminal pressure. This presses upon the blood vessels to produce ischaemic injury which in turn favours the bacterial proliferation and hence acute appendicitis. The common causes of appendicitis are as under:

A. Obstructive:

1. Faecolith
2. Calculi
3. Foreign body
4. Tumour
5. Worms (especially *Enterobius vermicularis*)
6. Diffuse lymphoid hyperplasia, especially in children.

B. Non-obstructive:

1. Haematogenous spread of generalised infection
2. Vascular occlusion
3. Inappropriate diet lacking roughage.

MORPHOLOGIC FEATURES *Grossly*, the appearance depends upon the stage at which the acutely-inflamed appendix is examined. In *early acute appendicitis*, the organ is swollen and serosa shows hyperaemia. In well-developed acute inflammation called *acute suppurative appendicitis*, the serosa is coated with fibrinopurulent exudate and engorged vessels on the surface. In further advanced cases called *acute gangrenous appendicitis*, there is necrosis and ulcerations of mucosa which extend through the wall so that the appendix becomes soft and friable and the surface is coated with greenish-black gangrenous necrosis (**Fig. 18.38**).

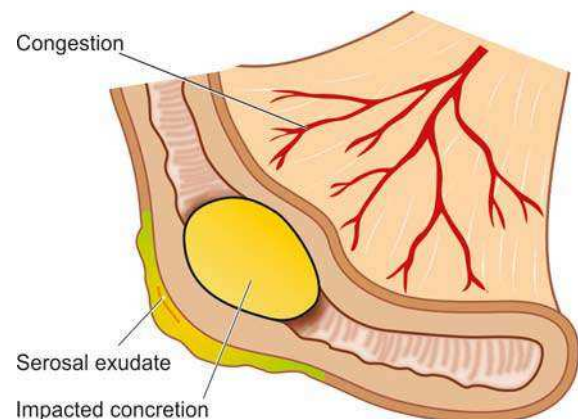

Figure 18.38 Acute appendicitis. Gross appearance of longitudinally opened appendix showing impacted faecolith in the lumen and exudate on the serosa.

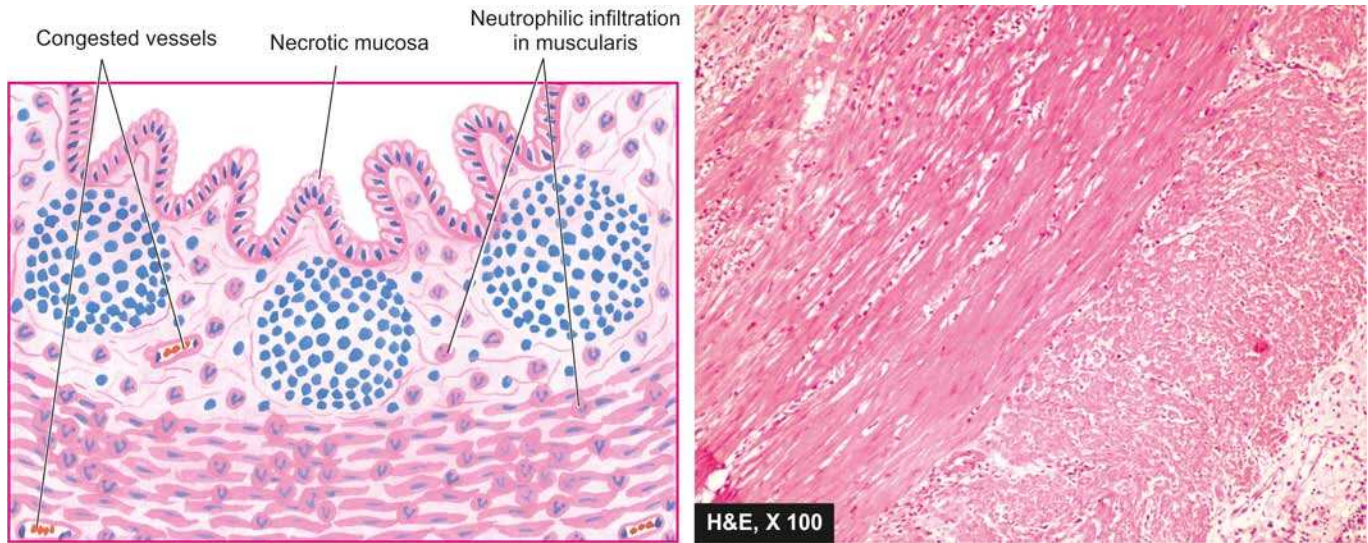

Figure 18.39 Acute appendicitis. Microscopic appearance showing diagnostic neutrophilic infiltration into the muscularis. Other changes present are necrosis of mucosa and periappendicitis.

Microscopically, the most important diagnostic histological criterion is the *neutrophilic infiltration of the muscularis*. In early stage, other changes besides acute inflammatory changes, are congestion and oedema of the appendiceal wall. In later stages, the mucosa is sloughed off, the wall becomes necrotic, the blood vessels may get thrombosed and there may be neutrophilic abscesses in the wall. In either case, an impacted foreign body, faecolith, or concretion may be seen in the lumen (**Fig. 18.39**).

Thus, there is good correlation between macroscopic and microscopic findings in acute appendicitis.

CLINICAL COURSE The patient presents with features of acute abdomen as under:

1. Colicky pain, initially around umbilicus but later localised to right iliac fossa
2. Nausea and vomiting
3. Pyrexia of mild grade
4. Abdominal tenderness
5. Increased pulse rate
6. Neutrophilic leucocytosis with toxic granules in neutrophils is most significant laboratory finding.

An attack of acute appendicitis predisposes the appendix to repeated attacks (*recurrent acute appendicitis*) and thus surgery has to be carried out. If appendicectomy is done at a later stage following acute attack (*interval appendicectomy*), pathological changes of healing by fibrosis of the wall and chronic inflammation are observed.

COMPLICATIONS If the condition is not adequately managed, the following complications may occur:

1. **Peritonitis** A perforated appendix as occurs in gangrenous appendicitis may cause localised or generalised peritonitis.
2. **Appendix abscess** This is due to rupture of an appendix giving rise to localised abscess in the right iliac fossa. This abscess may spread to other sites such as between the liver and diaphragm (subphrenic abscess), into the pelvis between the

urinary bladder and rectum, and in the females may involve uterus and fallopian tubes.

3. **Adhesions** Late complications of acute appendicitis are fibrous adhesions to the greater omentum, small intestine and other abdominal structures.

4. **Portal pylephlebitis** Spread of infection into mesenteric veins may produce septic phlebitis and liver abscess.

5. **Mucocele** Distension of distal appendix by mucus following recovery from an attack of acute appendicitis is referred to as mucocele. It occurs generally due to proximal obstruction but sometimes may be due to a benign or malignant neoplasm in the appendix. An infected mucocele may result in formation of *empyema* of the appendix.

TUMOURS OF APPENDIX

Tumours of the appendix are quite rare. These include: carcinoid tumour (the most common), pseudomyxoma peritonei and adenocarcinoma.

CARCINOID TUMOUR It is already described on page 559. Both argentaffin and argyrophil types are encountered, the former being more common.

Grossly, carcinoid tumour of the appendix is mostly situated near the tip of the organ and appears as a circumscribed nodule, usually less than 1 cm in diameter, involving the wall but metastases are rare.

Histologically, carcinoid tumour of the appendix resembles other carcinoids of the midgut.

ADENOCARCINOMA It is an uncommon tumour in the appendix and is morphologically similar to adenocarcinoma elsewhere in the alimentary tract.

PSEUDOMYXOMA PERITONEI Pseudomyxoma peritonei is accumulation of gelatinous mucinous ascites. Mucinous collection is generally secondary to an appendiceal neoplasm

and may be acellular or may contain tumour cells (either benign or signet ring cells). The associated appendiceal tumour is frequently benign mucinous cystadenoma of the appendix but occasionally invasive carcinoma of the appendix are also encountered. In assessing an ovarian mucinous tumour associated with pseudomyxoma peritonei, the state of appendix is important—the mucinous tumor of the ovary associated with mucinous ascites is presumed to be appendiceal origin unless proved otherwise (page 733).

GIST BOX 18.13 Diseases of Appendix

- ▣ Acute appendicitis an acute abdomen associated with colicky pain and neutrophilic leucocytosis.
- ▣ Characteristically, there is neutrophilic infiltration in the muscularis propria.
- ▣ Complications of acute appendicitis are peritonitis, abscess formation, adhesions, portal pylephlebitis and mucocele.
- ▣ Pseudomyxoma peritoei may accompany appendiceal tumours.
- ▣ Tumours of appendix include carcinoid, cystadenoma and rarely adenocarcinoma.

LARGE BOWEL

NORMAL STRUCTURE

The large bowel consists of 6 parts—the caecum, ascending colon, transverse colon, descending colon, sigmoid colon and rectum, and in all measures about 1.5 meters in length. The serosal surface of the large intestine except the rectum is studded with *appendices epiploicae* which are small, rounded collections of fatty tissue covered by peritoneum.

Histologically, the wall of large bowel consists of 4 layers as elsewhere in the alimentary tract—serosa, muscularis, submucosa and mucosa.

◆ The **mucosa** lacks villi and there is preponderance of goblet cells over columnar epithelial cells. The lymphoid tissue is less abundant than in the small bowel but lymphoid follicles are seen in the caecum and rectum.

◆ The **muscularis propria** of the large intestine is quite peculiar—the inner circular muscle layer ensheathes whole length of the intestine, while the outer longitudinal muscle layer is concentrated into 3 muscle bands called *taenia coli*. The length of outer muscle layer is shorter than the length of the intestine and therefore, it forms the *sacculations or haustra* of the large intestine. At the rectosigmoid junction, the three muscle bands fuse to form a complete covering.

The **blood supply** to the right colon is from the superior mesenteric artery which also supplies blood to the small bowel. The remaining portion of large bowel except the lower part of rectum receives blood supply from inferior mesenteric artery. The lower rectum is supplied by haemorrhoidal branches.

The **innervation** of the large bowel consists of 3 plexuses of ganglion cells—*Auerbach's* or *myenteric plexus* lying between the two layers of muscularis, *Henle's plexus* lying in the deep submucosa inner to circular muscle layer, and *Meissner plexus* that lies in the superficial mucosa just beneath the muscularis mucosae. These are interconnected by non-myelinated nerve fibres.

Anal canal, 3-4 cm long tubular structure, begins at the lower end of the rectum, though is not a part of large bowel, but is included here to cover simultaneously lesions pertaining to this region. It is lined by keratinised or nonkeratinised stratified squamous epithelium. *Anal verge* is the junction between the anal canal and perineal skin, while *pectinate line* is the squamo-columnar junction between the anal canal and the rectum.

CONGENITAL AND OTHER MISCELLANEOUS CONDITIONS

HIRSCHSPRUNG'S DISEASE (CONGENITAL MEGACOLON)

The term 'megacolon' is used for any form of marked dilatation of the entire colon or its segment and may occur as a congenital or acquired disorder. *Congenital form* characterised by congenital absence of ganglion cells in the bowel wall (enteric neurons) is called Hirschsprung's disease. As a result, the aganglionic segment remains contracted. Genetically, Hirschsprung's disease is a heterogeneous disorder as under:

1. Autosomal dominant inheritance with mutation in *RET* proto-oncogene in some cases.
2. Autosomal recessive form with mutation in endothelin-B receptor gene in many other cases.

Clinically, the condition manifests shortly after birth with constipation, gaseous distension and sometimes with acute intestinal obstruction. Its frequency is 1 in 5,000 live-births, has familial tendency in about 4% of cases and has predilection for development in Down's syndrome. Pathogenesis lies in the failure of neuroblasts to migrate to the rectum which normally occurs at about 12 weeks of gestation.

MORPHOLOGIC FEATURES Two types of biopsies may be done on infants suspected of having Hirschsprung's disease—full-thickness rectal biopsy, and suction biopsy that includes mucosa and submucosa.

Grossly, typical case of Hirschsprung's disease shows 2 segments—a *distal narrow segment* that is aganglionic and a *dilated proximal segment* that contains normal number of ganglion cells (**Fig. 18.40**).

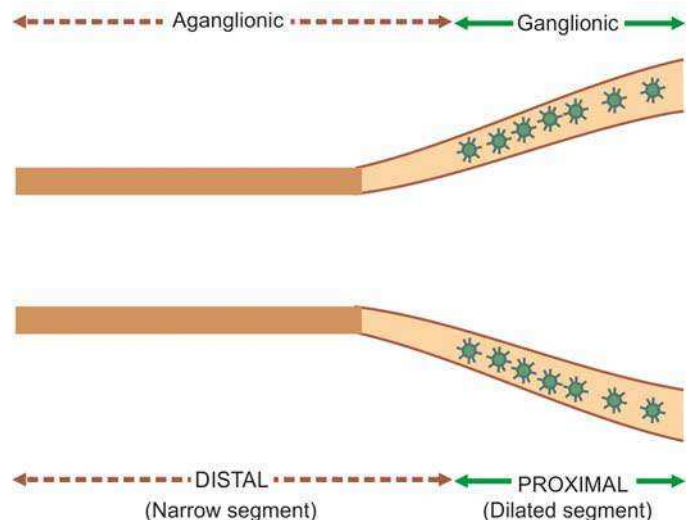

Figure 18.40 Hirschsprung's disease, diagrammatic representation of the pathologic changes.

Microscopically, the distal narrow segment shows total absence of ganglion cells of all the three plexuses (Auerbach's or myenteric plexus present between the two layers of muscularis, deep submucosal or Henle's plexus, and superficial mucosal or Meissner's plexus) and prominence of non-myelinated nerve fibres. Histochemical staining for acetylcholine esterase activity provides confirmation for identifying ganglion cells and nerve trunks.

Depending upon the length of the segment affected by aganglionosis in Hirschsprung's disease, following patterns are recognised:

1. **Classic form:** Aganglionosis from distal colorectal region to proximal dilated colon.
2. **Short segment (rectal and recto-sigmoid) form:** Aganglionosis involving a few centimeters of the rectum and rectosigmoid only.
3. **Ultra-short form:** Aganglionosis is in a very small segment which can be missed in a biopsy.
4. **Long segment (subtotal colonic) form:** Aganglionosis involves most of the colon from rectosigmoid to the ileo-caecal valve, and sometimes may even extend into small bowel.
5. **Zonal colonic aganglionosis:** A short segment is involved in aganglionosis in which the ganglia cells are absent both above and below the aganglionic segment.

In addition to congenital megacolon discussed above, megacolon may occur from certain *acquired causes* as under:

- i. **Obstructive** e.g. due to tumour, post-inflammatory strictures.
- ii. **Endocrine** e.g. in myxoedema, cretinism.
- iii. **CNS disorders** e.g. spina bifida, paraplegia, parkinsonism.
- iv. **Psychogenic** e.g. emotional disturbances, psychiatric disorders.
- v. **Chagas' disease** due to infection with *Trypanosoma cruzi* is the only example resulting in acquired loss of ganglion cells. In all other acquired causes listed above, the bowel innervation is normal.

COLITIS

Colitis may occur in isolation but more commonly involvement of small intestine is also present (enterocolitis). In view of the considerable overlapping of enteritis and colitis, these lesions have already been described under small intestine (page 546). **Table 18.9** presents a classification of the various types of colitis/enterocolitis.

DIVERTICULOSIS COLI

Diverticula are the outpouchings or herniations of the mucosa and submucosa of the colon through the muscle wall. *Diverticular disease*, as it is commonly known, is rare under 30 years of age and is seen more commonly as the age advances. Multiple diverticula of the colon are very common in the Western societies, probably due to ingestion of low-fibre diet but is seen much less frequently in tropical countries and in Japan. Diverticulosis is often asymptomatic and may be detected as an incidental finding at autopsy. However, a proportion of patients develop clinical symptoms such as low abdominal pain, distension, constipation and sometimes intermittent bleeding.

Table 18.9 Classification of colitis/enterocolitis.

| | |
|------|---|
| I. | ISCHAEMIC BOWEL DISEASE |
| | Ischaemic colitis ('Membranous' colitis) |
| II. | INFLAMMATORY BOWEL DISEASE |
| 1. | Ulcerative colitis |
| 2. | Crohn's disease |
| III. | OTHER INFLAMMATORY LESIONS |
| 1. | Infective enterocolitis (Dysenteries—bacillary, amoebic, other parasitic) |
| 2. | 'Pseudomembranous' enterocolitis (Antibiotic-associated diarrhoea) |
| 3. | Necrotising enterocolitis |

Based on the etiologic role of low fibre diet, pathogenesis of diverticular disease of the colon can be explained as under:

1. **Increased intraluminal pressure** such as due to low fibre content of the diet causing hyperactive peristalsis and thereby sequestration, of mucosa and submucosa.
2. **Muscular weakness** of the colonic wall at the junction of the muscularis with submucosa.

MORPHOLOGIC FEATURES *Grossly*, diverticulosis is seen most commonly in the sigmoid colon (95%) but any other part of the entire colon may be involved. They appear as small, spherical or flask-shaped outpouchings, usually less than 1 cm in diameter, commonly extend into appendices epiploicae and may contain inspissated faeces. They are connected to the intestinal lumen by a narrow neck (**Fig. 18.41**).

Histologically, the flask-shaped structures extend from the intestinal lumen through the muscle layer. The colonic wall in the affected area is thin and is composed of atrophic mucosa, compressed submucosa and thin or deficient muscularis. However, muscularis propria in between the diverticular protrusions is hypertrophied. While diverticular disease may remain asymptomatic, inflammatory changes in the diverticula (diverticulitis) produce clinical symptoms.

Figure 18.41 Diverticulosis coli. The outpouchings on the mesentery communicate with lumen of colon.

The *complications* of diverticulosis and diverticulitis are perforation, haemorrhage, intestinal obstruction and fistula formation.

HAEMORRHOIDS (PILES)

Haemorrhoids or piles are varicosities of the haemorrhoidal veins. They are called *internal piles* if dilatation is of superior haemorrhoidal plexus covered over by mucous membrane, and *external piles* if they involve inferior haemorrhoidal plexus covered over by the skin. They are common lesions in the elderly and in pregnant women. They commonly result from increased venous pressure. Their possible causes include the following:

1. Portal hypertension
2. Chronic constipation and straining at stool
3. Cardiac failure
4. Venous stasis of pregnancy
5. Hereditary predisposition
6. Tumours of the rectum.

Microscopically, thin-walled and dilated tortuous veins are seen under the rectal mucosa (*internal piles*) or anal skin (*external piles*) (Fig. 18.42). Secondary changes and complications that may occur include: thrombosis, haemorrhage, inflammation, scarring and strangulation (*prolapsed piles*).

MELANOSIS COLI

Melanosis coli is a peculiar condition in which mucosa of the large intestine acquires brown-black colouration. The condition is said to occur in individuals who are habitual users of cathartics of anthracene type.

Grossly, the mucosal surface is intact and is pigmented brown-black.

Microscopically, large number of pigment-laden macrophages are seen in the lamina propria. The nature of this pigment is found to be both melanin and lipofuscin.

ANGIODYSPLASIA

Angiodysplasia is a submucosal telangiectasia affecting caecum and right colon that causes recurrent acute and chronic haemorrhage. The condition is more common in the elderly past 6th decade. The pathogenesis is obscure but is possibly due to mechanical obstruction of the veins.

MISCELLANEOUS INFLAMMATORY CONDITIONS

◆ **Fistula-in-ano** It is a well known and common condition in which one or more fistulous tracts pass from the internal opening at the pectinate line through the internal sphincter on to the skin surface. The condition probably results from infection of the anal glands.

Histologically, nonspecific inflammatory granulation tissue is seen lining the fistulous tract. Foreign body giant cells may be seen (Fig. 18.43).

◆ **Anal fissure** It is an ulcer in the anal canal below the level of the pectinate line, mostly in midline and posteriorly. The common cause is trauma due to passage of hard stools, followed by chronic infection.

◆ **Solitary rectal ulcer syndrome** It is a condition characterised usually by solitary, at times multiple, rectal ulcers with prolapse of rectal mucosa and development of proctitis. The histological appearance is quite characteristic. Besides ulceration and inflammation of the rectal mucosa, lamina propria is occupied by spindle-shaped fibroblasts and smooth muscle cells. The condition is also called as '*localised form of colitis cystica profunda*' and must be differentiated from '*diffuse form of colitis cystica profunda*' seen in cases of ulcerative colitis. Submucosal cysts lined by foreign body giant cells and containing gas are also seen in '*pneumatosis cystoides intestinalis*'.

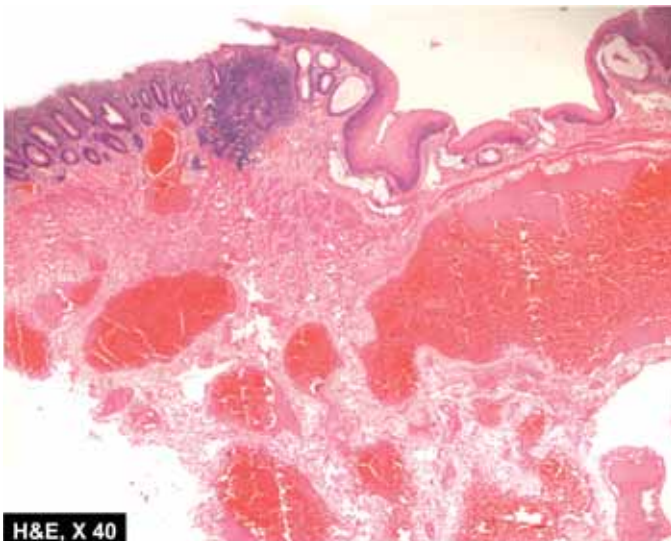

Figure 18.42 External piles. There are thrombosed veins underneath the squamocolumnar anorectal mucosa.

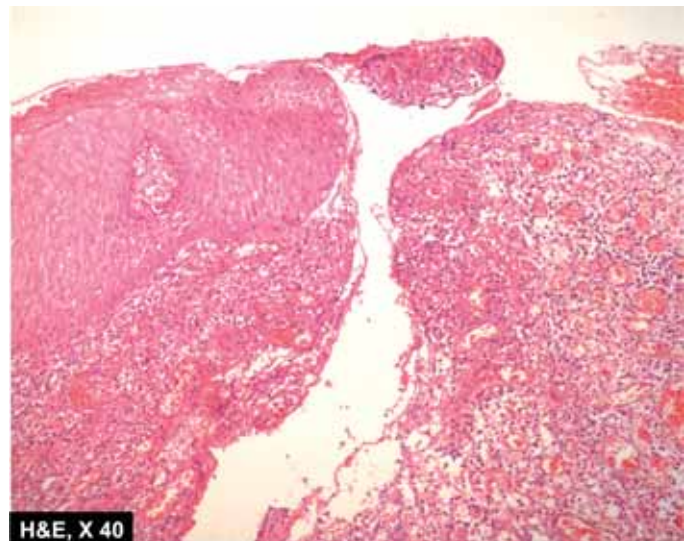

Figure 18.43 Fistula-in-ano. The fistulous tract is lined by non-specific inflammatory granulation tissue.

GIST BOX 18.14 Congenital and Other Miscellaneous Conditions of Large Bowel

- ▣ Megacolon characterised by congenital absence of ganglion cells in the bowel wall is called Hirschsprung's disease. The condition has a distal narrow segment that is aganglionic and a dilated proximal segment that contains normal number of ganglion cells.
- ▣ Diverticulosis coli is presence of outpouchings of the mucosa and submucosa of the colon through the muscle wall.
- ▣ Haemorrhoids or piles are the varicosities of the haemorrhoidal veins.
- ▣ Fistula-in-ano and anal fissure are common inflammatory conditions.

POLYPS AND TUMOURS OF LARGE BOWEL

Large bowel is the most common site for a variety of benign and malignant tumours, majority of which are of epithelial origin. Most of the benign tumours present clinically as polyps. A classification of polyps, along with benign tumours and malignant tumours, is presented in **Table 18.10**.

Table 18.10 Polyps and tumours of the large intestine.

| | |
|------|--|
| I. | COLORECTAL POLYPS |
| A. | <i>Non-neoplastic polyps</i> |
| 1. | Hyperplastic (metaplastic) polyps |
| 2. | Hamartomatous polyps |
| | (i) Peutz-Jeghers polyps and polyposis |
| | (ii) Juvenile (Retention) polyps and polyposis |
| 3. | Inflammatory polyps (Pseudopolyps) |
| 4. | Lymphoid polyps |
| B. | <i>Neoplastic polyps (Adenomas)</i> |
| 1. | Tubular adenoma (Adenomatous polyp) |
| 2. | Villous adenoma (Villous papilloma) |
| 3. | Tubulovillous adenoma (Papillary adenoma, villoglandular adenoma) |
| C. | <i>Familial polyposis syndromes</i> |
| 1. | Familial polyposis coli (Adenomatosis) |
| 2. | Gardner's syndrome |
| 3. | Turcot's syndrome |
| 4. | Juvenile polyposis syndrome |
| II. | OTHER BENIGN COLORECTAL TUMOURS (Leiomyomas, leiomyoblastoma, neurilemmoma, lipoma and vascular tumours) |
| III. | MALIGNANT COLORECTAL TUMOURS |
| A. | <i>Carcinoma</i> |
| 1. | Adenocarcinoma |
| 2. | Other carcinomas (Mucinous adenocarcinoma, signet-ring cell carcinoma, adenosquamous carcinoma, undifferentiated carcinoma) |
| B. | <i>Other malignant tumours</i> (Leiomyosarcoma, malignant lymphoma, carcinoid tumours) |
| IV. | TUMOURS OF THE ANAL CANAL |
| A. | <i>Benign</i> (viral warts or condyloma acuminata) |
| B. | <i>Malignant</i> (squamous cell carcinoma, basaloid carcinoma, mucoepidermoid carcinoma, adenocarcinoma, undifferentiated carcinoma, malignant melanoma) |

COLORECTAL POLYPS

A polyp is defined as any growth or mass protruding from the mucous membrane into the lumen. Polyps are much more common in the large intestine than in the small intestine and are more common in the rectosigmoid colon than the proximal colon. Polyps are broadly classified into 2 groups—non-neoplastic and neoplastic. Non-neoplastic polyps have further subtypes indicating their mode of origin. Neoplastic polyps, on the other hand, include epithelial tumours, both benign and malignant.

A. NON-NEOPLASTIC POLYPS

Non-neoplastic polyps are more common and include the following 4 subtypes:

Hyperplastic (Metaplastic) Polyps

The hyperplastic or metaplastic polyps are the most common amongst all epithelial polyps, particularly in the rectosigmoid. They are called '*hyperplastic*' because there is epithelial hyperplasia at the base of the crypts, and '*metaplastic*' as there are areas of cystic metaplasia. They may be seen at any age but are more common in the elderly (6th-7th decade).

Grossly, hyperplastic polyps are generally multiple, sessile, smooth-surfaced and small (less than 0.5 cm).

Microscopically, they are composed of long and cystically dilated glands and crypts lined by normal epithelial cells. Their lining is partly flat and partly papillary. The luminal border of the lining epithelium is often serrated or saw-toothed.

Hyperplastic polyps are usually symptomless and have no malignant potential unless there is a coexistent adenoma.

Hamartomatous Polyps

These are tumour-like lesions composed of abnormal mixture of tissues indigenous to the part. They are further of 2 types:

PEUTZ-JEGHERS POLYPS AND POLYPOSIS Peutz-Jeghers syndrome is autosomal dominant defect, characterised by hamartomatous intestinal polyposis and melanotic pigmentation of lips, mouth and genitalia. The polyps may be located in the stomach, small intestine or colon but are most common in the jejunum and ileum. The most common age is adolescence and early childhood.

Grossly, these polyps are of variable size but are often large, multiple and pedunculated and more commonly situated in the small intestine.

Microscopically, the most characteristic feature is the tree-like branching of muscularis mucosae. The lining epithelium is by normal-appearing epithelial cells. The glands may show hyperplasia and cystic change (**Fig. 18.44**).

Peutz-Jeghers polyps do not undergo malignant transformation unless a coexistent adenoma is present. However, patients with Peutz-Jeghers syndrome are more prone to certain other cancers such as of pancreas, lung, breast, ovary and uterus.

Tree-like branching of muscularis mucosa

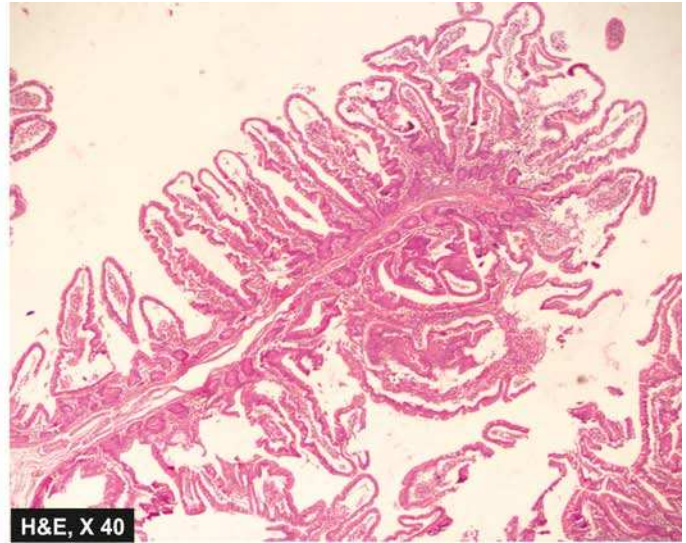

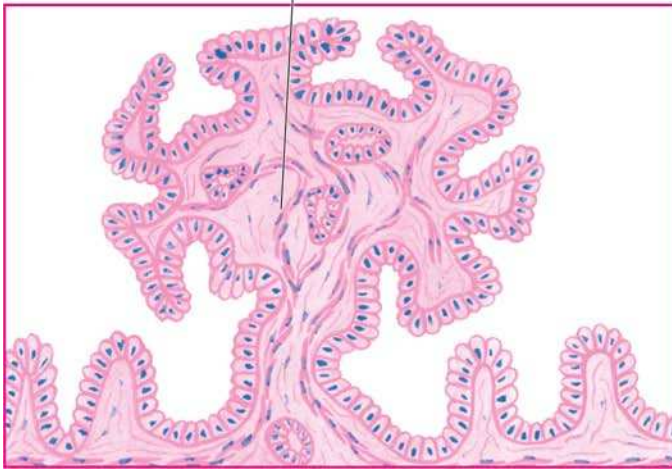

Figure 18.44 Hamartomatous polyps: Peutz-Jeghers polyp.

JUVENILE (RETENTION) POLYPS Juvenile or retention polyps, another form of hamartomatous polyps, occur more commonly in children below 5 years of age. Solitary juvenile polyps occur more often in the rectum, while juvenile polyposis may be present anywhere in the large bowel.

Grossly, juvenile polyps are spherical, smooth-surfaced, about 2 cm in diameter and are often pedunculated.

Microscopically, the classical appearance is of cystically dilated glands containing mucus and lined by normal mucus-secreting epithelium. The stroma may show inflammatory cell infiltrate if there is chronic ulceration of the surface (**Fig. 18.45**).

Most cases, on becoming symptomatic in the form of rectal bleeding, are removed. In common with other non-neoplastic polyps, they are also not precancerous.

Inflammatory Polyps (Pseudopolyps)

Inflammatory polyps or pseudopolyps appear due to re-epithelialisation of the undermined ulcers and overhanging margins

in inflammatory bowel disease, most frequently in ulcerative colitis (colitis polyposa) and sometimes in Crohn's disease.

Grossly, they are usually multiple, cylindrical to rounded overgrowths of mucosa and may vary from minute nodules to several centimeters in size.

Microscopically, the centre of inflammatory polyp consists of connective tissue core that shows some inflammatory cell infiltrate and is covered superficially by regenerating epithelial cells and some cystically-dilated glands.

These lesions have no malignant potential; carcinomas seen in long-standing cases of ulcerative colitis arise in the region of epithelial dysplasia and not from the polyps.

Lymphoid Polyyps

Reactive hyperplasia of lymphoid tissue that is normally also more prominent in the rectum and terminal ileum, gives rise to localised or diffuse lymphoid polyyps, also called *rectal tonsils*. Localised form occurs more often in the rectum in elderly, while diffuse form is seen at younger age and in children.

Cystically-dilated glands

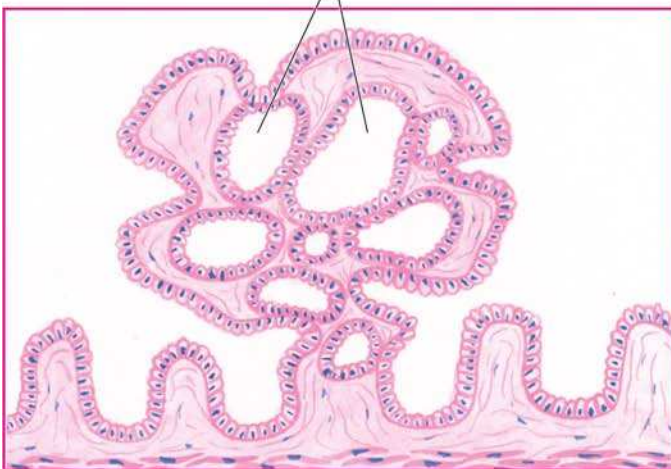

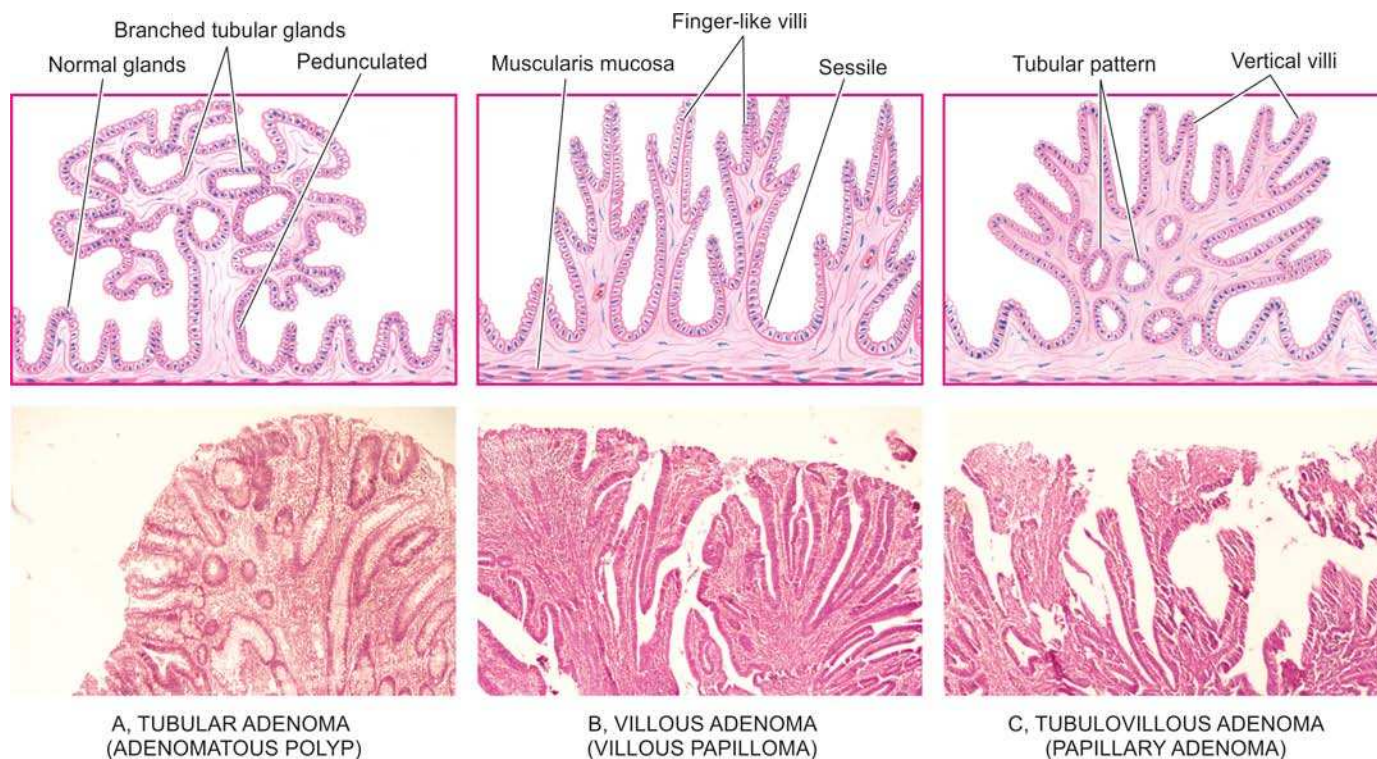

Figure 18.45 Juvenile polyp.

A, TUBULAR ADENOMA (ADENOMATOUS POLYP)

B, VILLOUS ADENOMA (VILLOUS PAPILLOMA)

C, TUBULOVILLOUS ADENOMA (PAPILLARY ADENOMA)

Figure 18.46 Adenomas (neoplastic polyps)—three main varieties.

Grossly, they are solitary or multiple, tiny elevated lesions.

Microscopically, they are composed of prominent lymphoid follicles with germinal centres located in the submucosa and mucosa, and are covered by epithelium that may be inflamed.

They are benign lesions and have to be distinguished from malignant lymphoma.

B. NEOPLASTIC POLYPS (ADENOMAS)

Neoplastic polyps are colorectal adenomas which have potential for malignant change while polypoid carcinoma is the term used for invasive epithelial tumours. Adenomas have 3 main varieties (tubular, villous and tubulovillous), each of which represents a difference in the growth pattern of the same neoplastic process and variable biological behaviour.

Tubular Adenoma (Adenomatous Polyp)

Tubular adenomas or adenomatous polyps are the most common neoplastic polyps (75%). They are common beyond 3rd decade of life and have slight male preponderance. They occur most often in the distal colon and rectum. They may be found singly as sporadic cases, or multiple tubular adenomas as part of familial polyposis syndrome with autosomal dominant inheritance pattern. Tubular adenomas may remain asymptomatic or may manifest by rectal bleeding.

Grossly, adenomatous polyps may be single or multiple, sessile or pedunculated, vary in size from less than 1 cm to large, spherical masses with an irregular surface. Usually, the larger lesions have recognisable stalks.

Microscopically, the usual appearance is of benign tumour overlying muscularis mucosa and is composed of branching tubules which are embedded in the lamina propria. The lining epithelial cells are of large intestinal type with diminished mucus secreting capacity, large nuclei and increased mitotic activity (Fig. 18.46,A). However, tubular adenomas may show variable degree of cytologic atypia ranging from atypical epithelium restricted within the glandular basement membrane called as 'carcinoma *in situ*' to invasion into the fibrovascular stromal core termed frank adenocarcinoma.

Malignant transformation is present in about 5% of tubular adenomas; the incidence being higher in larger adenomas.

Villous Adenoma (Villous Papilloma)

Villous adenomas or villous papillomas of the colon are much less common than tubular adenomas. The mean age at which they appear is 6th decade of life with approximate equal sex incidence. They are seen most often in the distal colon and rectum, followed in decreasing frequency, by rest of the colon.

Grossly, villous adenomas are round to oval exophytic masses, usually sessile, varying in size from 1 to 10 cm or more in diameter. Their surface may be haemorrhagic or ulcerated.

Microscopically, the characteristic histologic feature is the presence of many slender, finger-like villi, which appear to arise directly from the area of muscularis mucosae. Each of the papillae has fibrovascular stromal core that is covered by epithelial cells varying from apparently benign to anaplastic cells. Excess mucus secretion is sometimes seen (Fig. 18.46,B).

Table 18.11 Contrasting features of non-neoplastic and neoplastic colorectal polyps.

| FEATURE | NON-NEOPLASTIC POLYPS | NEOPLASTIC POLYPS (ADENOMAS) |
|----------------------------|---|---|
| 1. Frequency | More common | Less common |
| 2. Number | Often sporadic | Sporadic as well as multiple |
| 3. Familial predisposition | No | Yes, in sporadic cases |
| 4. Types | Hyperplastic (90%) Others: hamartomatous (Peutz-Jeghers, juvenile) inflammatory, lymphoid | Tubular, villous and tubulovillous adenomas |
| 5. Familial syndromes | Juvenile polyposis syndrome | Familial polyposis coli, Gardner's, Turcot's |
| 6. Biologic behaviour | Always benign | Variable malignant potential: Tubular adenoma 5%, villous 30%, tubulovillous intermediate |

Villous adenomas are invariably symptomatic; rectal bleeding, diarrhoea and mucus being the common features. The presence of severe atypia, carcinoma *in situ* and invasive carcinoma are seen more frequently. Invasive carcinoma has been reported in 30% of villous adenomas.

Tubulovillous Adenoma (Papillary Adenoma, Villoglandular Adenoma)

Tubulovillous adenoma is an intermediate form of pattern between tubular adenoma and villous adenoma. It is also known by other names like papillary adenoma and villoglandular adenoma. The distribution of these adenomas is the same as for tubular adenomas.

Grossly, tubulovillous adenomas may be sessile or pedunculated and range in size from 0.5-5 cm.

Microscopically, they show intermediate or mixed pattern, characteristic vertical villi and deeper part showing tubular pattern (Fig. 18.46,C).

The behaviour of tubulovillous adenoma is intermediate between tubular and villous adenomas.

The contrasting features of non-neoplastic and neoplastic colorectal polyps are given in Table 18.11.

C. FAMILIAL POLYPOSIS SYNDROMES

Familial polyposis syndromes are a group of disorders with multiple polyposis of the colon with autosomal dominant inheritance pattern. Important conditions included in familial polyposis are:

1. Familial polyposis coli (adenomatosis)
2. Gardner's syndrome
3. Turcot's syndrome
4. Juvenile polyposis syndrome

Some other conditions in which multiple polyposis of colon occur but do not have familial basis are Peutz-Jeghers syndrome (hamartomatous), Cronkhite-Canada syndrome (inflammatory), and nodular lymphoid hyperplasia. The familial polyposis syndromes are as follows:

Familial Polyposis Coli (Adenomatosis)

This hereditary disease is defined as the presence of more than 100 neoplastic polyps (adenomas) on the mucosal

surface of the colon; the average number is about 1000 (Fig. 18.47). Adenomatosis can be distinguished from multiple adenomas in which the number of adenomas is fewer, not exceeding 100. The condition has autosomal dominant transmission and is due to germline mutations in *APC* gene which results in occurrence of hundreds of adenomas which progress to invasive cancer. The average age at diagnosis is 2nd and 3rd decades of life with equal incidence in both the sexes.

Grossly and microscopically, the commonest pattern is that of adenomatous polyps (tubular adenomas) discussed above.

Figure 18.47 Familial polyposis coli. The mucosal surface is straddled with multiple polyoid structures (arrow) of varying sizes many of which are pedunculated.

The malignant potential of familial polyposis coli is very high. Colorectal cancer develops virtually in 100% of cases by age of 50 years if not treated with colectomy. The subject of 'adenoma-carcinoma sequence' has been discussed in detail later on this page.

Gardner's Syndrome

Gardner's syndrome is combination of familial polyposis coli and certain extra-colonic lesions such as multiple osteomas (particularly of the mandible and maxilla), sebaceous cysts and connective tissue tumours (page 832). The number of polyps in Gardner's syndrome is generally fewer than in the familial polyposis coli but their clinical behaviour is identical.

Turcot's Syndrome

Turcot's syndrome is combination of familial polyposis coli and malignant neoplasms of the central nervous system.

Juvenile Polyposis Syndrome

Juvenile polyposis is appearance of multiple juvenile polyps in the colon, stomach and small intestine but their number is not as high as in familial polyposis coli. Family history in some cases may show autosomal dominant inheritance pattern, while it may be negative in others. They resemble the typical juvenile polyps as regards their age (under 5 years), sex distribution and morphology. They lack the malignant potential.

OTHER BENIGN TUMOURS

Some non-epithelial benign tumours that may rarely occur in large intestine are leiomyomas, leiomyoblastoma, neurolemmoma, lipoma and vascular tumours (haemangioma, lymphangioma).

MALIGNANT COLORECTAL TUMOURS

A. Colorectal Carcinoma

Colorectal cancer comprises 98% of all malignant tumours of the large intestine. It is the commonest form of visceral cancer accounting for deaths from cancer in the United States, next only to lung cancer. The incidence of carcinoma of the large intestine rises with age; average age of patients is about 60 years. Cancer in the rectum is more common in males than females in the ratio of 2:1, while at other locations in the large bowel the overall incidence is equal for both sexes.

ETIOLOGY As with most other cancers, etiology of colorectal carcinoma is not clear but a few etiological factors have been implicated:

1. Geographic variations The incidence of large bowel carcinoma shows wide variation throughout the world. It is much more common in North America and Northern Europe than in South America, Africa and Asia. Colorectal cancer is generally thought to be a disease of affluent societies because its incidence is directly correlated with the socioeconomic status of the countries. In Japan, however, colon cancer is much less common than in the US but the incidence of rectal cancer is similar.

2. Dietary factors Diet plays a significant part in the causation of colorectal cancer:

- i) A low intake of vegetable fibre-diet leading to low stool bulk is associated with higher risk of colorectal cancer.
- ii) Consumption of large amounts of fatty foods by populations results in excessive cholesterol and their metabolites which may be carcinogenic.
- iii) Excessive consumption of refined carbohydrates that remain in contact with the colonic mucosa for prolonged duration changes the bacterial flora of the bowel, thus resulting in production of carcinogenic substances.

3. Adenoma-carcinoma sequence There is strong evidence to suggest that colonic adenocarcinoma evolves from pre-existing adenomas, referred to as adenoma-carcinoma sequence (**Fig. 18.48**). The following evidences are cited to support this hypothesis:

- i) In a case with early invasive cancer, the surrounding tissue often shows *preceding changes* of evolution from adenoma → hyperplasia → dysplasia → carcinoma *in situ* → invasive carcinoma.
- ii) *Incidence* of adenomas in a population is directly proportionate to the prevalence of colorectal cancer.
- iii) The risk of adenocarcinoma colon declines with *endoscopic removal* of all identified adenomas.
- iv) Peak incidence of adenomas generally *precedes* by some years to a few decades the peak incidence for colorectal cancer.
- v) The risk of malignancy increases with the following *adenoma-related factors*:
 - a) *Number of adenomas*: familial polyposis coli syndrome almost certainly evolves into malignancy.
 - b) *Size of adenomas*: large size increases the risk.
 - c) *Type of adenomas*: greater villous component associated with higher prevalence.

4. Hereditary non-polyposis colonic cancer (HNPCC or Lynch syndrome) HNPCC is an autosomal dominant condition associated with multiple primary cancers at different sites (endometrium, ovary) including colorectal cancer without evidence of familial polyposis coli. In HNPCC, colorectal cancer is seen in at least two generations of first-degree relatives, occurs at a relatively early age (≤ 50 years), located more often in proximal colon, and has better prognosis than sporadic colon cancer cases. It is due to germline mutations in mismatch repair genes, human mutL homolog abbreviated as *hMLH2* located on chromosome 2 and *hMLH1* on chromosome 3 resulting in DNA instability.

5. Other factors Presence of certain pre-existing diseases and some other factors increase the risk of developing colorectal cancer subsequently, e.g.:

- i) Inflammatory bowel disease (especially ulcerative colitis).
- ii) Diverticular disease for long duration. Low fibre diet is implicated in the pathogenesis of diverticular disease as well.
- iii) Role of tobacco smoking in development of colorectal cancer in younger patients.

GENETIC BASIS OF COLORECTAL CARCINOGENESIS

Studies by molecular genetics have revealed that there are sequential multistep mutations in evolution of colorectal cancer from adenomas by one of the following two mechanisms (**Fig. 18.48**):

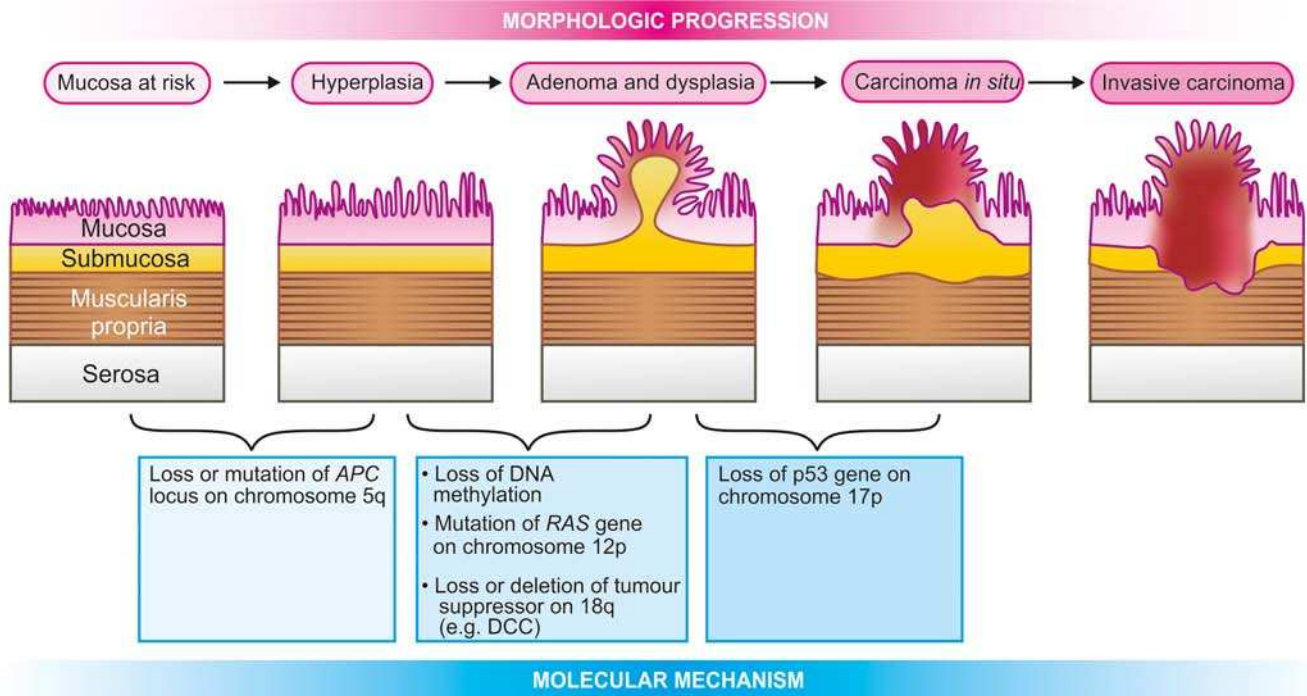

Figure 18.48 Adenoma-carcinoma sequence—schematic diagram of molecular and morphologic evolution.

1. APC mutation/ β -catenin mechanism This pathway of multiple mutations is generally associated with morphologically identifiable changes as described earlier in adenoma-carcinoma sequence. These changes are as under:

- i) *Loss of tumour suppressor APC* (adenomatous polyposis coli) gene located on the long arm of chromosome 5 (5q) is observed in 80% cases of sporadic colon cancer. Since the function of *APC* gene is linked to β -catenin, loss of *APC* gene results in translocation of β -catenin to the nucleus where it activates transcription of other genes, mainly *MYC* and cyclin D1, both of which stimulate cell proliferation.
- ii) *Point mutation in K-RAS gene* follows loss of *APC* gene and is seen in 10 to 50% cases of adenoma-carcinoma.
- iii) *Deletion of DCC gene* located on long arm of chromosome 18 i.e. 18q (*DCC* for *deleted in colorectal cancer*) in 60-70% cases of colon cancer.
- iv) *Loss of p53 tumour suppressor gene* seen in 70-80% cases of colon cancer.

2. Microsatellite instability mechanism In this pathway also, there are multiple mutations but of different genes, and unlike *APC* mutation/ β -catenin mechanism, there are no morphologically identifiable changes. This pathway accounts for 10-15% cases of colon cancer. Basic mutation is loss of DNA repair gene. This results in a situation in which repetitive DNA sequences (i.e. microsatellites) become unstable during replication cycle, termed microsatellite instability, which is the hallmark of this pathway. The significant DNA repair genes which are mutated in colon cancer are as under:

- i) *TGF- β receptor gene* which normally inhibits cell proliferation but in mutated form allows the uncontrolled proliferation of colonic epithelium in adenoma.
- ii) *BAX gene* which normally causes apoptosis but a defect in it results in loss of apoptosis and dysregulated growth.

MORPHOLOGIC FEATURES Distribution of the primary colorectal cancer reveals that about 60% of the cases occur in the rectum, followed in descending order, by sigmoid and descending colon (25%), caecum and ileocaecal valve (10%); ascending colon, hepatic and splenic flexures (5%); and quite uncommonly in the transverse colon (Fig. 18.49).

Grossly, there are distinct differences between the growth on the right and left half of the colon (Fig. 18.50).

◆ **Right-sided colonic growths** tend to be large, cauliflower-like, soft and friable masses projecting into the lumen (*fungating polypoid carcinoma*).

◆ **Left-sided colonic growths**, on the other hand, have napkin-ring configuration i.e. they encircle the bowel wall

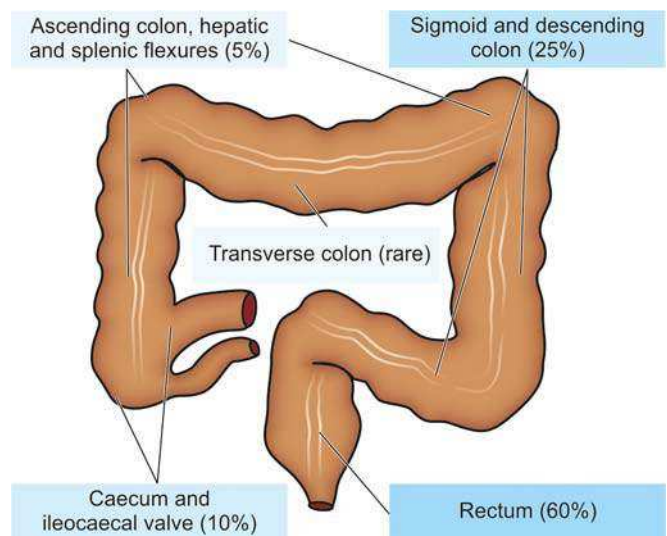

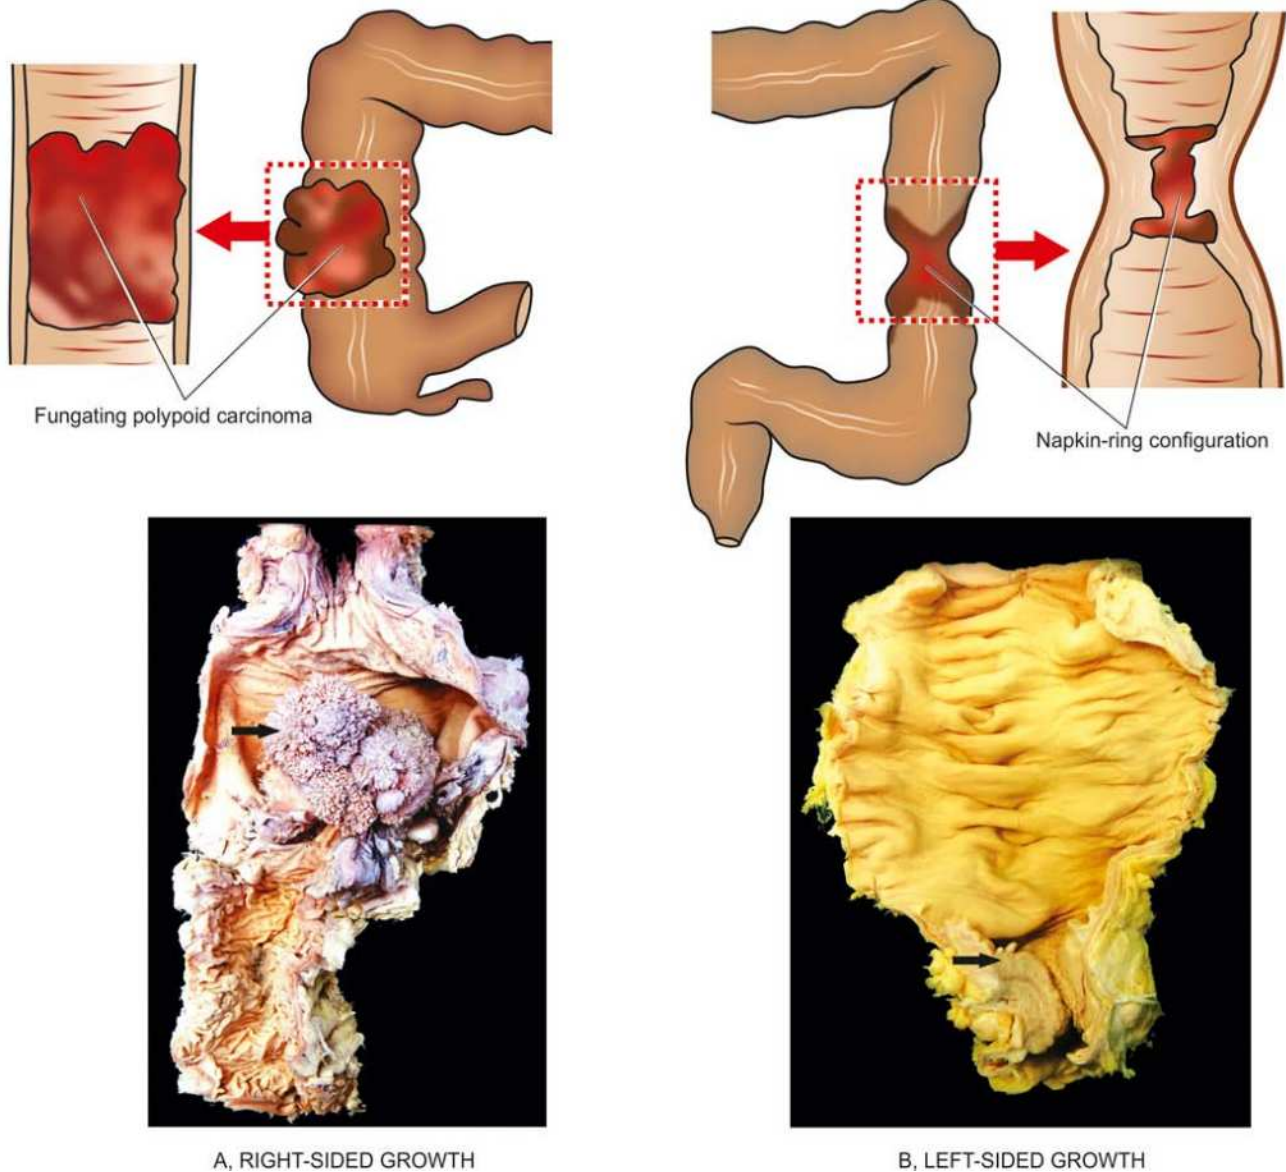

Figure 18.49 Distribution of the primary colorectal cancer.

A, RIGHT-SIDED GROWTH

B, LEFT-SIDED GROWTH

Figure 18.50 Gross appearance of colorectal carcinoma. A, *Right-sided growth*—fungating polypoid carcinoma showing cauliflower-like growth projecting into the lumen. B, *Left-sided growth*—napkin-ring configuration with spread of growth into the bowel wall.

circumferentially with increased fibrous tissue forming annular ring, and have central ulceration on the surface with slightly elevated margins (*carcinomatous ulcers*).

These differences in right and left colonic growths are probably due to the liquid nature of the contents in the ascending colon leaving space for luminal growth on right side, while the contents in left colon are more solid permitting the spread of growth into the bowel wall. However, early lesion in left as well as right colon are small, button-like areas of elevation.

Microscopically, the appearance of right and left-sided growths is similar. About 95% of colorectal carcinomas are adenocarcinomas of varying grades of differentiation, out of which approximately 10% are mucin-secreting colloid carcinomas (Fig. 18.51). The remaining 5% tumours include uncommon microscopic patterns like undifferentiated carcinoma, signet-ring cell carcinoma, and adeno-

squamous carcinomas seen in more distal colon near the anus. The histologic grades indicating the degree of differentiation may range from well-differentiated, to moderately-differentiated and poorly-differentiated.

SPREAD Carcinoma of the large intestine may spread by the following routes:

1. Direct spread The tumour spreads most commonly by direct extension in both ways—*circumferentially* into the bowel wall as well as *directly* into the depth of the bowel wall to the serosa, pericolic fat, and sometimes into peritoneal cavity.

2. Lymphatic spread Spread via lymphatics occurs rather commonly and involves, firstly the regional lymph nodes in the vicinity of the tumour, and then into other groups of lymph nodes like preaortic, internal iliac and the sacral lymph nodes.

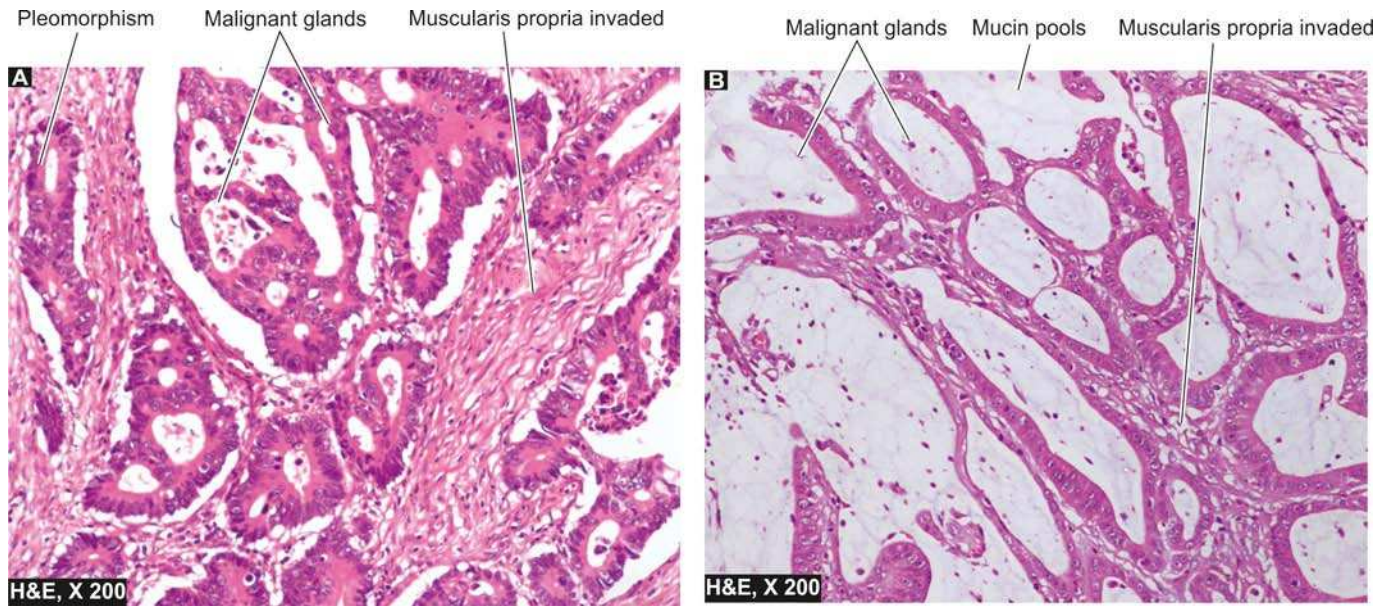

Figure 18.51 Colonic adenocarcinoma. A, Moderately differentiated. B, Mucin-secreting adenocarcinoma.

3. Haematogenous spread Blood spread of large bowel cancer occurs relatively late and involves the liver, lungs, brain, bones and ovary.

CLINICAL FEATURES Clinical symptoms in colorectal cancer appear after considerable time. These are as follows:

- i) Occult bleeding (melaena)
- ii) Change in bowel habits, more often in left-sided growth
- iii) Loss of weight (cachexia)
- iv) Loss of appetite (anorexia)
- v) Anaemia, weakness, malaise.

The most common *complications* are obstruction and haemorrhage; less often perforation and secondary infection may occur. Aside from the diagnostic methods like stool test for occult blood, PR examination, proctoscopy, radiographic contrast studies and CT scan, recently the role of tumour-markers has been emphasised. Of particular importance is the estimation of carcinoembryonic antigen (CEA) level which is elevated in 100% cases of metastatic colorectal cancers, while it is positive in 20-40% of early lesions, and 60-70% of advanced primary lesions. However, the test may have prognostic significance only and is not diagnostic of colorectal cancer because it is positive in other cancers too such as of the lungs, breast, ovary, urinary bladder and prostate. CEA levels are elevated in some non-neoplastic conditions also like in ulcerative colitis, pancreatitis and alcoholic cirrhosis.

STAGING AND PROGNOSIS The *prognosis* of colorectal cancer depends upon a few variables:

- i) Extent of the bowel involvement
- ii) Presence or absence of metastases
- iii) Histologic grade of the tumour
- iv) Location of the tumour

The most important prognostic factor in colorectal cancer is, however, the *stage* of the disease at the time of diagnosis. Three staging systems are in use:

1. *Dukes' ABC staging* (modified Duke's includes stage D as well).

2. *Astler-Coller staging* which is a further modification of Duke's staging and is most widely used.

3. *TNM staging* described by American Joint Committee is also used.

Table 18.12 and **Fig. 18.52** sum up the features of staging classification and the overall 5-year survival rate in disease stage.

B. Other Colorectal Malignant Tumours

Besides colorectal carcinoma, other malignant tumours which are encountered sometimes in the large bowel are leiomyosarcoma (page 726) and malignant lymphoma (page 543). Hindgut carcinoids may occur in the rectum and colon (page 559).

TUMOURS OF THE ANAL CANAL

Epithelial tumours of the anal canal are uncommon and may be combination of several histological types. Amongst the *benign tumours* of the anal canal, multiple viral warts called as condyloma acuminata are the only tumours of note. *Malignant tumours* of the anal canal include the following:

1. Squamous cell carcinoma (**Fig. 18.53**)
2. Basaloid carcinoma
3. Mucoepidermoid carcinoma
4. Adenocarcinoma (rectal, of anal glands, within anorectal fistulas)
5. Undifferentiated carcinoma
6. Malignant melanoma.

These tumours resemble in morphology with similar lesion elsewhere in the body.

CAUSES OF GASTROINTESTINAL BLEEDING

Gastrointestinal bleeding from upper (haematemesis), middle (small intestinal) and lower (melaena) part is a major presenting

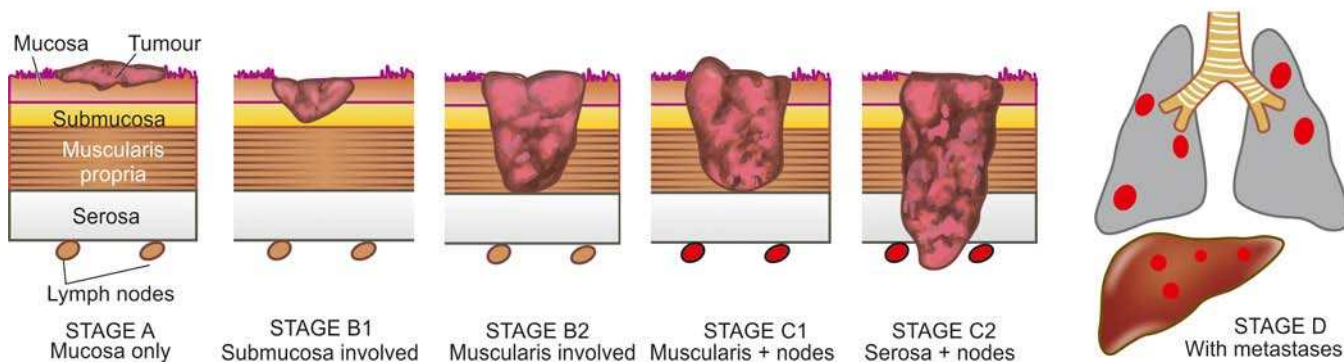

Figure 18.52 Pathologic staging according to Astler-Coller system. (Also see facing Table 18.12).

clinical feature of a variety of gastrointestinal diseases. **Table 18.13** summarises the main causes of gastrointestinal bleeding.

GIST BOX 18.15 Polyps and Tumours of Large Bowel

- ☐ Colorectal polyps may be non-neoplastic and neoplastic.
- ☐ Non-neoplastic polyps are more common and include hyperplastic, hamartomatous, and inflammatory polyps.
- ☐ Neoplastic polyps or adenomas are tubular, villous and tubulovillous adenomas. These are more significant due to their possible malignant change.
- ☐ Colorectal polyps may occur as a part of syndromes e.g. familial polyposis, Gardner's, Turcot's etc.

- ☐ Colorectal carcinoma is common and has etiologic relation to adenomas and dietary factors.
- ☐ Genetically, colorectal carcinoma is explained more often on basis of APC mutation/ β -catenin mechanism.
- ☐ Left-sided and right-sided colorectal cancers have distinct gross appearance but microscopy shows similar morphology of adenocarcinoma which is often mucinous.

PERITONEUM

NORMAL STRUCTURE

The peritoneal cavity is lined by a layer of surface mesothelium derived from mesoderm. The lining rests on vascularised subserosal fibrous tissue. Other structures topographically related to peritoneum are retroperitoneum, omentum, mesentery and umbilicus. These structures are involved in a variety of pathologic states but a few important conditions as follows.

PERITONITIS

Inflammatory involvement of the peritoneum may result from chemical agents or bacteria.

1. Chemical peritonitis can be caused by the following:

- ◆ *Bile* extravasated due to trauma or diseases of the gallbladder.
- ◆ *Pancreatic secretions* released from pancreas in acute haemorrhagic pancreatitis.
- ◆ *Gastric juice* leaked from perforation of stomach.
- ◆ *Barium sulfate* from perforation of bowel during radiographic studies.
- ◆ Chemical peritonitis is localised or generalised sterile inflammation of the peritoneum.

2. Bacterial peritonitis may be primary or secondary; the latter being more common.

Primary form is caused by streptococcal infection, especially in children. *Secondary* bacterial peritonitis may occur from the following disorders:

- i) Appendicitis
- ii) Cholecystitis
- iii) Salpingitis
- iv) Rupture of peptic ulcer
- v) Gangrene of bowel
- vi) Tuberculosis (specific inflammation).

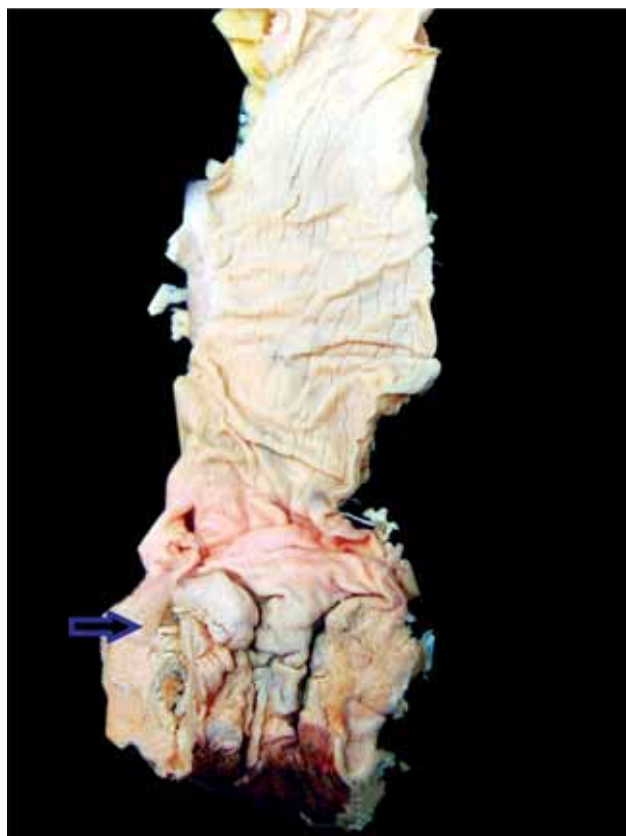

Figure 18.53 Anorectal carcinoma. The anorectal margin shows an ulcerated mucosa with thickened wall (arrow). The sectioned surface of rectal wall is grey-white and fleshy due to infiltration by the tumour.

Table 18.12 Staging and prognosis of colorectal cancer (Duke's system as modified by Astler-Coller).

| STAGE | TNM | 5-YEAR SURVIVAL | PATHOLOGIC FEATURES | |
|----------------|-----|----------------------|---------------------|---|
| A | I | T ₁ N0 M0 | >90% | Cancer confined to mucosa only |
| B ₁ | II | T ₂ N0 M0 | 85% | Cancer extends into submucosa |
| B ₂ | II | T ₃ N0 M0 | 70-80% | Cancer extends into muscularis±serosa |
| C ₁ | III | Tx N ₁ M0 | 35-65% | Cancer involves muscularis+regional lymph nodes |
| C ₂ | III | Tx N ₁ M0 | 20-35% | Cancer extends into serosa+regional lymph nodes |
| D | IV | Tx Nx M ₁ | 5% | Cancer with distant metastases |

MORPHOLOGIC FEATURES Depending upon duration, the features in bacterial peritonitis vary. It may be generalised or may get localised by omentum such as in appendiceal abscess following acute appendicitis. Depending upon duration, the fluid accumulation varies from serous, turbid, creamy to frankly suppurative. The fluid may eventually resolve or may heal by organisation with formation of fibrous adhesions.

TUMOUR-LIKE LESIONS AND TUMOURS

These include idiopathic retroperitoneal fibrosis, mesenteric cysts and primary and metastatic tumours.

Idiopathic Retroperitoneal Fibrosis

Also known as Ormond's disease or sclerosing retroperitonitis, this rare entity of unknown etiology is characterised by diffuse fibrous overgrowth and chronic inflammation. The condition is, therefore, more like inflammatory rather than neoplastic in origin. It may be associated with similar process in the mediastinum, sclerosing cholangitis and Riedel's thyroiditis and termed *multifocal fibrosclerosis*. Though idiopathic, the etiologic role of ergot derivative drugs and autoimmune reaction has been suggested.

Mesenteric Cysts

Mesenteric cysts of unknown etiology and varying sizes may be found in the peritoneal cavity. On the basis of their possible origin, they are of various types:

1. *Chylous cyst* is a thin-walled cyst arising from lymph vessels and lined by endothelium.

2. *Pseudocysts* are those which are formed following walled-off infection or pancreatitis.

3. *Neoplastic cysts* occur due to cystic change in tumours.

Tumours

Peritoneum may be involved in malignant tumours—primary and metastatic.

◆ **Mesothelioma** is an example of primary peritoneal tumour (benign and malignant) and is similar in morphology as in pleural cavity (page 486).

◆ **Intra-abdominal desmoplastic small cell tumour** is a recently described highly malignant tumour belonging to the group of other round cell or blue cell tumours such as small cell carcinoma lung, Ewing's sarcoma, rhabdomyosarcoma, neuroblastoma and others.

◆ **Metastatic peritoneal tumours** are quite common and may occur from dissemination from any intra-abdominal malignancy.

GIST BOX 18.16 Diseases of Peritoneum

- ☐ Peritonitis may be due to bacterial infection or chemical substances (e.g. bile, pancreatic secretion, gastric juice etc).
- ☐ Idiopathic retroperitoneal fibrosis has unknown origin and is often multifocal.
- ☐ Mesenteric cysts of unknown etiology may be seen in peritoneal cavity.
- ☐ Metastatic tumours in the peritoneum are more common while rare primary tumour of note is mesothelioma.

Table 18.13 Causes of gastrointestinal (G.I.) bleeding.

| UPPER G.I. BLEEDING | SMALL INTESTINAL BLEEDING | LOWER G.I. BLEEDING |
|-----------------------------------|---|----------------------------------|
| 1. Oesophageal varices | Vascular ectasias | Inflammatory bowel disease (IBD) |
| 2. Mallory-Weiss tear | Tumours (adenocarcinoma, lymphoma, leiomyoma) | Carcinoma colon |
| 3. Haemorrhagic/erosive gastritis | NSAIDs | Carcinoma rectosigmoid |
| 4. Duodenal ulcer | Meckel's diverticulum | Haemorrhoids |
| 5. Gastric ulcer | Intussusception | Anal fissure |
| 6. Cancer stomach | Crohn's disease | Diverticulosis |

✦ CLINICAL CASE 15

A 35 years old male executive in a multinational company complains of dull pain in the midepigastic region for the last one month. The pain gets worse at night and is somewhat better immediately after he eats his meals. There is no history of any fever, nausea, or vomiting. He has been frequently taking analgesic (about 1-2 tablets per week) for headache but there is no history of intake of any other medications.

He underwent upper GI endoscopy once earlier but no records are available with him.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 910 (Appendix II)

✦ CLINICAL CASE 16

A 25 years old man returns home after playing cricket, and starts complaining of pain in the mid-abdomen without history of any injury. The pain remains unremitting for the next few hours; instead it becomes more severe and gets localised to the lower right quadrant. He also develops nausea and vomiting but no diarrhoea. Over the next 24 hours, he remains sick and keeps rolling in bed with severe pain and is brought to the hospital emergency.

On examination, his body temperature is 102°F and appears ill. His abdomen is mildly distended and diffusely tender on palpation, especially in the right lower quadrant.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 910 (Appendix II)

LIVER

NORMAL STRUCTURE

ANATOMY The liver is the largest organ in the body weighing 1400-1600 gm in the males and 1200-1400 gm in the females. There are 2 main anatomical lobes—right and left, the right being about six times the size of the left lobe. The right lobe has quadrate lobe on its inferior surface and a caudate lobe on the posterior surface. The right and left lobes are separated anteriorly by a fold of peritoneum called the *falciform ligament*, inferiorly by the fissure for the *ligamentum teres*, and posteriorly by the fissure for the *ligamentum venosum* (Fig. 19.1).

The *porta hepatis* is the region on the inferior surface of the right lobe where blood vessels, lymphatics and common hepatic duct form the hilum of the liver. A firm smooth layer of connective tissue called *Glisson's capsule* encloses the liver and is continuous with the connective tissue of the porta hepatis forming a sheath around the structures in the porta hepatis. The liver has a double blood supply—the portal vein brings the venous blood from the intestines and spleen, and the hepatic artery coming from the coeliac axis supplies arterial blood to the liver. This dual blood supply provides sufficient protection against infarction in the liver. The portal vein and hepatic artery divide into branches to the right and left lobes in the porta. The right and left hepatic ducts also join in the porta to form the common hepatic duct. The venous drainage from the liver is into the right and left hepatic veins which enter the inferior

vena cava. Lymphatics and the nerve fibres accompany the hepatic artery into their branchings and terminate around the porta hepatis.

HISTOLOGY The hepatic parenchyma is composed of numerous hexagonal or pyramidal *classical lobules*, each with a diameter of 0.5 to 2 mm. Each classical lobule has a central tributary from the hepatic vein and at the periphery are 4 to 5 portal tracts or triads containing branches of bile duct, portal vein and hepatic artery. Cords of hepatocytes and blood-containing sinusoids radiate from the central vein to the peripheral portal triads. The *functioning lobule* or *liver acinus* as described by Rappaport has a portal triad in the centre and is surrounded at the periphery by portions of several classical lobules. However, in most descriptions on pathology of the liver, the term *lobule* is used in its classical form.

The blood supply to the liver parenchyma flows from the portal triads to the central veins. Accordingly, the hepatic parenchyma of liver lobule is divided into 3 zones (Fig. 19.2):

◆ **Zone 1** or the *periportal (peripheral) area* is closest to the arterial and portal blood supply and hence bears the brunt of all forms of toxic injury.

◆ **Zone 3** or the *centrilobular area* surrounds the central vein and is most remote from the blood supply and thus suffers from the effects of hypoxic injury.

◆ **Zone 2** is the intermediate *midzonal area*.

The **hepatocytes** are polygonal cells with a round single nucleus and a prominent nucleolus. The liver cells have a remarkable capability to undergo mitosis and regeneration. Thus it is not uncommon to find liver cells containing more than one nucleus and having polyploidy up to octoploidy. A hepatocyte has 3 surfaces: *one* facing the sinusoid and the space of Disse, the *second* facing the canaliculus, and the *third* facing neighbouring hepatocytes.

The blood-containing *sinusoids* between cords of hepatocytes are lined by discontinuous endothelial cells and scattered flat Kupffer cells belonging to the reticuloendothelial system.

The *space of Disse* is the space between hepatocytes and sinusoidal lining endothelial cells. A few scattered fat storing *Ito cells* lie within the space of Disse.

The *portal triad or tract* besides containing portal vein radicle, the hepatic arteriole and bile duct, has a few mononuclear cells and scanty connective tissue considered to be extension of Glisson's capsule. The portal triads are surrounded by a limiting plate of hepatocytes.

The *intrahepatic biliary system* begins with the bile canaliculi interposed between the adjacent hepatocytes. The bile canaliculi are simply grooves between the contact surfaces of the liver cells and are covered by microvilli. These canaliculi join at the periphery of the lobule to drain eventually into terminal bile ducts or ductules (canal of Hering) which are lined by cuboidal epithelium.

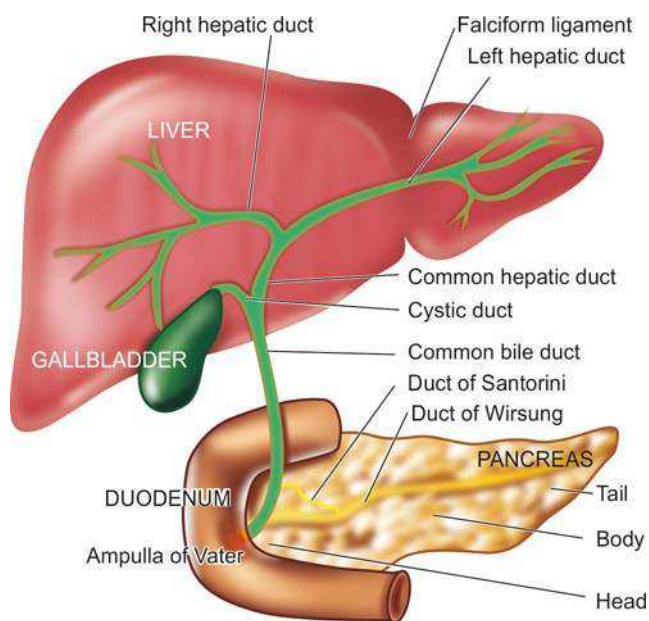

Figure 19.1 Anatomy of the liver and its relationship to the gallbladder, pancreas and duodenum.

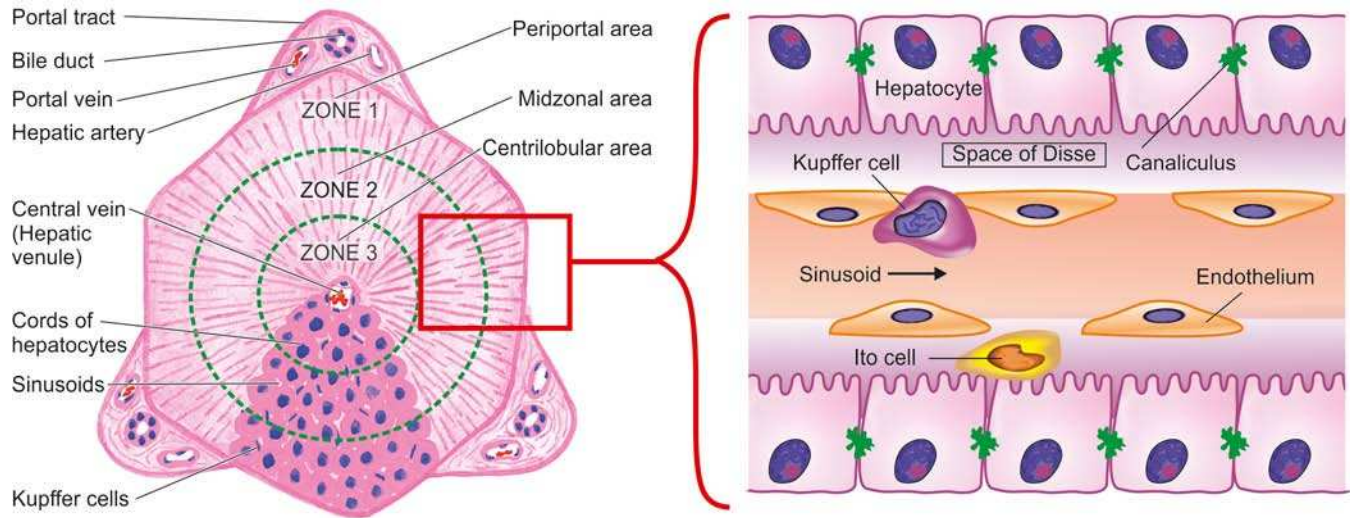

Figure 19.2 Histology of hepatic lobule. The hexagonal or pyramidal structure with central vein and peripheral 4 to 5 portal triads is termed the classical lobule. The figure on left shows functional divisions of the lobule into 3 zones shown by circles. The figure on right shows hepatic sinusoidal perisinusoidal space and cords of hepatocytes.

FUNCTIONS The liver performs multifold functions listed below:

1. Manufacture and excretion of bile.
2. Manufacture of several major plasma proteins such as albumin, fibrinogen and prothrombin.
3. Metabolism of proteins, carbohydrates and lipids.
4. Storage of vitamins (A, D and B₁₂) and iron.
5. Detoxification of toxic substances such as alcohol and drugs.

LIVER FUNCTION TESTS

In view of multiplicity and complexity of the liver functions, it is obvious that no single test can establish the disturbance in liver function. Thus a battery of liver function tests is employed for accurate diagnosis, to assess the severity of damage, to judge prognosis and to evaluate therapy. These tests are described below in relation to major liver functions. A summary of various liver function tests is given in **Table 19.1**.

I. TESTS FOR MANUFACTURE AND EXCRETION OF BILE

Bile is produced by the liver, stored in the gallbladder and secreted via biliary ducts into the duodenum. Bile consists of biliary phospholipids and primary and secondary bile acids. To understand the mechanisms underlying biliary pathology, it is important to understand normal bilirubin metabolism (page 582). In brief, jaundice will develop if bilirubin is excessively produced, or there is impaired hepatic uptake and conjugation of bilirubin, or it is insufficiently excreted into the duodenum. Tests employed to assess the synthesis and elimination of bilirubin pigment, urobilinogen and bile acids are as follows:

1. BILIRUBIN Bilirubin pigment can be detected in serum, faeces and urine.

i) Serum bilirubin estimation is based on *van den Bergh diazo reaction* by spectrophotometric method. Diazo reagent consists of diazotised sulfanilic acid. *Water-soluble conjugated bilirubin* gives *direct* van den Bergh reaction with diazo reagent within one minute, whereas *alcohol-soluble unconjugated*

bilirubin is determined by *indirect* van den Bergh reaction. Addition of alcohol to the reaction mixture gives positive test for both conjugated and unconjugated bilirubin pigment. The unconjugated bilirubin level is then estimated by subtracting direct bilirubin value from this total value. The serum of normal adults contains less than 1 mg/dl of total bilirubin, out of which less than 0.25 mg/dl is conjugated bilirubin. Bilirubin level rises in diseases of hepatocytes, obstruction to biliary excretion into the duodenum, in haemolysis, and defects of hepatic uptake and conjugation of bilirubin pigment such as in Gilbert's disease.

ii) In faeces, excretion of bilirubin is assessed by inspection of stools. Clay-coloured stool due to absence of faecal excretion of the pigment indicates obstructive jaundice.

iii) In urine, presence of bilirubin imparts deep yellow colour. Conjugated bilirubinuria can be detected by commercially available 'dipsticks', Fouchet's test, foam test or ictotest tablet method. Bilirubinuria does not occur in normal subjects nor is unconjugated bilirubin excreted in the urine. Bilirubinuria occurs only when there is raised level of conjugated bilirubin (filterable). Its excretion depends upon the level of conjugated bilirubin in plasma that is not protein-bound and is therefore available for glomerular filtration. Bilirubinuria appears in patients of hepatitis before the patient becomes jaundiced.

2. UROBILINOGEN Urobilinogen is normally excreted in the urine. Its semiquantitative estimation in the urine can be done by preparing dilutions with Ehrlich's aldehyde reagent or by 'dipstick' method. An increase in urobilinogen in the urine is found in hepatocellular dysfunctions such as in alcoholic liver disease, cirrhosis and malignancy of the liver. It is also raised in haemolytic disease and in pyrexia. In cholestatic jaundice due to complete biliary obstruction, urobilinogen disappears from the urine.

3. BILE ACIDS (BILE SALTS) The primary bile acids (cholic acid and cheno-deoxycholic acid) are formed from cholesterol in the hepatocytes. These bile acids on secretion into the gut come in contact with colonic bacteria and undergo deconjugation with the production of secondary bile acids (deoxycholic acid and lithocholic acid). Most of these bile acids

Table 19.1 Liver function tests.

| TESTS | SIGNIFICANCE |
|---|--|
| I. TESTS FOR MANUFACTURE AND EXCRETION OF BILE | |
| 1. <i>Bilirubin:</i> | |
| i) Serum bilirubin (0.3-1.3 mg/dl) | Increased in hepatocellular, obstructive and haemolytic disease, Gilbert's disease |
| ii) In faeces | Absent in biliary obstruction |
| iii) In urine | Conjugated bilirubinuria in patients of hepatitis |
| 2. <i>Urobilinogen:</i> | Increased in hepatocellular and haemolytic diseases, absent in biliary obstruction |
| 3. <i>Bile acid (Bile salts):</i> | Increased in serum and detectable in urine in cholestasis |
| II. SERUM ENZYME ASSAYS | |
| 1. <i>Alkaline phosphatase</i> (33-96 U/L) | Increased in hepatobiliary disease (highest in biliary obstruction), bone diseases, pregnancy |
| 2. <i>γ-Glutamyl transpeptidase (γ-GT)</i> (9-58 IU/L) | Rise parallels alkaline phosphatase but is specific for hepatobiliary diseases |
| 3. <i>Transaminases:</i> | |
| i) SGOT (AST) (12-38 U/L) | Increased in tissue injury to liver as well as to other tissues like in myocardial infarction |
| ii) SGPT (ALT) (7-41 U/L) | Increase is fairly specific for liver cell injury |
| 4. <i>Other enzymes:</i> | |
| i) 5'-Nucleotidase | Rise parallels alkaline phosphatase but more specific for diseases of hepatic origin |
| ii) Lactate dehydrogenase (115-221 U/L) | Increased in tumours involving the liver |
| iii) Cholinesterase | Decreased in hepatocellular disease, malnutrition |
| III. TESTS FOR METABOLIC FUNCTIONS | |
| 1. <i>Amino acid and protein metabolism:</i> | |
| i) Serum proteins (total=6.7-8.6 g/dl; A/G ratio=1.5-3:1) | Hypoalbuminaemia in hepatocellular diseases; hyperglobulinaemia in cirrhosis and chronic active hepatitis |
| ii) Immunoglobulins | Nonspecific alterations in IgA, IgG and IgM |
| iii) Clotting factors | Prothrombin time and partial thromboplastin time prolonged in patients with hepatocellular disease |
| iv) Plasma ammonia (19-60 µg/dl) | Increased in acute fulminant hepatitis, cirrhosis, hepatic encephalopathy |
| v) Aminoaciduria | In fulminant hepatitis |
| 2. <i>Lipid and lipoprotein metabolism:</i> | |
| Blood lipids (total serum cholesterol <200 mg/dl; triglycerides < 150 mg/dl; and lipoprotein fractions) | Increased in cholestasis, decreased in acute and chronic diffuse liver disease and in malnutrition |
| 3. <i>Carbohydrate metabolism:</i> | |
| Blood glucose and GTT | Decreased in hepatic necrosis |
| IV. IMMUNOLOGIC TESTS | |
| 1. <i>Nonspecific immunologic reactions:</i> | |
| i) Smooth muscle antibody | In hepatic necrosis |
| ii) Mitochondrial antibody | In primary biliary cirrhosis |
| iii) Antinuclear antibody and LE cell test | In chronic active hepatitis |
| 2. <i>Antibodies to specific etiologic agents:</i> | |
| i) Antibodies to hepatitis B (HBsAg, HBc, HBeAg) | In hepatitis B |
| ii) Amoeba antibodies | Amoebic liver abscess |
| V. ANCILLARY DIAGNOSTIC TESTS | |
| 1. <i>Ultrasound examination</i> | Cholestasis of various etiologies; SOLs, US-guided-FNAC/liver biopsy |
| 2. <i>FNAC and/or percutaneous liver biopsy</i> | Unknown cause of hepatocellular disease, hepatomegaly and splenomegaly; long-standing hepatitis; PUO and SOLs of the liver |

are reabsorbed through enterohepatic circulation and reach the liver. Only about 10% of the total bile acids are excreted in the faeces normally as unabsorbable toxic lithocholic acid.

Hepatobiliary diseases with cholestasis are associated with raised levels of serum bile acids which are responsible for producing itching (pruritus). These acids are excreted in

the urine by active transport and passive diffusion and can be detected by simple methods as Hay's test and 'dipsticks'.

4. BROMSULPHALEIN EXCRETION Bromsulphalein (BSP) is a dye which is removed from circulation by the same mechanisms of binding, conjugation and excretion as bilirubin. BSP is injected intravenously and a sample of venous blood 45 minutes later is tested for percentage of injected dye remaining in the blood. The test is rarely performed nowadays because of the availability of enzyme estimations which are better indicators of hepatic dysfunction. Presently, the only value of BSP excretion test is in the diagnosis of Dubin-Johnson's syndrome (page 586).

II. SERUM ENZYME ASSAYS

Determination of certain serum enzymes is considered useful in various types of liver injury, whether hepatocellular or cholestatic, as well as in quantifying liver damage. A combination of serum transaminases and alkaline phosphatase estimation is adequate to diagnose liver injury.

1. ALKALINE PHOSPHATASE Serum alkaline phosphatase is produced by many tissues, especially bone, liver, intestine and placenta and is excreted in the bile. Most of the normal serum alkaline phosphatase (range 33-96 U/L) is derived from bone. Elevation in activity of the enzyme can thus be found in diseases of bone, liver and in pregnancy. In the absence of bone disease and pregnancy, an elevated serum alkaline phosphatase levels generally reflect hepatobiliary disease. The greatest elevation (3 to 10 times normal) occurs in biliary tract obstruction. Slight to moderate increase is seen in parenchymal liver diseases such as in hepatitis and cirrhosis and in metastatic liver disease. It is possible to distinguish serum hepatic alkaline phosphatase from bony alkaline phosphatase by fractionation into isoenzymes but this is not routinely done.

2. γ -GLUTAMYL TRANSPEPTIDASE (γ -GT) The primary source of the enzyme, γ -GT, in serum is the liver. Its serum level parallels serum alkaline phosphatase and is used to confirm that the elevated serum alkaline phosphatase is of hepatobiliary origin. Besides its elevation in cholestasis and hepatocellular disease, the levels are high in patients with alcohol abuse even without liver disease.

3. TRANSAMINASES (AMINOTRANSFERASES) Assessment of liver cell necrosis is most frequently done by estimation of the following 2 serum enzymes:

i) Serum aspartate transaminase or AST (formerly glutamic oxaloacetic transaminase or SGOT): AST or SGOT is a *mitochondrial enzyme* released from heart, liver, skeletal muscle and kidney. Its normal serum level is 0.20-0.65 μ kat/L (12-38 U/L).

ii) Serum alanine transaminase or ALT (formerly glutamic pyruvic transaminase or SGPT): ALT or SGPT is a *cytosolic enzyme* primarily present in the liver. Its normal serum level is 0.12-0.70 μ kat/L (7-41 U/L).

Serum levels of SGOT and SGPT are increased on damage to the tissues producing them. Thus serum estimation of SGPT (ALT) which is fairly specific for liver tissue is of greater value in liver cell injury, whereas SGOT (AST) level may rise in acute necrosis or ischaemia of other organs such as the myocardium, besides liver cell injury.

Transaminase estimations are useful in the early diagnosis of viral hepatitis. Very high levels are seen in extensive acute

hepatic necrosis such as in severe viral hepatitis and acute cholestasis. Alcoholic liver disease and cirrhosis are associated with mild to moderate elevation of transaminases.

4. OTHER SERUM ENZYMES The determination of a few other serum enzymes is done sometimes but without any extra diagnostic advantage over the above-mentioned enzyme assays. These are as under:

i) *5'-Nucleotidase* is another phosphatase derived from the liver. Its determination is useful to distinguish alkaline phosphatase of hepatic origin from that of bony tissue.

ii) *Lactate dehydrogenase (LDH)* is found to be elevated in serum of patients with metastatic liver involvement.

iii) *Choline esterase* synthesised by the liver is diminished in hepatocellular disease and malnutrition due to impaired synthesis.

III. TESTS FOR METABOLIC FUNCTIONS

The liver is the principal site of metabolism and synthesis of plasma proteins and amino acids, lipids and lipoproteins, carbohydrates and vitamins, besides detoxification of drugs and alcohol.

1. AMINO ACID AND PLASMA PROTEIN METABOLISM

Amino acids derived from the diet and from tissue breakdown are metabolised in the liver to ammonia and urea. A number of plasma proteins and immunoglobulins are synthesised on polyribosomes bound to the rough endoplasmic reticulum within the hepatocytes and discharged into plasma. Based on these metabolic functions of the liver, serum estimation of proteins, immunoglobulins and ammonia and aminoaciduria are employed to assess the liver cell damage.

i) Serum proteins Liver cells synthesise albumin, fibrinogen, prothrombin, alpha-1-antitrypsin, haptoglobin, ceruloplasmin, transferrin, alpha fetoproteins and acute phase reactant proteins. The blood levels of these plasma proteins are decreased in extensive liver damage. Routinely estimated are total concentration of serum proteins (normal 6.7 to 8.6 gm/dl), serum albumin (normal 3.5 to 5.5 gm/dl), serum globulin (normal 2 to 3.5 gm/dl) and albumin/globulin (A/G) ratio (normal 1.5-3:1). Electrophoresis is used to determine the proportions of α_1 , α_2 , β and γ globulins. Due to the availability of protein electrophoresis, thymol turbidity and flocculation tests based on altered plasma protein components have been discontinued.

Hypoalbuminaemia may occur in liver diseases having significant destruction of hepatocytes. Hyperglobulinaemia may be present in chronic inflammatory disorders such as in cirrhosis and chronic hepatitis.

ii) Immunoglobulins The levels of serum immunoglobulins produced by lymphocytes and plasma cells (IgG, IgM and IgA) show nonspecific abnormalities in liver diseases and represent inflammatory or immune response rather than liver cell dysfunction. IgA is the predominant immunoglobulin in bile and its level is raised in cirrhosis, IgG is markedly raised in chronic active hepatitis and IgM is markedly increased in primary biliary cirrhosis.

iii) Clotting factors Hepatic synthetic function of several clotting factors can be assessed by a few simple coagulation tests. Prothrombin time and partial thromboplastin time, both of which reflect the activities of various clotting factors,

are prolonged in patients with hepatocellular disease. Prothrombin time is dependent upon both hepatic synthesis of clotting factors and intestinal uptake of vitamin K, a fat-soluble vitamin. Thus, obstruction of the bile duct and intra-hepatic cholestasis which result in vitamin K deficiency due to impaired lipid absorption, are associated with prolonged prothrombin time. However, parenteral injection of vitamin K will normalise prothrombin time if the prolongation was due to obstruction, but there will be no improvement in prothrombin time if there is extensive hepatocellular disease.

iv) Serum ammonia High blood levels of ammonia are found in acute fulminant hepatitis, cirrhosis and hepatic encephalopathy. The rise in serum ammonia is due to inability of severely damaged liver to convert ammonia to urea. Thus, urea synthesis is reduced in chronic liver disease.

2. LIPID AND LIPOPROTEIN METABOLISM Lipids synthesised in the liver include cholesterol and cholesterol esters, phospholipids and triglycerides. These lipids are insoluble in water and are carried in circulation with three major types of lipoproteins which contain apoproteins. These are: high density lipoproteins (HDL), low density lipoproteins (LDL) and very low density lipoproteins (VLDL).

Blood lipids Estimations of total serum cholesterol, triglycerides and lipoprotein fractions are frequently done in patients with liver disease.

◆ There is rise in total serum cholesterol in cholestasis, probably due to retention of cholesterol which is normally excreted in the bile (normal < 200 mg/dl). Serum triglyceride is also elevated in cholestasis.

◆ Values are lowered in acute and chronic diffuse liver diseases and in malnutrition.

3. CARBOHYDRATE METABOLISM The liver plays a central role in carbohydrate metabolism. Blood glucose level is lowered in fulminant acute hepatic necrosis. In chronic liver disease, there is impaired glucose tolerance and relative insulin resistance.

IV. IMMUNOLOGIC TESTS

Liver diseases are associated with various immunologic abnormalities which may be nonspecific immunologic reactions or may be antibodies against specific etiologic agents.

1. NONSPECIFIC IMMUNOLOGIC REACTIONS These include the following:

- Smooth muscle antibody* to actin component of muscle is formed in certain hepatic disorders with hepatic necrosis. It appears that hepatocytes have a protein which is immunologically similar to actin.
- Mitochondrial antibody* develops in patients with primary biliary cirrhosis.
- Antinuclear antibody* is present in some patients of chronic hepatitis. The LE cell test may be positive in these cases.

2. ANTIBODIES TO SPECIFIC ETIOLOGIC AGENTS These vary according to the etiologic agent causing the liver cell injury.

- Hepatitis B surface antigen (HBsAg)* can be demonstrated in cases of serum hepatitis. A confirmed positive test for HBsAg is definite proof of hepatitis B infection.
- Hepatitis B core antibody (HBc)* can be detected in all patients with hepatitis B.
- Hepatitis Be antigen (HBeAg)* can be found in chronic varieties of hepatitis B.

iv) *Amoeba antibodies* to *Entamoeba histolytica* develop in patients with amoebic liver abscess.

V. ANCILLARY DIAGNOSTIC TESTS

In addition to laboratory tests described above, two ancillary tests which are invariably done by the physician are ultrasonography and percutaneous liver biopsy and/or FNAC.

1. ULTRASONOGRAPHY Ultrasound (US) examination of the liver is indicated in the following situations:

- Cholestasis of various etiologies to see the dilated intra- and extrahepatic canalicular tree.
- Space-occupying lesions (SOLs) within the liver to determine whether they are neoplasms or non-neoplastic cysts.
- To provide US-guidance for FNAC or liver biopsy.

2. FNAC AND/OR PERCUTANEOUS LIVER BIOPSY Lastly, FNAC and percutaneous liver biopsy are employed to examine the microscopic changes of hepatic morphology in various diseases. Both these tests are done after evaluation of signs of obstruction since these tests are contraindicated in cholestasis. FNAC and liver biopsy are otherwise easily performed bedside tests of value. Their main indications are as follows:

- hepatocellular disease of unknown cause;
- suspected cases of chronic hepatitis;
- hepatomegaly of various etiologies;
- splenomegaly of unknown cause;
- fever of unknown cause; and
- SOLs visualised in radiologic examination

GIST BOX 19.1

Normal Structure of Liver and Liver Function Tests

- ☐ Liver is the largest organ in the body with average weight of 1500 gm in males and 1300 gm in females.
- ☐ It has microscopic lobules composed of cords of hepatocytes and 3-5 portal tracts in each lobule.
- ☐ Liver performs various metabolic functions.
- ☐ Manufacture and excretion of bile can be tested in blood, urine and stool.
- ☐ Serum enzymes can be estimated to assess hepatocellular injury.
- ☐ Blood tests for manufacture of proteins, lipids and carbohydrates are routinely done.
- ☐ Specific immunologic tests, ultrasound and FNA or biopsy are done in some clinical situations.

JAUNDICE—GENERAL

Jaundice or icterus refers to the yellow pigmentation of the skin or sclerae by bilirubin (page 24). Bilirubin pigment has high affinity for elastic tissue and hence jaundice is particularly noticeable in tissues rich in elastin content. Jaundice is the result of elevated levels of bilirubin in the blood termed hyperbilirubinaemia. Normal serum bilirubin concentration ranges from 0.3-1.3 mg/dl, about 80% of which is unconjugated. Jaundice becomes clinically evident when the total serum bilirubin exceeds 2 mg/dl. A rise of serum bilirubin between the normal and 2 mg/dl is generally not accompanied by visible jaundice and is called *latent jaundice*.

Before considering the features and types of jaundice, it is essential to review the normal bilirubin metabolism.

Normal metabolism of bilirubin can be conveniently described under 4 main headings—source, transport, hepatic phase and intestinal phase as illustrated schematically earlier (see Fig. 10.9, page 267).

1. SOURCE OF BILIRUBIN About 80-85% of the bilirubin is derived from the catabolism of haemoglobin present in senescent red blood cells. The destruction of effete erythrocytes at the end of their normal lifespan of 120 days takes place in the reticuloendothelial system in the bone marrow, spleen and liver. The remaining 15-20% of the bilirubin comes partly from non-haemoglobin haem-containing pigments such as myoglobin, catalase and cytochromes, and partly from ineffective erythropoiesis. In either case, haem moiety is formed which is converted to biliverdin by microsomal haem oxygenase for which oxygen and NADPH are essential requirements. Bilirubin is formed from biliverdin by biliverdin reductase.

2. TRANSPORT OF BILIRUBIN Bilirubin on release from macrophages circulates as unconjugated bilirubin in plasma tightly bound to albumin. Certain drugs such as sulfonamides and salicylates compete with bilirubin for albumin binding and displace bilirubin from albumin, thus facilitating bilirubin to enter into the brain in neonates and increase the risk of *kernicterus*. Bilirubin is found in body fluids in proportion to their albumin content such as in CSF, joint effusions, cysts etc.

3. HEPATIC PHASE On coming in contact with the hepatocyte surface, unconjugated bilirubin is preferentially metabolised which involves 3 steps: hepatic uptake, conjugation and secretion in bile.

i) Hepatic uptake Albumin-bound unconjugated bilirubin upon entry into the hepatocyte, is dissociated into bilirubin and albumin. The bilirubin gets bound to cytoplasmic protein *glutathione-S-transferase (GST)* (earlier called ligandin).

ii) Conjugation Unconjugated bilirubin is not water-soluble but is alcohol-soluble and is converted into water-soluble compound by conjugation. Conjugation occurs in endoplasmic reticulum and involves conversion to bilirubin mono- and diglucuronide by the action of microsomal enzyme, *bilirubin-UDP-glucuronosyl transferase* (Fig. 19.3). The process of conjugation can be induced by drugs like phenobarbital.

Conjugated bilirubin is bound to albumin in two forms: reversible and irreversible. Reversible binding is similar to that of unconjugated bilirubin. However, when present in serum for a long time (e.g. in cholestasis, long-standing biliary obstruction, chronic active hepatitis), conjugated bilirubin is bound to albumin irreversibly and is termed *delta bilirubin* or *biliprotein*. This irreversible conjugated delta bilirubin is not excreted by the kidney, and remains detectable in serum for sufficient time after recovery from the diseases listed above.

iii) Secretion into bile Conjugated (water-soluble) bilirubin is rapidly transported directly into bile canaliculi by energy-dependent process and then excreted into the bile.

4. INTESTINAL PHASE Appearance of conjugated bilirubin in the intestinal lumen is followed by either direct excretion in the stool as stercobilinogen which imparts the normal yellow colour to stool, or may be metabolised to urobilinogen by the action of intestinal bacteria. Conjugated bilirubin is normally not reabsorbable whereas its metabolic product, urobilinogen, is reabsorbed from the small intestine and reaches entero-

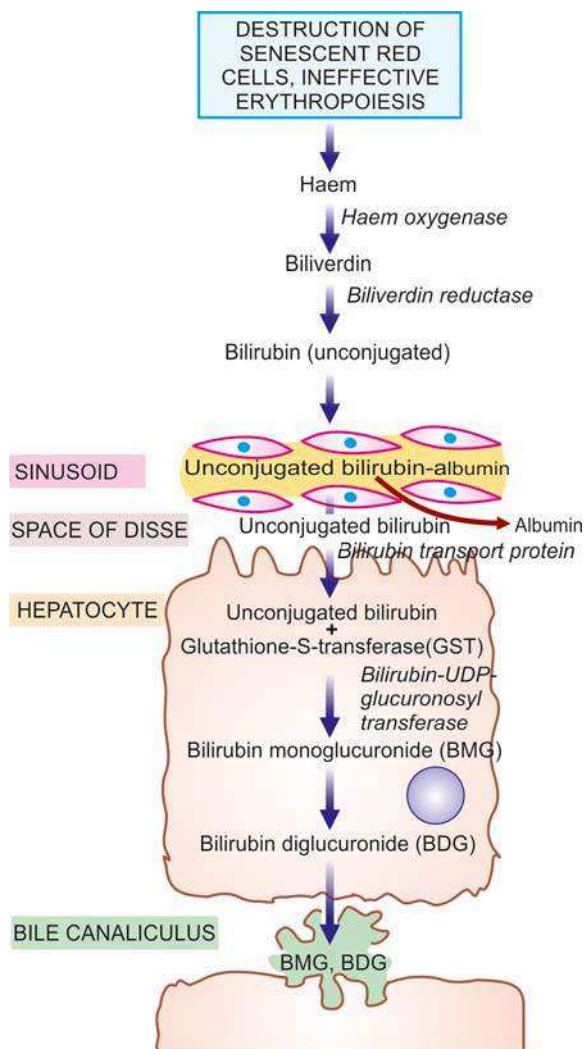

Figure 19.3 Schematic representation of hepatic phase of bilirubin transport.

hepatic circulation. Some of the absorbed urobilinogen is resecreted by the liver into the bile while the rest is excreted in the urine as urobilinogen.

The major differences between unconjugated and conjugated bilirubin are summarised in Table 19.2.

Table 19.2 Major differences between unconjugated and conjugated bilirubin.

| FEATURE | UNCONJUGATED BILIRUBIN | CONJUGATED BILIRUBIN |
|---|-------------------------------|-----------------------------|
| 1. Normal serum level | More | Less (less than 0.25 mg/dl) |
| 2. Water solubility | Absent | Present |
| 3. Affinity to lipids (alcohol solubility) | Present | Absent |
| 4. Serum albumin binding | High | Low |
| 5. van den Bergh reaction | Indirect (Total minus direct) | Direct |
| 6. Renal excretion | Absent | Present |
| 7. Bilirubin albumin covalent complex formation | Absent | Present |
| 8. Affinity to brain tissue (Kernicterus) | Present (Kernicterus) | Absent |

TYPES OF LIVER CELL NECROSIS

All forms of injury to the liver such as microbiologic, toxic, circulatory or traumatic, result in necrosis of liver cells. The extent of involvement of hepatic lobule in necrosis varies. Accordingly, liver cell necrosis is divided into 3 types: *diffuse* (submassive to massive), *zonal* and *focal*.

1. DIFFUSE (SUBMASSIVE TO MASSIVE) NECROSIS

When there is extensive and diffuse necrosis of the liver involving all the cells in groups of lobules, it is termed diffuse, or submassive to massive necrosis. It is most commonly caused by viral hepatitis or drug toxicity.

2. ZONAL NECROSIS Zonal necrosis is necrosis of hepatocytes in 3 different zones of the hepatic lobule (see Fig. 19.2). Accordingly, it is of 3 types; each type affecting respective zone is caused by different etiologic factors:

i) Centrilobular necrosis is the commonest type involving hepatocytes in zone 3 (i.e. located around the central vein). Centrilobular necrosis is characteristic feature of ischaemic injury such as in shock and CHF since zone 3 is farthest from the blood supply. Besides, it also occurs in poisoning with chloroform, carbon tetrachloride and certain drugs.

ii) Midzonal necrosis is uncommon and involves zone 2 of the hepatic lobule. This pattern of necrosis is seen in yellow fever and viral hepatitis. In viral hepatitis, some of the necrosed hepatocytes of the mid-zone are transformed into acidophilic, rounded Councilman bodies.

iii) Periportal (peripheral) necrosis is seen in zone 1 involving the parenchyma closest to the arterial and portal blood supply. Since zone 1 is most well perfused, it is most vulnerable to the effects of circulating hepatotoxins e.g. in phosphorus poisoning and eclampsia.

3. FOCAL NECROSIS This form of necrosis involves small groups of hepatocytes irregularly distributed in the hepatic lobule. Focal necrosis is most often caused by microbiologic infections. These include viral hepatitis, miliary tuberculosis, typhoid fever and various other forms of bacterial, viral and fungal infections. Focal necrosis may also occur in drug-induced hepatitis.

CLASSIFICATION AND FEATURES OF JAUNDICE

Based on pathophysiology, jaundice may result from one or more of the following mechanisms:

1. Increased bilirubin production
2. Decreased hepatic uptake
3. Decreased hepatic conjugation
4. Decreased excretion of bilirubin into bile

Accordingly, a simple age-old classification of jaundice was to divide it into 3 predominant types: *pre-hepatic* (*haemolytic*), *hepatic*, and *post-hepatic cholestatic*. However, hyperbilirubinaemia due to first three mechanisms is *mainly unconjugated* while the last variety yields *mainly conjugated* hyperbilirubinaemia. Hence, currently pathophysiologic classification of jaundice is based on predominance of the type of hyperbilirubinaemia. A simple test to determine whether hyperbilirubinaemia is of unconjugated or conjugated variety is to determine whether bilirubin is present in urine or not; its absence in urine suggests unconjugated hyperbilirubinaemia since unconjugated bilirubin is not filtered by the glomerulus. The presence of bilirubin in the urine is evidence of conjugated hyperbilirubinaemia.

Table 19.3 Pathophysiologic classification of jaundice.

| I. | PREDOMINANTLY UNCONJUGATED HYPERBILIRUBINAEMIA |
| 1. | <i>Increased bilirubin production (Haemolytic, acholuric or prehepatic jaundice)</i> <ol style="list-style-type: none"> i) Intra- and extravascular haemolysis ii) Ineffective erythropoiesis |
| 2. | <i>Decreased hepatic uptake</i> <ol style="list-style-type: none"> i) Drugs ii) Prolonged starvation iii) Sepsis |
| 3. | <i>Decreased bilirubin conjugation</i> <ol style="list-style-type: none"> i) Hereditary disorders (e.g. Gilbert's syndrome, Crigler-Najjar syndrome) ii) Acquired defects (e.g. drugs, hepatitis, cirrhosis) iii) Neonatal jaundice |
| II. | PREDOMINANTLY CONJUGATED HYPERBILIRUBINAEMIA (CHOLESTASIS) |
| 1. | <i>Intrahepatic cholestasis (Impaired hepatic excretion)</i> <ol style="list-style-type: none"> i) Hereditary disorders or 'pure cholestasis' (e.g. Dubin-Johnson syndrome, Rotor's syndrome, fibrocystic disease of pancreas, benign familial recurrent cholestasis, intrahepatic atresia, cholestatic jaundice of pregnancy) ii) Acquired disorders or 'hepatocellular cholestasis' (e.g. viral hepatitis, drugs, alcohol-induced injury, sepsis, cirrhosis) |
| 2. | <i>Extrahepatic cholestasis (Extrahepatic biliary obstruction)</i> Mechanical obstruction (e.g. gallstones, inflammatory strictures, carcinoma head of pancreas, tumours of bile ducts, sclerosing cholangitis, congenital atresia of extrahepatic ducts) |

Based on these mechanisms, the pathogenesis and main features of the two predominant forms of hyperbilirubinaemia are discussed below (**Table 19.3**).

I. Predominantly Unconjugated Hyperbilirubinaemia

This form of jaundice can result from the following three sets of conditions:

1. INCREASED BILIRUBIN PRODUCTION (HAEMOLYTIC, ACHOLURIC OR PREHEPATIC JAUNDICE) This results from excessive red cell destruction as occurs in intra- and extravascular haemolysis or due to ineffective erythropoiesis. There is increased release of haemoglobin from excessive breakdown of red cells that leads to overproduction of bilirubin. Hyperbilirubinaemia develops when the capacity of the liver to conjugate large amount of bilirubin is exceeded. In premature infants, the liver is deficient in enzyme necessary for conjugation while the rate of red cell destruction is high. This results in *icterus neonatorum* which is particularly severe in haemolytic disease of the newborn due to maternal isoantibodies (page 319). Since there is predominantly unconjugated hyperbilirubinaemia in such cases, there is danger of permanent brain damage in these infants from kernicterus when the serum level of unconjugated bilirubin exceeds 20 mg/dl.

Laboratory data in haemolytic jaundice, in addition to predominant unconjugated hyperbilirubinaemia, reveal normal serum levels of transaminases, alkaline phosphatase and proteins. Bile pigment being unconjugated type is absent from urine (acholuric jaundice). However, there is dark brown colour of stools due to excessive faecal excretion of bile pigment and there is increased urinary excretion of urobilinogen.

2. DECREASED HEPATIC UPTAKE The uptake of bilirubin by the hepatocyte that involves dissociation of the pigment from albumin and its binding to cytoplasmic protein, GST or ligandin, may be deranged in certain conditions e.g. due to drugs, prolonged starvation and sepsis.

3. DECREASED BILIRUBIN CONJUGATION This mechanism involves deranged hepatic conjugation due to defect or deficiency of the enzyme, glucuronosyl transferase. This can occur in certain inherited disorders of the enzyme (e.g. Gilbert's syndrome and Crigler-Najjar syndrome), or acquired defects in its activity (e.g. due to drugs, hepatitis, cirrhosis). However, hepatocellular damage causes deranged excretory capacity of the liver more than its conjugating capacity (*see below*). The physiologic neonatal jaundice is also partly due to relative deficiency of UDP-glucuronosyl transferase in the neonatal liver and is partly as a result of increased rate of red cell destruction in neonates.

II. Predominantly Conjugated Hyperbilirubinaemia (Cholestasis)

This form of hyperbilirubinaemia is defined as failure of normal amounts of bile to reach the duodenum. Morphologically, cholestasis means accumulation of bile in liver cells and biliary passages. The defect in excretion may be within the biliary canaliculi of the hepatocyte and in the microscopic bile ducts (*intrahepatic cholestasis or medical jaundice*), or there may be mechanical obstruction to the extrahepatic biliary excretory apparatus (*extrahepatic cholestasis or obstructive jaundice*). It is important to distinguish these two forms of cholestasis since extrahepatic cholestasis or obstructive jaundice is often treatable with surgery, whereas the intrahepatic cholestasis or medical jaundice cannot be benefitted by surgery but may in fact worsen by the operation. Prolonged cholestasis of either of the two types may progress to biliary cirrhosis (page 609).

1. INTRAHEPATIC CHOLESTASIS Intrahepatic cholestasis is due to impaired hepatic excretion of bile and may occur from hereditary or acquired disorders.

i) Hereditary disorders producing intrahepatic obstruction to biliary excretion are characterised by 'pure cholestasis' e.g. in Dubin-Johnson syndrome, Rotor syndrome, fibrocystic disease of pancreas, benign familial recurrent cholestasis, intrahepatic atresia and cholestatic jaundice of pregnancy.

ii) Acquired disorders with intrahepatic excretory defect of bilirubin are largely due to hepatocellular diseases and hence

are termed '*hepatocellular cholestasis*' e.g. in viral hepatitis, alcoholic hepatitis, and drug-induced cholestasis such as from administration of chlorpromazine and oral contraceptives.

The **features** of intrahepatic cholestasis include: predominant conjugated hyperbilirubinaemia due to regurgitation of conjugated bilirubin into blood, bilirubinuria, elevated levels of serum bile acids and consequent pruritus, elevated serum alkaline phosphatase, hyperlipidaemia and hypoprothrombinaemia. 'Pure cholestasis' can be distinguished from 'hepatocellular cholestasis' by elevated serum levels of transaminases in the latter due to liver cell injury.

◆ **Liver biopsy** in cases with intrahepatic cholestasis reveals milder degree of cholestasis than the extrahepatic disorders (**Fig. 19.4A**). The biliary canaliculi of the hepatocytes are dilated and contain characteristic elongated green-brown *bile plugs*. The cytoplasm of the affected hepatocytes shows feathery degeneration. Canalicular bile stasis eventually causes proliferation of intralobular ductules followed by periportal fibrosis and produces a picture resembling biliary cirrhosis (page 609).

2. EXTRAHEPATIC CHOLESTASIS Extrahepatic cholestasis results from mechanical obstruction to large bile ducts outside the liver or within the porta hepatis. The common causes are gallstones, inflammatory strictures, carcinoma head of pancreas, tumours of bile duct, sclerosing cholangitis and congenital atresia of extrahepatic ducts. The obstruction may be complete and sudden with eventual progressive obstructive jaundice, or the obstruction may be partial and incomplete resulting in intermittent jaundice.

The **features** of extrahepatic cholestasis (obstructive jaundice), like in intrahepatic cholestasis, are: predominant conjugated hyperbilirubinaemia, bilirubinuria, elevated serum bile acids causing intense pruritus, high serum alkaline phosphatase and hyperlipidaemia. However, there are certain features which help to distinguish extrahepatic from intrahepatic cholestasis. In obstructive jaundice, there is malabsorption of fat-soluble vitamins (A,D,E and K) and steatorrhoea resulting in vitamin K deficiency. Prolonged prothrombin time in such cases shows improvement following parenteral administration of vitamin K, whereas hypoprothrombinaemia due to hepatocellular disease shows no such improvement in prothrombin time with vitamin K administration. The stools of such patients are clay-coloured due to absence of bilirubin metabolite, stercobilin, in faeces and there is virtual disappearance of urobilinogen from the

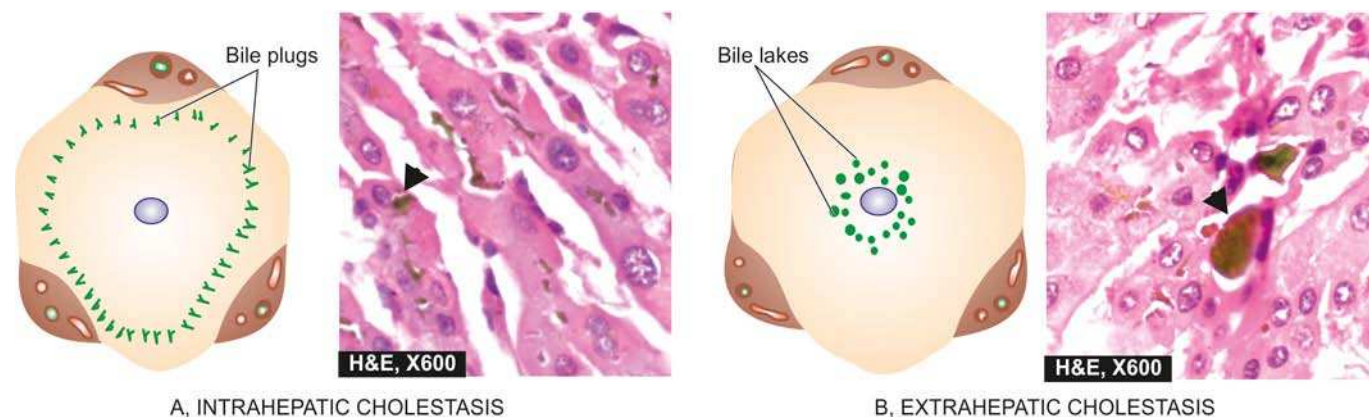

Figure 19.4 Salient features in morphology of liver in intra- and extrahepatic cholestasis. A, Intrahepatic cholestasis is characterised by elongated bile plugs in the canaliculi of hepatocytes at the periphery of the lobule. B, Extrahepatic cholestasis shows characteristic bile lakes due to rupture of canaliculi in the hepatocytes in the centrilobular area.

urine. These patients may have fever due to high incidence of ascending bacterial infections (ascending cholangitis).

◆ **Liver biopsy** in cases with extrahepatic cholestasis shows more marked changes of cholestasis (**Fig. 19.4,B**). Since the obstruction is in the extrahepatic bile ducts, there is progressive retrograde extension of bile stasis into intrahepatic duct system. This results in dilatation of bile ducts and rupture of canaliculi with extravasation of bile producing *bile lakes*. Since bile is toxic, the regions of bile lakes are surrounded by focal necrosis of hepatocytes. Stasis of bile predisposes to ascending bacterial infections with accumulation of polymorphs around the dilated ducts (ascending cholangitis). Eventually, there is proliferation of bile ducts and the appearance may mimic biliary cirrhosis (page 609).

GIST BOX 19.2 General Aspects of Jaundice

- ▣ Jaundice is yellow pigmentation of the skin or sclerae by bilirubin.
- ▣ It is due to rise in bilirubin level in the blood (hyperbilirubinaemia) above normal (0.3-1.3 mg/dl).
- ▣ Normally, bilirubin formed in the body is transported and metabolised through the liver, and excreted through the intestines and kidneys.
- ▣ All forms of liver cell injury result in necrosis of liver cells in the hepatic lobule which may be *diffuse* (submassive to massive), *zonal* and *focal*. Zonal necrosis may pertain to respective zone: centrilobular (zone 1), midzonal (zone 2) and periportal (zone 3).
- ▣ Predominantly unconjugated hyperbilirubinaemia is due to increased production and decreased hepatic uptake and conjugation, while reduced excretion causes mainly conjugated hyperbilirubinaemia.

NEONATAL JAUNDICE

Jaundice appears in neonates when the total serum bilirubin is more than 3 mg/dl. It may be the result of unconjugated or conjugated hyperbilirubinaemia; the former being more common. Important causes of neonatal jaundice are listed in **Table 19.4**. Some of these conditions are considered below, while others are discussed elsewhere in the relevant sections.

Table 19.4 Causes of neonatal jaundice.

| | |
|----|--|
| A. | UNCONJUGATED HYPERBILIRUBINAEMIA |
| 1. | Physiologic and prematurity jaundice |
| 2. | Haemolytic disease of the newborn and kernicterus (page 319) |
| 3. | Congenital haemolytic disorders (page 291) |
| 4. | Perinatal complications (e.g. haemorrhage, sepsis) |
| 5. | Gilbert's syndrome |
| 6. | Crigler-Najjar syndrome (type I and II) |
| B. | CONJUGATED HYPERBILIRUBINAEMIA |
| 1. | Hereditary (Dubin-Johnson syndrome, Rotor's syndrome) |
| 2. | Infections (e.g. hepatitis B, hepatitis C or non-A non-B hepatitis, rubella, coxsackievirus, cytomegalovirus, echovirus, herpes simplex, syphilis, toxoplasma, gram-negative sepsis) |
| 3. | Metabolic (e.g. galactosaemia, alpha-1-antitrypsin deficiency, cystic fibrosis, Niemann-Pick disease) |
| 4. | Idiopathic (neonatal hepatitis, congenital hepatic fibrosis) |
| 5. | Biliary atresia (intrahepatic and extrahepatic) |
| 6. | Reye's syndrome |

HEREDITARY NON-HAEMOLYTIC HYPERBILIRUBINAEMIAS

Hereditary non-haemolytic hyperbilirubinaemias are a small group of uncommon familial disorders of bilirubin metabolism when haemolytic causes have been excluded. The commonest is Gilbert's syndrome; others are Crigler-Najjar syndrome, Dubin-Johnson syndrome, Rotor's syndrome, benign recurrent intrahepatic cholestasis and progressive familial intrahepatic cholestasis. The features common to all these conditions are presence of icterus but almost normal liver function tests and no well-defined morphologic changes except in Dubin-Johnson syndrome. Gilbert's syndrome and Crigler-Najjar syndrome are examples of *hereditary non-haemolytic unconjugated hyperbilirubinaemia*, whereas Dubin-Johnson syndrome, Rotor's syndrome and benign familial recurrent cholestasis are conditions with *hereditary conjugated hyperbilirubinaemia*. These conditions are briefly described below. Their distinguishing features of major forms are summarised in **Table 19.5**.

Table 19.5 Contrasting features of major hereditary non-haemolytic hyperbilirubinaemias.

| FEATURE | GILBERT'S SYNDROME | TYPE 1 CRIGLER-NAJJAR SYNDROME | TYPE 2 CRIGLER-NAJJAR SYNDROME | DUBIN-JOHNSON SYNDROME |
|---|---|---|--------------------------------|--|
| 1. <i>Inheritance</i> | Autosomal dominant | Autosomal recessive | Autosomal dominant | Autosomal recessive |
| 2. <i>Predominant hyperbilirubinaemia</i> | Unconjugated | Unconjugated | Unconjugated | Conjugated |
| 3. <i>Intensity of jaundice</i> | Mild (< 5 mg/dl) | Marked (>20 mg/dl) | Mild to moderate (<20 mg/dl) | Mild (<5 mg/dl) |
| 4. <i>Basic defect</i> | ↓ UDP-glucuronosyl transferase activity | Absence of UDP-glucuronosyl transferase | ↓ UDP-glucuronosyl transferase | Defect in canalicular excretion (Prolonged BSP excretion test) |
| 5. <i>Hepatic morphology</i> | Normal (except slightly increased lipofuscin) | Normal (except mild canalicular stasis) | Normal | Greenish-black pigment |
| 6. <i>Prognosis</i> | Excellent | Poor (due to kernicterus) | Good | Excellent |

Gilbert's Syndrome

This is the commonest of the familial, genetically-determined diseases of the liver affecting 2-5% of the population. Gilbert's syndrome is characterised by mild, benign, unconjugated hyperbilirubinaemia (serum bilirubin 1-5 mg/dl) which is not due to haemolysis. The condition is inherited as an autosomal dominant character. The defect in bilirubin metabolism is complex and appears to be reduced activity of UDP-glucuronosyl transferase with decreased conjugation, or an impaired hepatic uptake of bilirubin. The jaundice is usually mild and intermittent.

MORPHOLOGIC FEATURES There are no morphologic abnormalities in the liver except some increased lipofuscin pigment in centrilobular hepatocytes.

The prognosis of patients with Gilbert's syndrome is excellent, though chronic jaundice persists throughout life.

Crigler-Najjar Syndrome

Crigler-Najjar syndrome is a rare form of familial non-haemolytic jaundice with very high *unconjugated hyperbilirubinaemia*. There are 2 forms of this condition: type I and type II.

Type I Crigler-Najjar syndrome This is inherited as an autosomal recessive disorder. There is complete absence of conjugating enzyme UDP-glucuronosyl transferase in the hepatocytes and hence no conjugated bilirubin is formed. There is extreme elevation of unconjugated bilirubin (usually more than 20 mg/dl) with high risk of developing permanent CNS damage from kernicterus. The prognosis is generally fatal, with death coming from kernicterus usually in the first year of life.

MORPHOLOGIC FEATURES There are no significant morphologic changes except some canalicular stasis.

Type II Crigler-Najjar syndrome This is inherited as an autosomal dominant disease. There is deficiency of enzyme UDP-glucuronosyl transferase but not complete absence. Thus, unconjugated hyperbilirubinaemia is generally mild to moderate (usually less than 20 mg/dl). Occurrence of kernicterus is exceptional and patients respond well to phenobarbital therapy.

MORPHOLOGIC FEATURES There are no morphologic changes in the liver.

Dubin-Johnson Syndrome

Dubin-Johnson syndrome is autosomal recessive disorder characterised by predominant *conjugated hyperbilirubinaemia* (usually less than 5 mg/dl) with genetic defect in canalicular excretion of conjugated bilirubin. A prolonged BSP dye excretion test is diagnostic of Dubin-Johnson syndrome (page 580).

MORPHOLOGIC FEATURES *Grossly*, the condition differs from other forms of hereditary hyperbilirubinaemias in producing greenish-black pigmented liver.

Microscopically, The hepatocytes show dark-brown, melanin-like pigment in the cytoplasm, the exact nature of which is obscure but it is neither iron nor bile. Unrelated

viral hepatitis mobilises the hepatic pigment of Dubin-Johnson syndrome leading to its excretion in urine but the pigment reappears after recovery from viral hepatitis.

The disease runs a benign course and does not interfere with life.

Other Rare Intrahepatic Cholestatic Disorders

Besides Dubin-Johnson syndrome, there are a few rarer familial disorders having intrahepatic (conjugated) hyperbilirubinaemias (ranging from mild to recurrent to severe jaundice):

ROTOR'S SYNDROME There is mild chronic jaundice similar to Dubin-Johnson syndrome but differs from it in having no brown pigment in the liver cells. The disease has autosomal recessive inheritance. The defect probably lies in intrahepatic storage of bilirubin and no cholestasis but the exact molecular basis is not known.

BENIGN RECURRENT INTRAHEPATIC CHOLESTASIS (BRIC) In this, there are recurrent attacks of pruritus and jaundice in early childhood followed by resolution and long gaps for recurrences. The genetic defect has been identified and two types of BRIC (type 1 and type 2) have been categorised.

PROGRESSIVE FAMILIAL INTRAHEPATIC CHOLESTASIS (FIC) Based on mutational defect, 3 types of FIC have been identified but all three types have similar phenotype i.e. progressive severe cholestasis beginning in childhood.

NEONATAL HEPATITIS

Neonatal hepatitis, also termed giant cell hepatitis or neonatal hepatocellular cholestasis, is a general term used for the constant morphologic change seen in conjugated hyperbilirubinaemia as a result of known infectious and metabolic causes listed in Table 19.4, or may have an idiopathic etiology. 'Idiopathic' neonatal hepatitis is more common and accounts for 75% of cases. Though all the cases with either known etiologies or idiopathic type are grouped together under neonatal hepatitis, all of them are not necessarily inflammatory conditions, thus belying their nomenclature as 'hepatitis.' The condition usually presents in the first week of birth with jaundice, bilirubinuria, pale stools and high serum alkaline phosphatase.

MORPHOLOGIC FEATURES Irrespective of the etiology, there is morphologic similarity in all these cases. The histologic features are as under:

1. Loss of normal lobular architecture of the liver.
2. Presence of prominent multinucleate giant cells derived from hepatocytes.
3. Mononuclear inflammatory cell infiltrate in the portal tracts with some periportal fibrosis.
4. Haemosiderosis.
5. Cholestasis in small proliferated ductules in the portal tract and between necrotic liver cells.

BILIARY ATRESIAS

Biliary atresias, also called as *infantile cholangiopathies*, are a group of intrauterine developmental abnormalities of the biliary system. Though they are often classified as congenital, the abnormality of development in most instances is extraneous infection during the intrauterine development or shortly after

birth that brings about inflammatory destruction of the bile ducts. The condition may, therefore, have various grades of destruction ranging from complete absence of bile ducts termed *atresia*, to reduction in their number called *paucity of bile ducts*.

Depending upon the portion of biliary system involved, biliary atresias may be extrahepatic or intrahepatic.

Extrahepatic Biliary Atresia

The extrahepatic bile ducts fail to develop normally so that in some cases the bile ducts are *absent* at birth, while in others the ducts may have been formed but start undergoing sclerosis in the perinatal period. It is common to have multiple defects and other congenital lesions. Extrahepatic biliary atresia is found in 1 per 10,000 livebirths. Cholestatic jaundice appears by the first week after birth. The baby has severe pruritus, pale stools, dark urine and elevated serum transaminases. In some cases, the condition is correctable by surgery, while in vast majority the atresia is not correctable and in such cases hepatic portoenterostomy (Kasai procedure) or hepatic transplantation must be considered. Death is usually due to intercurrent infection, liver failure, and bleeding due to vitamin K deficiency or oesophageal varices. Cirrhosis and ascites are late complications appearing within 2 years of age.

MORPHOLOGIC FEATURES *Grossly*, the liver is enlarged and dark green. The atretic segments of biliary system are reduced to cord-like structures.

Histologically, the condition must be distinguished from idiopathic neonatal hepatitis as surgical treatment is possible in extrahepatic biliary atresia but not in the latter. Besides, α -1-antitrypsin deficiency also produces similar appearance in liver biopsy. The main histologic features are as under:

1. Inflammation and fibrous obliteration of the extrahepatic ducts with absence of bile in them.
2. Ductular proliferation and periductular inflammation.
3. Cholestasis and bile thrombi in the portal area.
4. Periportal fibrosis and later secondary biliary cirrhosis (page 609).
5. Transformation of hepatic parenchyma to neonatal (giant cell) hepatitis in 15% of cases.

Intrahepatic Biliary Atresia

Intrahepatic biliary atresia is characterised by biliary hypoplasia so that there is *paucity of bile ducts* rather than their complete absence. The condition probably has its origin in viral infection acquired during intrauterine period or in the neonatal period. Cholestatic jaundice usually appears within the first few days of birth and is characterised by high serum bile acids with associated pruritus, and hypercholesterolaemia with appearance of xanthomas by first year of life. Hepatic as well as urinary copper concentrations are elevated. In some cases, intrahepatic biliary atresia is related to α -1-antitrypsin deficiency.

MORPHOLOGIC FEATURES The microscopic features are as follows:

1. Paucity of intrahepatic bile ducts.
2. Cholestasis.
3. Increased hepatic copper.
4. Inflammation and fibrosis in the portal area, eventually leading to cirrhosis.

REYE'S SYNDROME

Reye's syndrome is defined as an acute postviral syndrome of encephalopathy and fatty change in the viscera. The syndrome may follow almost any known viral disease but is most common after influenza A or B and varicella. Viral infection may act singly, but more often its effect is modified by certain exogenous factors such as by administration of salicylates, aflatoxins and insecticides. These effects cause mitochondrial injury and decreased activity of mitochondrial enzymes in the liver. This eventually leads to rise in blood ammonia and accumulation of triglycerides within hepatocytes.

The patients are generally children between 6 months and 15 years of age. Within a week after a viral illness, the child develops intractable vomiting and progressive neurological deterioration due to encephalopathy, eventually leading to stupor, coma and death. Characteristic laboratory findings are elevated blood ammonia, serum transaminases, bilirubin and prolonged prothrombin time.

MORPHOLOGIC FEATURES *Grossly*, the liver is enlarged and yellowish-orange.

Microscopically, hepatocytes show small droplets of neutral fat in their cytoplasm (microvesicular fat). Similar fatty change is seen in the renal tubular epithelium and in the cells of skeletal muscles and heart. The brain shows oedema and sometimes focal necrosis of neurons.

GIST BOX 19.3

Neonatal Jaundice

- Jaundice appears in neonates at serum bilirubin level of more than 3 mg/dl and is more often unconjugated hyperbilirubinaemia.
- Hereditary non-haemolytic hyperbilirubinaemias are familial disorders of bilirubin metabolism; most common is Gilbert's syndrome; others are Crigler-Najjar syndrome (type 1 and 2), and Dubin-Johnson syndrome. Gilbert's and Dubin-Johnson syndrome have excellent prognosis.
- Neonatal hepatitis or giant cell hepatitis is morphologic change seen in conjugated hyperbilirubinaemia as a result of known infectious and metabolic causes.
- Biliary atresias (intrahepatic and extrahepatic) are intra-uterine developmental abnormalities of the biliary system.
- Reye's syndrome is an acute postviral syndrome of encephalopathy and fatty change in the viscera including liver.

HEPATIC FAILURE

Though the liver has a marked regenerative capacity and a large functional reserve, hepatic failure may develop from severe acute and fulminant liver injury with massive necrosis of liver cells (*acute hepatic failure*), or from advanced chronic liver disease (*chronic hepatic failure*). Acute hepatic failure develops suddenly with severe impairment of liver functions whereas chronic liver failure comes insidiously. The prognosis is much worse in acute hepatic failure than that in chronic liver failure.

ETIOLOGY Acute and chronic hepatic failure result from different causes:

◆ **Acute (fulminant) hepatic failure** occurs most frequently in *acute viral hepatitis*. Other causes are hepatotoxic drug reactions (e.g. anaesthetic agents, nonsteroidal anti-inflammatory drugs, anti-depressants), carbon tetrachloride poisoning, acute alcoholic hepatitis, mushroom poisoning and pregnancy complicated with eclampsia.

◆ **Chronic hepatic failure** is most often due to *cirrhosis*. Other causes include chronic active hepatitis, chronic cholestasis (cholestatic jaundice) and Wilson's disease.

MANIFESTATIONS In view of the diverse functions performed by the liver, the syndrome of acute or chronic hepatic failure produces complex manifestations. The major manifestations are briefly discussed below and diagrammatically illustrated in **Fig. 19.5**.

1. Jaundice Jaundice usually reflects the severity of liver cell damage since it occurs due to failure of liver cells to metabolise bilirubin. In acute failure such as in viral hepatitis, jaundice nearly parallels the extent of liver cell damage, while in chronic failure such as in cirrhosis jaundice appears late and is usually of mild degree.

2. Hepatic encephalopathy (Hepatic coma) Neuro-psychiatric syndrome may complicate liver disease of both acute and chronic types. The features include disturbed consciousness, personality changes, intellectual deterioration, low slurred speech, flapping tremors, and finally, coma and death. The genesis of CNS manifestations in liver disease is by toxic products not metabolised by the diseased liver. The toxic products may be ammonia and other nitrogenous substances from intestinal bacteria which reach the systemic circulation without detoxification in the damaged liver and thus damage the brain. Advanced cases of hepatic coma have poor prognosis but may respond favourably to hepatic transplantation.

3. Hyperkinetic circulation All forms of hepatic failure are associated with a hyperkinetic circulation characterised

by peripheral vasodilatation, increased splanchnic blood flow and increased cardiac output. There is increased splenic flow but reduced renal blood flow resulting in impaired renal cortical perfusion. These changes result in tachycardia, low blood pressure and reduced renal function.

4. Hepatorenal syndrome The term hepatorenal syndrome is applied to patients of both acute and chronic hepatic failure who develop renal failure as well, in the absence of clinical, laboratory or morphologic evidence of other causes of renal dysfunction. Hepatorenal syndrome develops in about 10% cases of acute and chronic liver diseases. The acute renal failure is usually associated with oliguria and uraemia but with good tubular function. The histology of kidney is virtually normal, suggesting functional defect for the renal failure. The pathogenesis of the syndrome is poorly understood but appears to be initiated by effective reduction of the renal blood flow (effective hypovolaemia) as a consequence of systemic vasodilatation and pooling of blood in portal circulation. The renal failure in the hepatorenal syndrome is reversible with improvement in hepatic function.

Diagnosis of hepatorenal syndrome should be made only after excluding other causes producing concomitant damage to both the organs, circulatory failure leading to acute tubular necrosis and other forms of reversible tubular damage.

5. Hepatopulmonary syndrome The pulmonary changes in chronic hepatic failure such as in cirrhosis consist of pulmonary vasodilatation with intra-pulmonary arteriovenous shunting. This results in ventilation-perfusion inequality that may lead to impaired pulmonary function, clubbing of fingers and sometimes cyanosis.

6. Coagulation defects Impaired synthesis of a number of coagulation factors by the diseased liver may result in coagulation disorders. These include disseminated intravascular coagulation (consumption coagulopathy), thrombocytopenia and presence of fibrin degradation products in the blood.

7. Ascites and oedema Chronic liver failure due to cirrhosis may result in portal hypertension and ascites (page 615). Decreased synthesis of albumin by the liver resulting in hypoproteinaemia and consequent fall in plasma oncotic pressure, increased hydrostatic pressure due to portal hypertension and secondary hyperaldosteronism, contribute to the development of ascites and oedema in these patients.

8. Endocrine changes Endocrine changes may be found in association with chronic hepatic failure. The changes are more common in alcoholic cirrhosis in active reproductive life. In the male, the changes are towards feminisation such as gynaecomastia and hypogonadism. In the female, the changes are less towards masculinisation but atrophy of gonads and breasts occurs. The underlying mechanism appears to be changed end-organ sensitiveness to sex hormones in cirrhosis.

9. Skin changes In alcoholic cirrhosis '*arterial spiders*' having radiating small vessels from a central arteriole are frequent in the vascular region drained by superior vena cava such as in the neck, face, forearms and dorsum of hands. Less frequently, *palmar erythema*, especially in the hypothenar and thenar eminences and on the pulps of the fingers, is observed in chronic liver disease.

10. Foetor hepaticus A sweetish pungent smell of the breath is found in severe cases of acute and chronic hepatocellular

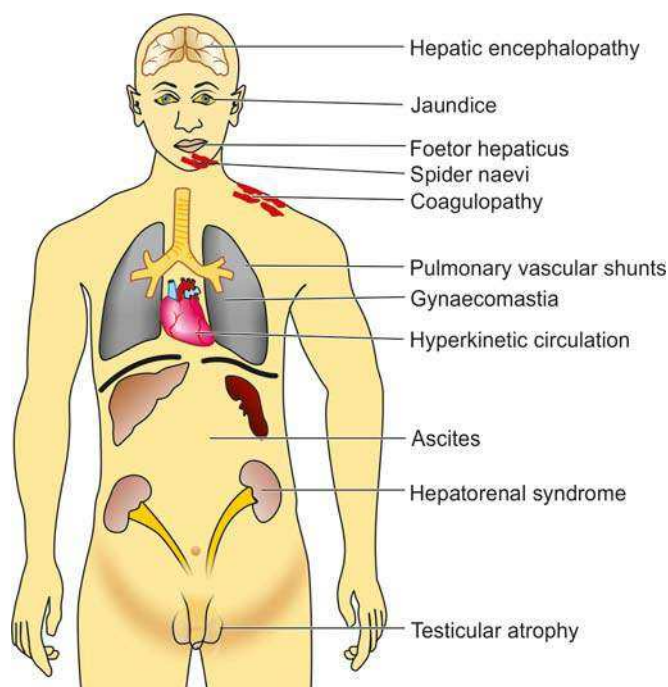

Figure 19.5 Complications of hepatic failure.

diseases. It appears to be of intestinal origin, possibly due to failure of the liver to detoxify sulfur-containing substances absorbed from the gut.

GIST BOX 19.4 Hepatic Failure

- ▣ Hepatic failure may develop from severe acute and fulminant liver injury with massive necrosis of liver cells (*acute hepatic failure*), or from advanced chronic liver disease (*chronic hepatic failure*).
- ▣ The clinical manifestations are systemic and include jaundice, hepatic coma, hyperkinetic circulation, hepatorenal syndrome, hepatopulmonary syndrome, coagulation defects, ascites, oedema, endocrine changes, skin changes and foer hepaticus.

CIRCULATORY DISTURBANCES

Vascular disorders of general nature involving the liver such as chronic passive congestion and infarction have already been discussed in Chapter 4. Hepatic and portal venous obstruction and hepatic arterial obstruction are considered here.

I. HEPATIC VENOUS OBSTRUCTION

The central veins of lobules of the liver are tributaries of the hepatic veins. In the normal liver, there are no anastomoses between hepatic vein and portal vein but in cirrhotic liver there are such anastomoses. Normal pressure in the free hepatic vein is about 6 mmHg.

Three uncommon diseases produced by obstruction of the hepatic veins: are Budd-Chiari syndrome (hepatic vein thrombosis), hepatic veno-occlusive disease and bacillary angiomatosis-peliosis hepatis.

Budd-Chiari Syndrome (Hepatic Vein Thrombosis)

Budd-Chiari syndrome in its pure form consists of slowly developing thrombosis of the hepatic veins and the adjacent inferior vena cava, while some workers include hepatic veno-occlusive disease (described below) in this syndrome.

ETIOLOGY The etiology of hepatic venous thrombosis in about a third of cases is unknown (idiopathic), while in the remaining cases various causes associated with increased thrombotic tendencies are attributed:

- i) Polycythaemia vera
- ii) Paroxysmal nocturnal haemoglobinuria
- iii) Use of oral contraceptives
- iv) Pregnancy and postpartum state
- v) Intra-abdominal cancers (e.g. hepatocellular carcinoma)
- vi) Chemotherapy and radiation
- vi) Myeloproliferative diseases
- vii) Formation of membranous webs in the suprahepatic portion of inferior vena cava (either congenital or as a consequence of organised thrombosis).

MORPHOLOGIC FEATURES *Grossly*, the liver is enlarged, swollen, red-purple and has a tense capsule.

Histologically, the changes in sudden hepatic vein occlusion are those of centrilobular congestion, necrosis and rupture of sinusoids into the space of Disse. In slowly

developing thrombosis, the changes are more chronic and include fibrosing reaction in the centrilobular zone that may progress to cardiac cirrhosis.

CLINICAL FEATURES Budd-Chiari syndrome is clinically characterised by either an acute form or chronic form depending upon the speed of occlusion.

- ◆ In the *acute form*, the features are abdominal pain, vomiting, enlarged liver, ascites and mild icterus.
- ◆ In the more usual *chronic form*, the patients present with pain over enlarged tender liver, ascites and other features of portal hypertension.

The acute form of illness leads to acute hepatic failure and death, whereas in chronic form the patient may live for months to a few years.

Hepatic Veno-occlusive Disease

Hepatic veno-occlusive disease consists of intimal thickening, stenosis and obliteration of the terminal central veins and medium-sized hepatic veins. The venous occlusion results in pathologic changes similar to those of Budd-Chiari syndrome and can be distinguished from the latter by demonstration of absence of thrombosis in the major hepatic veins.

The etiology of hepatic veno-occlusive disease can be explained by following associations:

- i) Since this condition is more widespread in countries such as Africa, India and certain other tropical countries where 'bush tea' (medicinal tea) is consumed that contains hepatotoxic alkaloids, it is implicated in the etiology.
- ii) The disease has also been found after high dose chemotherapy administered before bone marrow transplantation.
- iii) It is also seen as part of a rare hereditary veno-occlusive disease with immunodeficiency which results from a gene mutation.

Bacillary Angiomatosis and Peliosis Hepatis

Although sinusoidal dilatation can occur secondary to many liver diseases, peliosis hepatis is an uncommon condition of primary sinusoidal dilatation that results in blockage of blood outflow and may result in massive intraperitoneal haemorrhage. Although exact etiology is not known, peliosis hepatis and another related condition, bacillary angiomatosis (page 589), have been found to occur in HIV-infected patients whose CD4+ T cell counts fall below 100/μl. Opportunistic infection with *Bartonella henselae* in poor hygienic conditions in these cases results in blood-filled cysts in liver partly lined by endothelial cells and having mixed inflammatory cells in a fibromyxoid background.

Etiologic association of peliosis hepatis with consumption of anabolic steroids and oral contraceptives has also been suggested and is self-limiting with withdrawal of the offending agent.

II. PORTAL VENOUS OBSTRUCTION

Obstruction of the portal vein may occur within the intrahepatic course or in extrahepatic site.

- ◆ **Intrahepatic cause** of portal venous occlusion is hepatic cirrhosis as the commonest and most important, followed in decreasing frequency by tumour invasion, congenital hepatic fibrosis and schistosomiasis.

◆ **Extrahepatic causes** of portal vein obstruction are intra-abdominal cancers, intra-abdominal sepsis, direct invasion by tumour, myeloproliferative disorders and upper abdominal surgical procedure followed by thrombosis.

The **effects** of portal venous obstruction depend upon the site of obstruction. The most important effect, irrespective of the site of occlusion or cause, is portal hypertension and its manifestations (page 615). If the obstruction is in the extrahepatic portal vein along with extension of occlusion into splenic vein, it may result in venous infarction of the bowel. Pylephlebitis may be followed by multiple pyaemic liver abscesses.

III. HEPATIC ARTERIAL OBSTRUCTION

Diseases from obstruction of the hepatic artery are uncommon. Rarely, accidental ligation of the main hepatic artery or its branch to right lobe may be followed by fatal infarction. Obstruction of the small intrahepatic arterial branches usually does not produce any effects because of good collateral circulation.

GIST BOX 19.5 Hepatic Circulatory Disturbances

- ▣ Obstruction of the hepatic veins may occur and produce Budd-Chiari syndrome (hepatic vein thrombosis), hepatic veno-occlusive disease and peliosis hepatis.
- ▣ Budd-Chiari syndrome is idiopathic or due to increased thrombotic tendencies.
- ▣ Veno-occlusive disease is related to consumption of alkaloids.
- ▣ In peliosis hepatis and bacillary angiomatosis in HIV-infected patients, there is sinusoidal dilatation.
- ▣ Obstruction of the portal vein may occur from intrahepatic (e.g. cirrhosis) or extrahepatic (e.g. abdominal cancer) causes.

VIRAL HEPATITIS

The term viral hepatitis is used to describe infection of the liver caused by hepatotropic viruses. Currently there are 5 main varieties of these viruses causing distinct types of viral hepatitis:

- ◆ *Hepatitis A virus (HAV)*, causing a faecally-spread self-limiting disease.
- ◆ *Hepatitis B virus (HBV)*, causing a parenterally transmitted disease that may become chronic.
- ◆ *Hepatitis C virus (HCV)*, previously termed non-A, non-B (NANB) hepatitis virus involved chiefly in transfusion-related hepatitis.
- ◆ *Hepatitis delta virus (HDV)* which is sometimes associated as superinfection with hepatitis B infection.
- ◆ *Hepatitis E virus (HEV)*, causing water-borne infection.

While HBV is a DNA virus, all other human hepatitis viruses are RNA viruses.

Though a number of other viral diseases such as infection with Epstein-Barr virus (in infectious mononucleosis), arbovirus (in yellow fever), cytomegalovirus, herpes simplex and several others affect the liver but the changes produced by them are nonspecific; the term 'viral hepatitis' is strictly applied to infection of the liver by the hepatitis viruses.

ETIOLOGIC CLASSIFICATION

Based on the etiologic agent, viral hepatitis is currently classified into 6 etiologic types—hepatitis A, hepatitis B, hepatitis C, hepatitis D, hepatitis E and hepatitis G. The contrasting features of major types are presented in **Table 19.6**.

Hepatitis A

Infection with HAV causes hepatitis A (infectious hepatitis). Hepatitis A is responsible for 20-25% of clinical hepatitis in the developing countries of the world but the incidence is much lower in the developed countries. Hepatitis A is usually a benign, self-limiting disease and has an incubation period of 15-45 days. The disease occurs in epidemic form as well as sporadically. It is almost exclusively spread by faeco-oral route. The spread is related to close personal contact such as in overcrowding, poor hygienic and sanitary conditions. Frozen and stored contaminated foods and water have been blamed in many epidemics. Most frequently affected age group is 5-14 years; adults are often infected by spread from children.

HEPATITIS A VIRUS (HAV) The etiologic agent for hepatitis A, HAV, is a small, 27 nm diameter, icosahedral non-enveloped, single-stranded RNA virus. Viral genome has been characterised but only a single serotype has been identified. HAV infection can be transmitted to primates and the virus can be cultivated *in vitro*. Inactivation of viral activity can be achieved by boiling for 1 minute, by ultraviolet radiation, or by contact with formaldehyde and chlorine. The virus is present in the liver cells, bile, stool and blood during the incubation period and in pre-icteric phase but viral shedding diminishes after the onset of jaundice. Chronic carriers have not been identified for HAV infection.

PATHOGENESIS Hepatitis A virus is present in the liver and replicates there. It is present in the liver, bile, blood and stools in the pre-icteric incubation period but viraemia and viral shedding in stool is diminished after jaundice appears. Evidence that hepatitis caused by HAV has an immunologic basis comes from demonstration of following antibodies acting as serum markers for hepatitis A infection (**Fig. 19.6**):

1. *IgM anti-HAV antibody* appears in the serum at the onset of symptoms of acute hepatitis A.
2. *IgG anti-HAV antibody* is detected in the serum after acute illness and remains detectable indefinitely. It gives life-long protective immunity against reinfection with HAV.

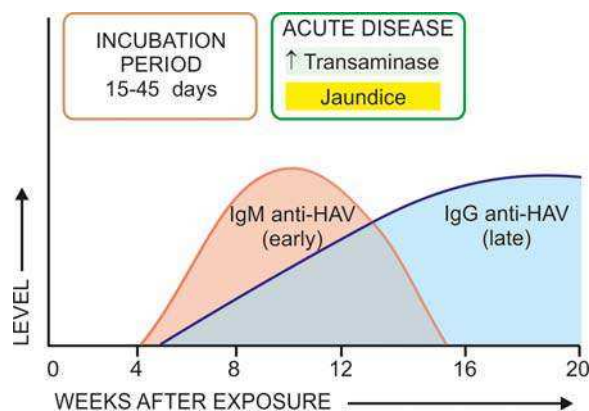

Figure 19.6 Sequence of appearance of antibodies to HAV.

Table 19.6 Features of various types of hepatitis viruses.

| FEATURE | HEPATITIS A | HEPATITIS B | HEPATITIS C | HEPATITIS D | HEPATITIS E |
|------------------------------|------------------------------|----------------------------------|------------------------------------|-------------------------------------|-------------------------------|
| 1. Agent | HAV | HBV | HCV | HDV | HEV |
| 2. Year identified | 1973 | 1965 | 1989 | 1977 | 1980 |
| 3. Viral particle | 27 nm | 42 nm | 30-60 nm | 35-37 nm | 32-34 nm |
| 4. Genome | RNA, ss, linear | DNA, ss/ds | RNA, ss, linear circular | RNA, ss, circular | RNA, ss, linear |
| 5. Morphology | Icosahedral non-enveloped | Double-shelled, enveloped | Enveloped | Enveloped, replication defective | Icosahedral, non-enveloped |
| 6. Spread | Faeco-oral | Parenteral, close contact | Parenteral, close contact | Parenteral, close contact | Water-borne |
| 7. Incubation period | 15-45 days | 30-180 days | 20-90 days | 30-50 days (In superinfection) | 15-60 days |
| 8. Antigen(s) | HAV | HBsAg HBcAg HBeAg HBxAg | HCV RNA C 100-3 C 33c NS5 | HBsAg HDV | HEV |
| 9. Antibodies | anti-HAV | anti-HBs anti-HBc anti-HBe | anti-HCV | anti-HBs anti-HDV | anti-HEV |
| 10. Severity | Mild | Occasionally severe | Moderate | Occasionally severe | Mild |
| 11. Chronic hepatitis | None | Occasional | Common | Common | None |
| 12. Carrier state | None | <1% | <1% | 1-10% | Unknown |
| 13. Hepatocellular carcinoma | No | + | + | ± | None |
| 14. Prognosis | Excellent | Worse with age | Moderate | Acute good; chronic poor | Good |

(ss= single-stranded; ss/ds= partially single-stranded partially double-stranded)

Hepatitis B

Hepatitis B (serum hepatitis) caused by HBV infection has a longer incubation period (30-180 days) and is transmitted parenterally such as in recipients of blood and blood products, intravenous drug addicts, patients treated by renal dialysis and hospital workers exposed to blood, and by intimate physical contact such as from mother to child and by sexual contact. The disease may occur at any age. HBV infection causes more severe form of illness that includes: acute hepatitis B, chronic hepatitis, progression to cirrhosis, fulminant hepatitis and an asymptomatic carrier stage. HBV plays some role in the development of hepatocellular carcinoma as discussed later (page 618).

HEPATITIS B VIRUS (HBV) The etiologic agent for hepatitis B, HBV, is a DNA virus which has been extensively studied. Electron microscopic studies on serum of patients infected with HBV show 3 forms of viral particles of 2 sizes: small (spheres and tubules/filaments) and large (spheres) as under:

- Small particles* are most numerous and exist in two forms— as 22 nm spheres, and as tubules 22 nm in diameter and 100 nm long. These are antigenically identical to envelope protein of HBV and represent excess of viral envelope protein referred to as hepatitis B surface antigen (HBsAg).
- Large particles*, 42 nm in diameter, are double-shelled spherical particles, also called as *Dane particles*. These are

about 100 to 1000 times less in number in serum compared to small 22 nm particles and represent intact virion of HBV.

The genomic structure of HBV is quite compact and complex. The HBV DNA consists of 4 overlapping genes which encode for multiple proteins (**Fig. 19.7**):

- S gene* codes for the surface envelope protein, hepatitis B surface antigen (HBsAg); this product is major protein. HBsAg is present on the outer surface of the large spherical particles as well as in small spherical and tubular structures. *Pre-S1 and pre-S2* regions of genome are upstream of S gene and code for pre-S gene protein products that includes receptor on the HBV surface and for hepatocyte membrane proteins. The protein product of S-gene plus adjacent pre-S2 region is the *middle protein*, while the protein products of pre-S1 plus pre-S2 regions is the *large protein*. Large protein coming from both pre-S proteins is rich in complete virions.
- P gene* is the largest and codes for DNA polymerase.
- C gene* codes for two nucleocapsid proteins, HBeAg and a core protein termed HBcAg.
- X gene* codes for HBxAg which is a small non-particulate protein. HbxAg has a role in transactivation the transcription of both viral and cellular genes. The processes transactivated by X-genes include signal-transduction pathways, increased replication of HBV DNA, replication of other viruses including HIV, enhanced susceptibility of HBV-infected hepatocytes to cytolytic T cells, and pro-apoptotic pathway. Expression of

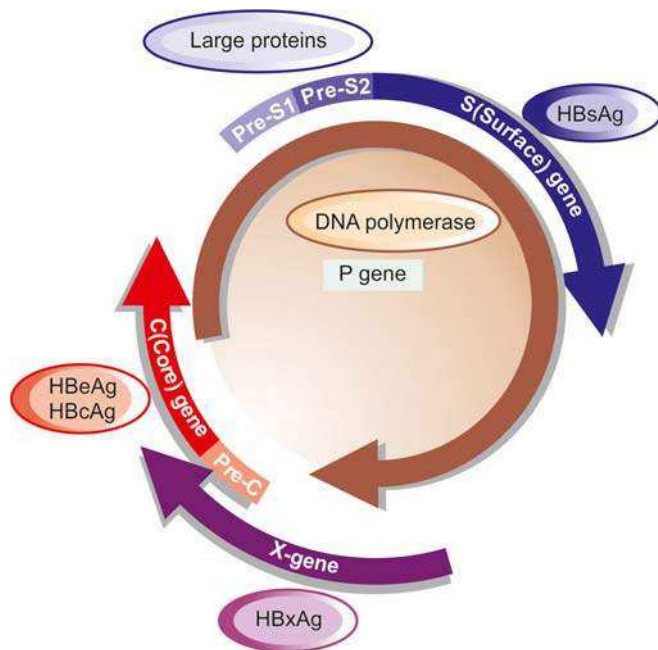

Figure 19.7 Genomic structure of hepatitis B virus (Dane particle).

HBxAg and its antibodies associated with enhanced HBV DNA replication has been implicated in hepatocellular carcinoma in patients of chronic hepatitis.

PATHOGENESIS There is strong evidence linking immune pathogenesis with hepatocellular damage:

- i) Since a carrier state of hepatitis B without hepatocellular damage exists, it means that HBV is not directly cytopathic.
- ii) It has been observed that individuals with defect or deficiency of cellular immunity have more persistent hepatitis B disease instead of clearing HBV from their blood.
- iii) In support of cell-mediated mechanism in hepatocellular damage by HBV comes from observation that viral antigens (in particular nucleocapsid proteins HbcAg and HbeAg) are attacked by host cytotoxic CD8+T lymphocytes.
- iv) The host response of CD8+T lymphocytes by elaboration of antiviral cytokines is variable in different individuals and that determines whether an HBV-infected person recovers, develops mild or severe disease, or progresses to chronic disease.

Serologic and viral markers. In support of immune pathogenesis is the demonstration of several immunological markers in the serum and in hepatocytes indicative of presence of HBV infection. These are as under (**Fig. 19.8**):

1. HBsAg In 1965, Blumberg and colleagues in Philadelphia found a lipoprotein complex in the serum of a multiple-transfused haemophiliac of Australian aborigine which was subsequently shown by them to be associated with serum hepatitis. This antigen was termed *Australia antigen* by them (In 1977, Blumberg was awarded the Nobel prize for his discovery). The term Australia antigen is now used synonymous with hepatitis B surface antigen (HBsAg). HBsAg appears early in the blood after about 6 weeks of infection and its detection is an indicator of active HBV infection. It usually disappears in 3-6 months. Its persistence for more than 6 months implies a carrier state. HBsAg may also be demonstrated in the cell membrane of hepatocytes of carriers and chronic hepatitis

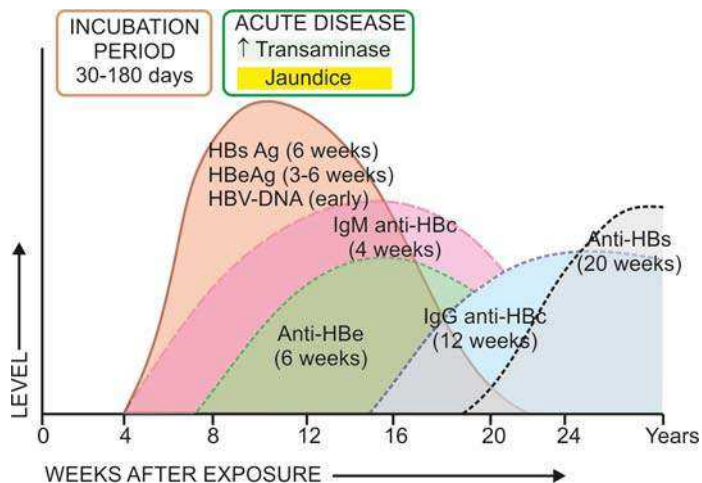

Figure 19.8 Sequence of serologic and viral markers in acute hepatitis B.

patients by *Orcein staining* (orange positivity) but not in the hepatocytes during acute stage of illness.

2. Anti-HBs Specific antibody to HBsAg in serum called anti-HBs appears late, about 3 months after the onset. Anti-HBs response may be both IgM and IgG type. The prevalence rate of anti-HBs ranges from 10-15%. In these individuals it persists for life providing protection against reinfection with HBV.

3. HBeAg HBeAg derived from core protein is present transiently (3-6 weeks) during an acute attack. Its persistence beyond 10 weeks is indicative of development of chronic liver disease and carrier state.

4. Anti-HBe Antibody to HBeAg called anti-HBe appears after disappearance of HBeAg. Seroconversion from HBeAg to anti-HBe during acute stage of illness is a prognostic sign for resolution of infection.

5. HBcAg HBcAg derived from core protein cannot be detected in the blood. But HBcAg can be demonstrated in the nuclei of hepatocytes in carrier state and in chronic hepatitis patients by Orcein staining but not in the liver cells during acute stage.

6. Anti-HBc Antibody to HBcAg called anti-HBc can, however, be detected in the serum of acute hepatitis B patients during pre-icteric stage. In the initial period, it is IgM class antibody which persists for 4-6 months and is followed later by IgG anti-HBc. Thus, detection of high titre of IgM anti-HBc is indicative of recent acute HBV infection, while elevated level of IgG anti-HBc suggests HBV infection in the remote past.

7. HBV-DNA Detection of HBV-DNA by molecular hybridisation using the Southern blot technique is the most sensitive index of hepatitis B infection. It is present in pre-symptomatic phase and transiently during early acute stage.

Hepatitis D

Infection with delta virus (HDV) in the hepatocyte nuclei of HBsAg-positive patients is termed hepatitis D. HDV is a defective virus for which HBV is the helper. Thus, hepatitis D develops when there is concomitant hepatitis B infection. HDV infection and hepatitis B may be simultaneous (*co-infection*), or HDV may infect a chronic HBsAg carrier (*superinfection*) (**Fig. 19.9**):

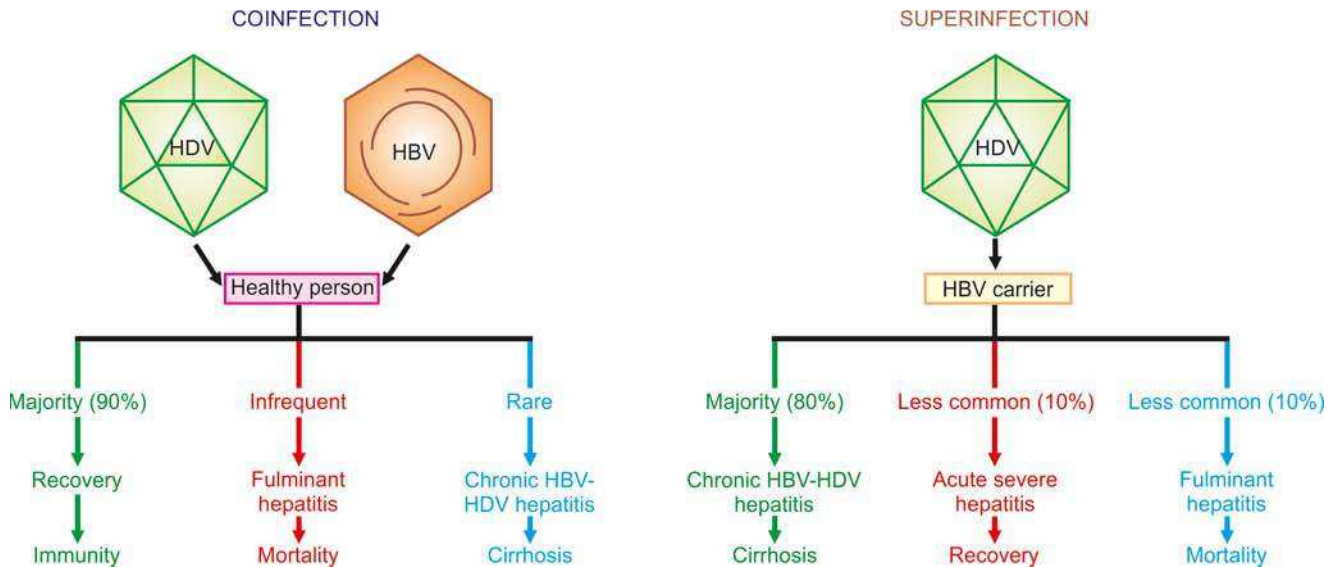

Figure 19.9 Consequences of coinfection versus superinfection in combined HDV-HBV infection.

◆ With **coinfection**, acute hepatitis D may range from mild to fulminant hepatitis but fulminant hepatitis is more likely in such simultaneous delta infection. Chronicity rarely develops in coinfection.

◆ With **superinfection** (incubation period 30-35 days), chronic HBV infection gets worsened indicated by appearance of severe and fulminant acute attacks, progression of carrier stage to chronic delta hepatitis or acceleration towards cirrhosis. Occurrence of hepatocellular carcinoma is, however, less common in HBsAg carriers with HDV infection.

Contrasting features of HDV co-infection and superinfection are summed up in **Table 19.7**.

HDV infection is worldwide in distribution though the incidence may vary in different countries. Endemic regions are Southern Europe, Middle-East, South India and parts of Africa. The high-risk individuals for HDV infection are the same as for HBV infection i.e. intravenous drug abusers, homosexuals, transfusion recipients, and health care workers.

HEPATITIS DELTA VIRUS (HDV) The etiologic agent, HDV, is a small single-stranded RNA particle with a diameter of 36 nm. It is double-shelled—the outer shell consists of HBsAg and the inner shell consists of delta antigen provided by a circular RNA strand. It is highly infectious and can induce hepatitis in any HBsAg-positive host. HDV replication and proliferation takes place within the nuclei of liver cells. Markers for HDV infection include the following:

1. *HDV identification* in the blood and in the liver cell nuclei.

Table 19.7 Coinfection versus super-infection of hepatitis D.

| FEATURE | CO-INFECTION | SUPER-INFECTION |
|---------------------------------------|----------------|-----------------|
| 1. <i>Patient status</i> | Healthy person | HBV carrier |
| 2. <i>Risk of fulminant hepatitis</i> | >HBV alone | >Co-infection |
| 3. <i>Risk of chronic hepatitis</i> | Rare | Much greater |
| 4. <i>Risk of cirrhosis</i> | Uncommon | More |
| 5. <i>Mortality</i> | Rare | ~20% |

2. *HDAg* detectable in the blood and on fixed liver tissue specimens.

3. *Anti-HD antibody* in acute hepatitis which is initially IgM type and later replaced by IgG type anti-HD antibody which persists for life to confer immunity against reinfection.

PATHOGENESIS HDV, unlike HBV, is thought to cause direct cytopathic effect on hepatocytes. However, there are examples of transmission of HDV infection from individuals who themselves have not suffered from any attack of hepatitis, suggesting that it may not be always cytopathic.

Hepatitis C

The diagnosis of this major category of hepatitis was earlier made after exclusion of infection with other known hepatitis viruses in those times and was initially designated non-A, non-B (NANB) hepatitis. However, now it has been characterised and is called hepatitis C.

Hepatitis C infection is acquired by blood transfusions, blood products, haemodialysis, parenteral drug abuse and accidental cuts and needle-pricks in health workers. About 90% of post-transfusion hepatitis is of hepatitis C type. About 1-2% of volunteer blood donors and up to 5% of professional blood donors are carriers of HCV. Hepatitis C has an incubation period of 20-90 days (mean 50 days). Clinically, acute HCV hepatitis is milder than HBV hepatitis but HCV has a higher rate of progression to chronic hepatitis than HBV. Persistence of infection and chronic hepatitis are the key features of HCV. Occurrence of cirrhosis after 5 to 10 years and progression to hepatocellular carcinoma are other late consequences of HCV infection. Currently, HCV is considered more important cause of chronic liver disease worldwide than HBV.

HEPATITIS C VIRUS (HCV) HCV is a single-stranded, enveloped RNA virus, having a diameter of 30-60 nm. HCV genome has about 3000 amino acids. The genomic organisation of HCV shows a 5' terminal end, C (capsid) region and the envelope regions E1 and E2 in the exons (**Fig. 19.10**).

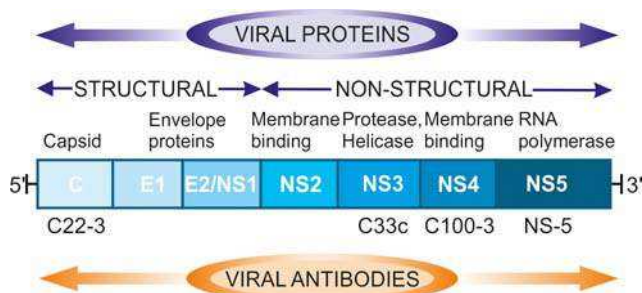

Figure 19.10 Diagrammatic structure of hepatitis C virus.

The viral proteins result in corresponding serologic and virologic markers for HCV infection as under (Fig. 19.11):

1. *Anti-HCV antibodies*. Three generations of anti-HCV IgG assays are available:

- i) First generation antibodies are against C100-3 region proteins and appear 1 to 3 months after infection.
- ii) Second generation antibodies are against C200 and C33c proteins and appear about one month earlier than the first generation.
- iii) Third generation antibodies are against C22-3 and NS-5 region proteins and are detected even earlier.

2. *HCV-RNA*. HCV infection is, however, confirmed by HCV-RNA employing PCR technique which can be detected within a few days after exposure to HCV infection, much before appearance of anti-HCV and persists for the duration of HCV infection.

PATHOGENESIS HCV induces hepatocellular injury by cell-mediated immune mechanism is supported by the following:

- i) It is possible that the host lymphoid cells are infected by HCV.
- ii) HCV-activated CD4+ helper T lymphocytes stimulate CD8+ T lymphocytes via cytokines elaborated by CD4+ helper T cells.
- iii) The stimulated CD8+T lymphocytes, in turn, elaborate antiviral cytokines against various HCV antigens.
- iv) Further support to this T- cell mediated mechanism comes from the observation that immune response is stronger in those HCV-infected persons who recover than those who harbour chronic HCV infection.
- v) There is some role of certain HLA alleles and innate immunity in rendering variable response by different hosts to HCV infection.
- vi) Natural killer (NK) cells also seem to contribute to containment of HCV infection.
- vii) In a subset of patients, there is crossreactivity between viral antigens of HCV and host autoantibodies to liver-kidney microsomal antigen (anti-LKM) which explains the association of autoimmune hepatitis and HCV hepatitis.

Hepatitis E

Hepatitis E is an enterically-transmitted virus, previously labelled as epidemic or enterically transmitted variant of non-A non-B hepatitis. The infection occurs in young or middle-aged individuals, primarily seen in India, other Asian countries, Africa and central America.

The infection is generally acquired by contamination of water supplies such as after monsoon flooding. However,

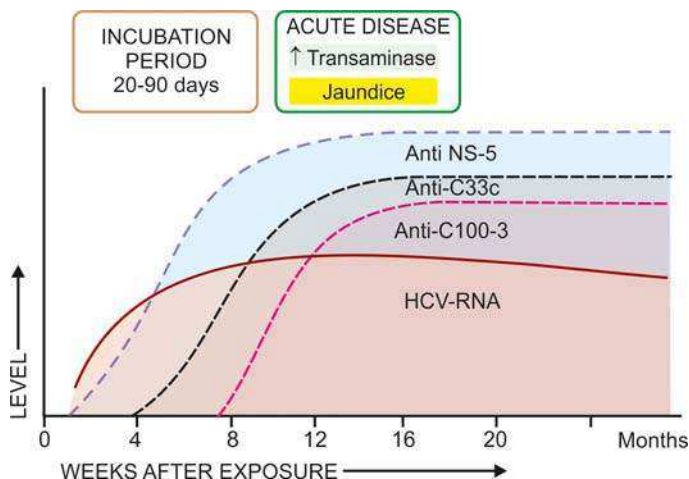

Figure 19.11 Sequence of serologic and viral markers of HCV infection.

compared with HAV, secondary person-to-person infection does not occur with HEV. Thus HEV has some common epidemiologic features with HAV. HEV infection has a particularly high mortality in pregnant women but is otherwise a self-limited disease and has not been associated with chronic liver disease.

HEPATITIS E VIRUS (HEV) HEV is a single-stranded 32-34 nm, icosahedral non-enveloped virus. The virus has been isolated from stools, bile and liver of infected persons. Serologic markers for HEV include the following:

1. Anti-HEV antibodies of both IgM and IgG class. Both fall rapidly after acute illness but routine serologic testing for HEV antibodies is not available.
2. HEV-RNA.

CLINICOPATHOLOGIC SPECTRUM

Among the various etiologic types of hepatitis, evidence linking HBV and HCV infection with the spectrum of clinicopathologic changes is stronger than with other hepatotropic viruses. The typical pathologic changes of hepatitis by major hepatotropic viruses are virtually similar. HAV and HEV, however, do not have a carrier stage nor cause chronic hepatitis. The various clinical patterns and pathologic consequences of different hepatotropic viruses can be considered under the following headings:

- i) Carrier state
- ii) Asymptomatic infection
- iii) Acute hepatitis
- iv) Chronic hepatitis
- v) Fulminant hepatitis (Submassive to massive necrosis)

In addition, progression to cirrhosis (page 609) and association with hepatocellular carcinoma (page 618) are known to occur in certain types of hepatitis which are discussed separately later.

I. Carrier State

An asymptomatic individual without manifest disease, harbouring infection with hepatotropic virus and capable of transmitting it is called carrier state. There can be 2 types of carriers:

1. An '*asymptomatic healthy carrier*' who does not suffer from ill-effects of the virus infection but is capable of transmitting.

2. An 'asymptomatic carrier with chronic disease' capable of transmitting the organisms.

As stated before, hepatitis A and E do not produce the carrier state. Hepatitis B is responsible for the largest number of carriers in the world, while concomitant infection with HDV more often causes progressive disease rather than an asymptomatic carrier state. There is geographic variation in incidence of HBV carrier state: while in normal population in US and western Europe it is less than 0.5%, its prevalence is much higher in Asian and tropical countries (5-20%). An estimated 2-3% of the general population are asymptomatic carriers of HCV. Data on HBV carrier state reveal role of 2 important factors rendering the individual more vulnerable to harbour the organisms—*early age at infection* and *impaired immunity*. Whereas approximately 10% of adults contracting hepatitis B infection develop carrier state, 90% of infected neonates fail to clear HBsAg from the serum within 6 months and become HBV carriers.

Clinical recognition of HBV carrier state is done by persistence of HBsAg in the serum of an infected person who fails to clear HBsAg from blood for more than 6 months. Concomitant infection of HDV with HBV depends upon the demonstration of anti-HD.

MORPHOLOGIC FEATURES Carriers of HBV may or may not show changes on liver biopsy.

◆ *Healthy HBV carriers* may show no changes or minor hepatic change such as presence of finely granular, ground-glass, eosinophilic cytoplasm as evidence of HBsAg.

◆ *Asymptomatic carriers with chronic disease* may show changes of chronic hepatitis and even cirrhosis.

II. Asymptomatic Infection

These are cases who are detected incidentally to have infection with one of the hepatitis viruses as revealed by their raised serum transaminases or by detection of the presence of antibodies but are otherwise asymptomatic.

III. Acute Hepatitis

The most common consequence of all hepatotropic viruses is acute inflammatory involvement of the entire liver. In general, type A, B, C, D and E run similar clinical course and show identical pathologic findings.

Clinically, acute hepatitis is categorised into 4 phases: incubation period, pre-icteric phase, icteric phase and post-icteric phase.

1. Incubation period It varies among different hepatotropic viruses: for hepatitis A it is about 4 weeks (15-45 days); for hepatitis B the average is 10 weeks (30-180 days); for hepatitis D about 6 weeks (30-50 days); for hepatitis C the mean incubation period is about 7 weeks (20-90 days), and for hepatitis E it is 2-8 weeks (15-60 days). The patient remains asymptomatic during incubation period but the infectivity is highest during the last days of incubation period.

2. Pre-icteric phase This phase is marked by prodromal constitutional symptoms that include anorexia, nausea, vomiting, fatigue, malaise, distaste for smoking, arthralgia and headache. There may be low-grade fever preceding the onset of jaundice, especially in hepatitis A. The earliest laboratory

evidence of hepatocellular injury in pre-icteric phase is the elevation of transaminases.

3. Icteric phase The prodromal period is heralded by the onset of clinical jaundice and the constitutional symptoms diminish. Other features include dark-coloured urine due to bilirubinuria, clay-coloured stools due to cholestasis, pruritus as a result of elevated serum bile acids, loss of weight and abdominal discomfort due to enlarged, tender liver. The diagnosis is based on deranged liver function tests (e.g. elevated levels of serum bilirubin, transaminases and alkaline phosphatase, prolonged prothrombin time and hyperglobulinaemia) and serologic detection of hepatitis antigens and antibodies.

4. Post-icteric phase The icteric phase lasting for about 1 to 4 weeks is usually followed by clinical and biochemical recovery in 2 to 12 weeks. The recovery phase is more prolonged in hepatitis B and hepatitis C. Up to 1% cases of acute hepatitis may develop severe form of the disease (fulminant hepatitis); and 5-10% of cases progress on to chronic hepatitis. Evolution into the carrier state (except in HAV and HEV infection) has already been described above.

MORPHOLOGIC FEATURES *Grossly*, the liver is slightly enlarged, soft and greenish.

Histologically, the changes are as follows (Fig. 19.12):

1. Hepatocellular injury There may be variation in the degree of liver cell injury but it is most marked in zone 3 (centrilobular zone):

i) Mildly injured hepatocytes appear swollen with granular cytoplasm which tends to condense around the nucleus (*ballooning degeneration*).

ii) Others show acidophilic degeneration in which the cytoplasm becomes intensely eosinophilic, the nucleus becomes small and pyknotic and is eventually extruded from the cell, leaving behind necrotic, acidophilic mass called *Councilman body* or *acidophil body* by the process of apoptosis.

iii) Another type of hepatocellular necrosis is *dropout necrosis* in which isolated or small clusters of hepatocytes undergo lysis.

iv) *Bridging necrosis* is a more severe form of hepatocellular injury in acute viral hepatitis and may progress to fulminant hepatitis or chronic hepatitis (discussed below). Bridging necrosis is characterised by bands of necrosis linking portal tracts to central hepatic veins, one central hepatic vein to another, or a portal tract to another tract.

2. Inflammatory infiltrate There is infiltration by mononuclear inflammatory cells, usually in the portal tracts, but may permeate into the lobules.

3. Kupffer cell hyperplasia There is reactive hyperplasia of Kupffer cells many of which contain phagocytosed cellular debris, bile pigment and lipofuscin granules.

4. Cholestasis Biliary stasis is usually not severe in viral hepatitis and may be present as intracytoplasmic bile pigment granules.

5. Regeneration As a result of necrosis of hepatocytes, there is lobular disarray. Surviving adjacent hepatocytes

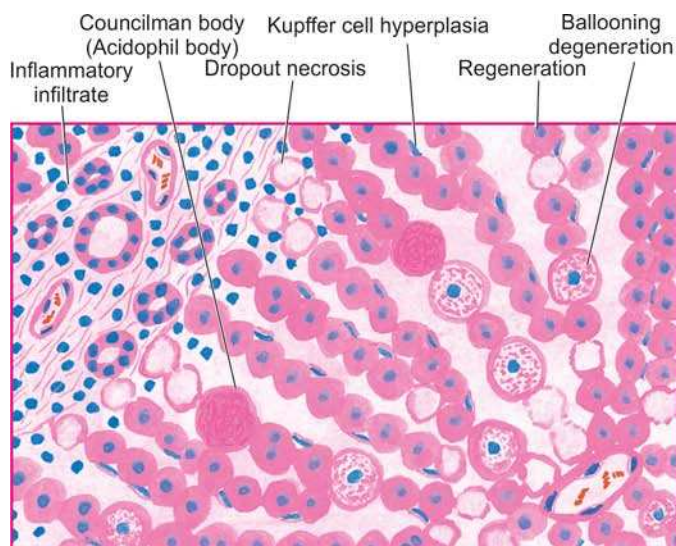

Figure 19.12 Acute viral hepatitis. The predominant histologic changes are: variable degree of necrosis of hepatocytes, most marked in zone 3 (centrilobular); and mononuclear cellular infiltrate in the lobule. Mild degree of liver cell necrosis is seen as ballooning degeneration while acidophilic Councilman bodies (inset) are indicative of more severe liver cell injury.

undergo regeneration and hyperplasia. If the necrosis causes collapse of reticulin framework of the lobule, healing by fibrosis follows, distorting the lobular architecture.

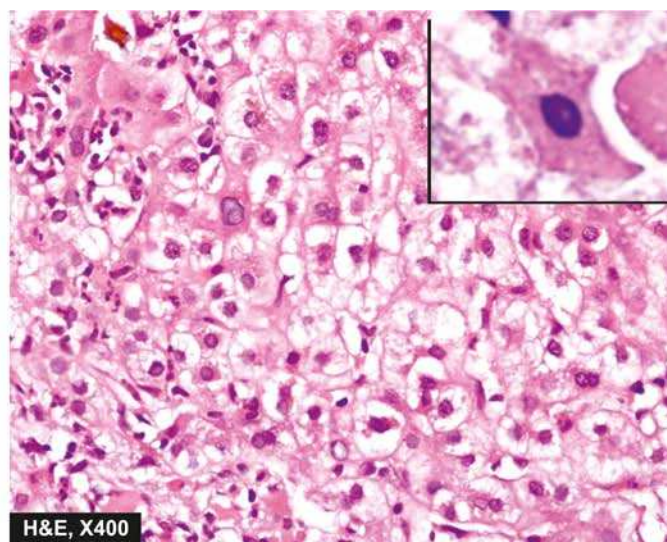

The above histologic changes apply to viral hepatitis by various types of hepatotropic viruses in general, and by HBV in particular. It is usually not possible to distinguish histologically between viral hepatitis of various etiologies, but the following morphologic features may help in giving an etiologic clue:

- ◆ **HAV hepatitis** is a panlobular involvement by heavy inflammatory infiltrate compared to other types.
- ◆ **HCV hepatitis** causes milder necrosis, with fatty change in hepatocytes, shows presence of lymphoid aggregates in the portal triads and degeneration of bile duct epithelium.

IV. Chronic Hepatitis

Chronic hepatitis is defined as continuing or relapsing hepatic disease for more than 6 months with symptoms along with biochemical, serologic and histopathologic evidence of inflammation and necrosis. Majority of cases of chronic hepatitis are the result of infection with hepatotropic viruses— hepatitis B, hepatitis C and combined hepatitis B and hepatitis D infection. However, some non-viral causes of chronic hepatitis include: Wilson's disease, α -1-antitrypsin deficiency, chronic alcoholism, drug-induced injury and autoimmune diseases. The last named gives rise to *autoimmune or lupoid hepatitis* which is characterised by positive serum autoantibodies (e.g. antinuclear, anti-smooth muscle and anti-mitochondrial) and a positive LE cell test but negative for serologic markers of viral hepatitis.

Until recent years, prediction of prognosis of chronic hepatitis used to be made on the basis of morphology which divided it into 2 main types—*chronic persistent* and *chronic active (aggressive) hepatitis*. A third form, *chronic lobular hepatitis* is distinguished separately by some as mild form of lobular inflammation without inflammation of portal tracts but these cases often recover completely. However, subsequent studies have revealed that morphologic subtypes do not

H&E, X400

necessarily correlate with prognosis since the disease is not essentially static but may vary from mild form to severe and *vice versa*. Besides, two other factors which determine the vulnerability of a patient of viral hepatitis to develop chronic hepatitis are: *impaired immunity* and *extremes of age* at which the infection is first contracted. Currently, therefore, chronic hepatitis is classified on the basis of etiology and hepatitis activity score (described below). The frequency and severity with which hepatotropic viruses cause chronic hepatitis varies with the organisms as under:

- ◆ **HCV infection** accounts for 40-60% cases of chronicity in adults. HCV infection is particularly associated with progressive form of chronic hepatitis that may evolve into cirrhosis.
- ◆ **HBV** causes chronic hepatitis in 90% of infected infants and in about 5% adult cases of hepatitis B.
- ◆ **HDV** superinfection on HBV carrier state may be responsible for chronic hepatitis in 10-40% cases.
- ◆ **HAV and HEV** do not produce chronic hepatitis.

MORPHOLOGIC FEATURES The pathologic features are common to both HBV and HCV infection and include the following lesions (**Fig. 19.13**).

1. Piecemeal necrosis Piecemeal necrosis is defined as periportal destruction of hepatocytes at the limiting plate (*piecemeal* = piece by piece). Its features in chronic hepatitis are as under:

- i) Necrosed hepatocytes at the limiting plate in periportal zone.
- ii) Interface hepatitis due to expanded portal tract by infiltration of lymphocytes, plasma cells and macrophages.
- iii) Expanded portal tracts are often associated with proliferating bile ductules as a response to liver cell injury.

2. Portal tract lesions All forms of chronic hepatitis are characterised by variable degree of changes in the portal tract.

- i) Inflammatory cell infiltration by lymphocytes, plasma cells and macrophages (triaditis).

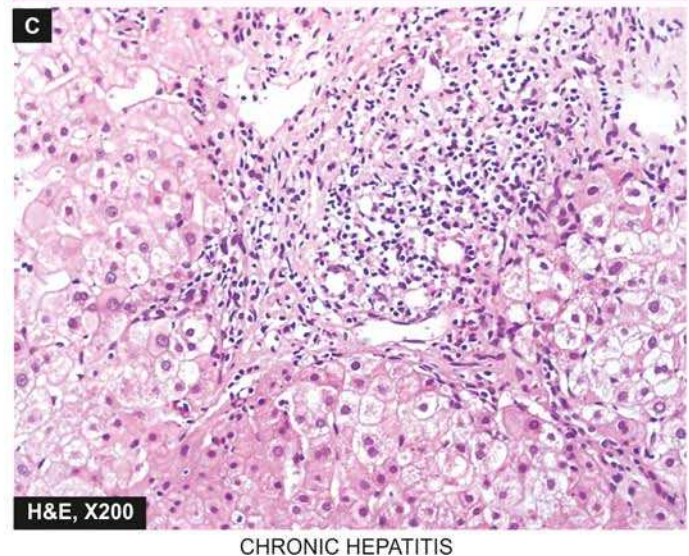

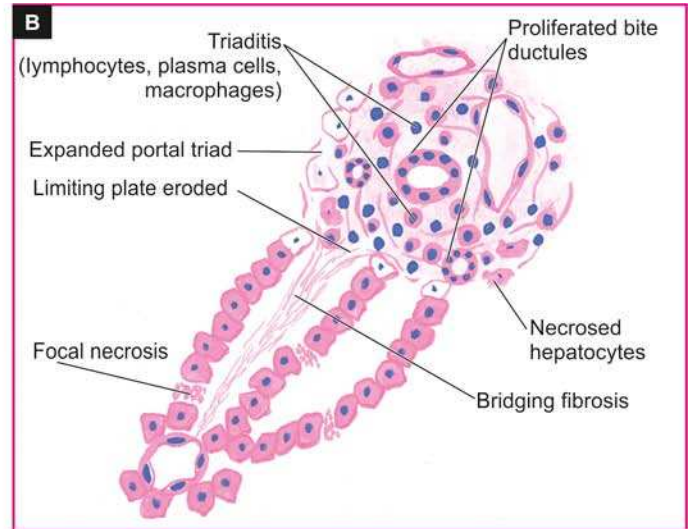

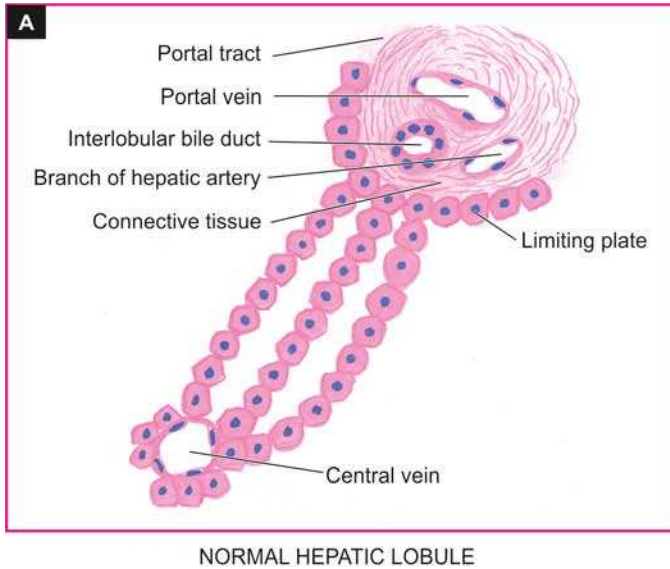

Figure 19.13 Chronic hepatitis. Diagrammatic representation of pathologic changes in chronic hepatitis (B) contrasted with normal morphology (A). Photomicrograph on right (C) shows stellate-shaped portal triad, with extension of fibrous spurs into lobules. The portal tract is expanded due to increased lymphomononuclear inflammatory cells which are seen to breach the limiting plate (i.e. hepatocytes at the interface of portal tract and lobule are destroyed).

- ii) Proliferated bile ductules in the expanded portal tracts.
- iii) Additionally, chronic hepatitis C may show lymphoid aggregates or follicles with reactive germinal centre and infiltration of inflammatory cells in the damaged bile duct epithelial cells.

3. Intralobular lesions Generally, the architecture of lobule is retained in mild to moderate chronic hepatitis.

- i) There are focal areas of necrosis and inflammation within the hepatic parenchyma.
- ii) Scattered acidophilic bodies in the lobule.
- iii) Kupffer cell hyperplasia.
- iv) More severe form of injury shows bridging necrosis (i.e. bands of necrosed hepatocytes that may bridge portal tract-to-central vein, central vein-to-central vein, and portal tract-to-portal tract).
- v) Regenerative changes in hepatocytes in cases of persistent hepatocellular necrosis.
- vi) Cases of chronic hepatitis C show moderate fatty change.
- vii) Cases of chronic hepatitis B show scattered ground-glass hepatocytes indicative of abundance of HBsAg in the cytoplasm.

4. Bridging fibrosis The onset of fibrosis in chronic hepatitis from the area of interface hepatitis and bridging necrosis is a feature of irreversible damage.

- i) At first, there is periportal fibrosis at the sites of interface hepatitis giving the portal tract stellate-shaped appearance.
- ii) Progressive cases show bridging fibrosis connecting portal tract-to-portal tract or portal tract-to-central vein traversing the lobule.
- iii) End-stage of chronic hepatitis is characterised by dense collagenous septa destroying lobular architecture and forming nodules resulting in postnecrotic cirrhosis.

As prognostic indicator of chronic hepatitis, a histologic grading of chronic hepatitis (ranging from none to minimal/mild to moderate and severe) was originally described by Knodell and Ishak. A combined histologic grade leads to hepatitis activity index (HAI) and takes the following features into consideration:

A. Necroinflammatory activity:

- ◆ *Periportal necrosis* i.e. *piecemeal necrosis* and/or *bridging necrosis* (ranging from score 0 as 'no necrosis' to score 4 as 'multilobular necrosis').

◆ *Intralobular necrosis, focal or confluent* (ranging from score 0 as 'none' to score 4 for '>10 foci' for focal necrosis, and score 6 as 'panacinar/multiacinar' for confluent necrosis).

◆ *Extent and depth of portal inflammation* (ranging from grade 0 as 'no inflammation' to grade 4 having 'marked portal inflammation').

B. Stage of fibrosis:

◆ *Extent and density of fibrosis* (ranging from score 0 as 'no fibrosis' to score 6 as 'cirrhosis').

CLINICAL FEATURES The clinical features of chronic hepatitis are quite variable ranging from mild disease to full-blown picture of cirrhosis.

i) Mild chronic hepatitis shows only slight but persistent elevation of transaminases ('transaminitis') with fatigue, malaise and loss of appetite.

ii) Other cases may show mild hepatomegaly, hepatic tenderness and mild splenomegaly.

iii) Laboratory findings may reveal prolonged prothrombin time, hyperbilirubinaemia, hyperglobulinaemia and markedly elevated alkaline phosphatase.

iv) Systemic features of circulating immune complexes due to HBV and HCV infection may produce features of immune complex vasculitis, glomerulonephritis and cryoglobulinaemia in a proportion of cases.

However, clinical features do not correlate with morphologic appearance of the liver biopsy. Some patients may have mild form of disease without progressing for several years while others may show rapid evolution into cirrhosis with its complications over a period of few years. Patients of long-standing HBV and HCV chronic infection are known to evolve into hepatocellular carcinoma.

V. Fulminant Hepatitis (Submassive to Massive Necrosis)

Fulminant hepatitis is the most severe form of acute hepatitis in which there is rapidly progressive hepatocellular failure. Two patterns are recognised—*submassive necrosis* having a less rapid course extending up to 3 months; and *massive necrosis* in

which the liver failure is rapid and fulminant occurring in 2-3 weeks.

Fulminant hepatitis of either of the two varieties can occur from viral and non-viral etiologies:

◆ *Acute viral hepatitis* accounts for about half the cases, most often from HBV and HCV; less frequently from combined HBV-HDV and rarely from HAV. However, HEV infection is a serious complication in pregnant women. In addition, herpesvirus can also cause serious viral hepatitis.

◆ *Non-viral causes* include acute hepatitis due to drug toxicity (e.g. acetaminophen, non-steroidal anti-inflammatory drugs, isoniazid, halothane and anti-depressants), poisonings, hypoxic injury and massive infiltration of malignant tumours into the liver.

The patients present with features of hepatic failure with hepatic encephalopathy (page 588). The mortality rate is high if hepatic transplantation is not undertaken.

MORPHOLOGIC FEATURES *Grossly*, the liver is small and shrunken, often weighing 500-700 gm. The capsule is loose and wrinkled. The sectioned surface shows diffuse or random involvement of hepatic lobes. There are extensive areas of muddy-red and yellow necrosis (previously called *acute yellow atrophy*) and patches of green bile staining.

Histologically, two forms of fulminant necrosis are distinguished—submassive and massive necrosis (**Fig. 19.14**).

i) In **submassive necrosis**, large groups of hepatocytes in zone 3 (centrilobular area) and zone 2 (mid zone) are wiped out leading to a collapsed reticulin framework. Regeneration in submassive necrosis is more orderly and may result in restoration of normal architecture.

ii) In **massive necrosis**, the entire liver lobules are necrotic. As a result of loss of hepatic parenchyma, all that is left is the collapsed and condensed reticulin framework and portal tracts with proliferated bile ductules plugged with bile. Inflammatory infiltrate is scanty. Regeneration, if it takes place, is disorderly forming irregular masses of hepatocytes. Fibrosis is generally not a feature of fulminant hepatitis.

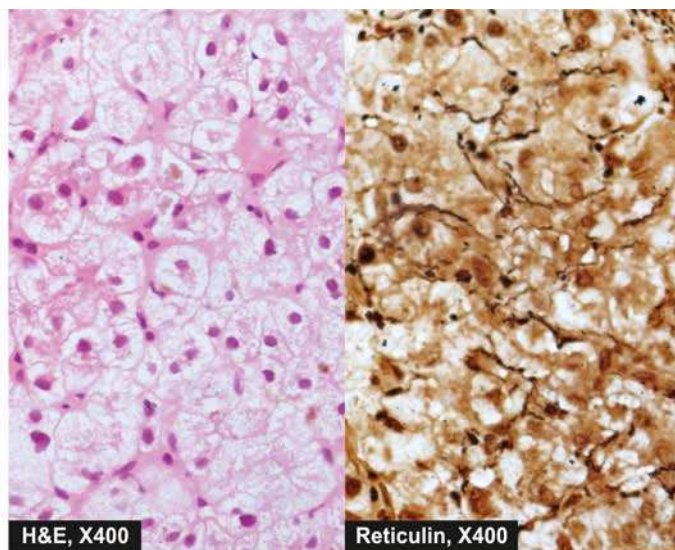

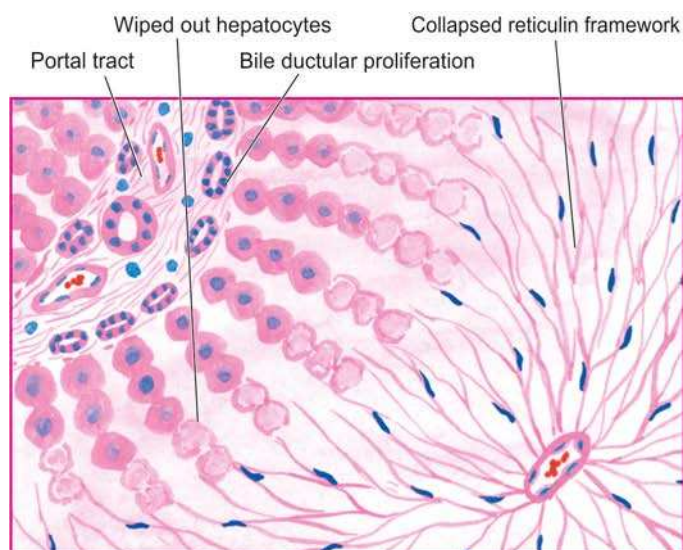

Figure 19.14 Fulminant hepatitis. There is wiping out of liver lobules with only collapsed reticulin framework left out in their place, highlighted by reticulin stain (right photomicrograph). There is no significant inflammation or fibrosis.

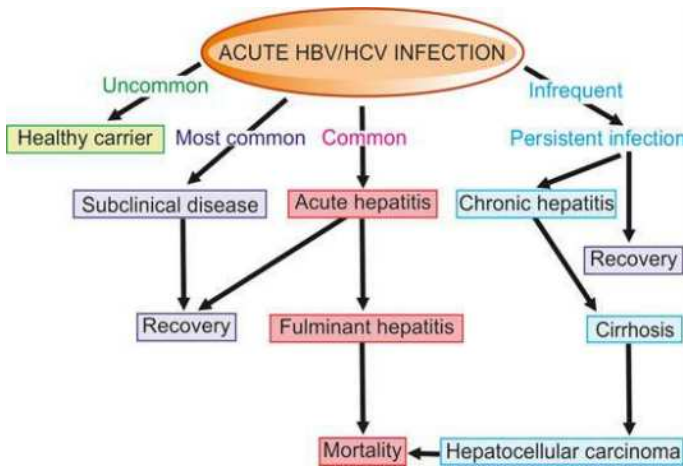

Figure 19.15 Clinicopathologic course of HBV and HCV infection.

The clinicopathologic course in two major forms of hepatitis, HBV and HCV, is summarised in **Fig. 19.15**.

IMMUNOPROPHYLAXIS AND HEPATITIS VACCINES

Best prophylaxis against the viral hepatitis remains prevention of its spread to the contacts after detection and identification of route by which infection is acquired such as from food or water contamination, sexual spread or parenteral spread. Of late, however, immunoprophylaxis and a few hepatitis vaccines have been developed and some more are under development. The principle underlying either of these two forms of prophylaxis is that the persons who develop good antibody response to the antigen of the hepatotropic virus following active infection are protected against the disease on reinfection. Thus, pre-testing of persons may be carried out so as to determine their antibody level. Immunoprophylaxis and hepatitis vaccination are unnecessary if the pre-testing for antibodies is positive.

1. Hepatitis A Passive immunisation with immune globulin as well as active immunisation with a killed vaccine are available.

2. Hepatitis B Earlier, only passive immunoprophylaxis with standard immune globulin was used. Later, active immunisation against HBsAg was introduced. Current recommendations include pre-exposure and post-exposure prophylaxis with recombinant hepatitis B vaccine:

◆ *Pre-exposure prophylaxis* is done for individuals at high-risk e.g. health care workers, haemodialysis patients and staff, haemophiliacs, intravenous drug users etc. Three intramuscular injections of hepatitis vaccine at 0, 1 and 6 months are recommended.

◆ *Post-exposure prophylaxis* is carried out for unvaccinated persons exposed to HBV infection and includes prophylaxis with combination of hepatitis B immune globulin and hepatitis B vaccine.

3. Hepatitis D Hepatitis D infection can also be prevented by hepatitis B vaccine.

4. Hepatitis C Currently, hepatitis C vaccine has yet not been feasible though antibodies to HCV envelope have been developed.

5. Hepatitis E It is not certain whether immune globulin (like for HAV) prevents hepatitis E infection or not but a vaccine against HEV is yet to be developed.

GIST BOX 19.6

Viral Hepatitis

- ▣ Viral hepatitis is infection of the liver caused by hepatotropic viruses. A, B, C, D and E.
- ▣ Hepatitis A is a faecally-spread self-limiting disease. Early, IgM and later IgG, antibodies appear in the blood.
- ▣ Hepatitis B is transmitted parenterally through blood and blood products. There are several immunological markers in the serum: HbsAg, anti-HBs, HbeAg, anti-Hbe, HbcAg, and anti-HBc.
- ▣ Hepatitis D develops with hepatitis B either as co-infection, or may infect an HBsAg carrier (superinfection).
- ▣ Hepatitis C infection is acquired by blood transfusions.
- ▣ Hepatitis E is an enterically-transmitted infection.
- ▣ Carrier state exists for hepatitis B and C only.
- ▣ Morphology of acute and fulminant hepatitis caused by different hepatotropic viruses is similar.
- ▣ Chronic hepatitis may occur in infection with hepatitis B, C and combined HBV-HDV.
- ▣ Immunoprophylaxis by a few hepatitis vaccines is done for high risk population.

OTHER INFECTIONS AND INFESTATIONS

Apart from viral hepatitis, the liver is affected by infections with bacteria, spirochaetes and fungi and is involved in some parasitic infestations. Some common examples of such conditions are described below.

CHOLANGITIS

Cholangitis is the term used to describe inflammation of the extrahepatic or intrahepatic bile ducts, or both. There are two main types of cholangitis—pyogenic and primary sclerosing. While primary sclerosing cholangitis is discussed later with biliary cirrhosis (page 610), pyogenic cholangitis is described below.

Pyogenic Cholangitis

Cholangitis occurring secondary to obstruction of a major extrahepatic duct causes pyogenic cholangitis. Most commonly, the obstruction is from impacted gallstone; other causes are carcinoma arising in the extrahepatic ducts, carcinoma head of pancreas, acute pancreatitis and inflammatory strictures in the bile duct. Bacteria gain entry to the obstructed duct and proliferate in the bile. Infection spreads along the branches of obstructed duct and reaches the liver, termed *ascending cholangitis*. The common infecting bacteria are enteric organisms such as *E. coli*, *Klebsiella* and *Enterobacter*.

MORPHOLOGIC FEATURES The affected ducts show small beaded abscesses accompanied by bile stasis along their course and larger abscesses within the liver. The abscesses are composed of acute inflammatory cells which in time are replaced by chronic inflammatory cells and enclosed by fibrous capsule.

PYOGENIC LIVER ABSCESS

Most liver abscesses are of bacterial (pyogenic) origin; less often they are amoebic, hydatid and rarely actinomycotic. Pyogenic liver abscesses have become uncommon due to improved diagnostic facilities and the early use of antibiotics. However, their incidence is higher in old age and in immunosuppressed patients such as in AIDS, transplant recipients and those on intensive chemotherapy.

Pyogenic liver abscesses can occur by following modes of entry:

1. *Ascending cholangitis* through ascending infection in the biliary tract due to obstruction e.g. gallstones, cancer, sclerosing cholangitis and biliary strictures.
2. *Portal pyaemia* by means of spread of pelvic or gastrointestinal infection resulting in portal pylephlebitis or septic emboli e.g. from appendicitis, empyema of gallbladder, diverticulitis, regional enteritis, pancreatitis, infected haemorrhoids and neonatal umbilical vein sepsis.
3. *Septicaemia* through spread by hepatic artery.
4. *Direct infection* resulting in solitary liver abscess e.g. from adjacent perinephric abscess, secondary infection in amoebic liver abscess, metastasis and formation of haematoma following trauma.
5. *Iatrogenic causes* include liver biopsy, percutaneous biliary drainage and accidental surgical trauma.
6. *Cryptogenic* from unknown causes, especially in the elderly.

The commonest infecting organisms are gram-negative bacteria chiefly *E. coli*; others are *Pseudomonas*, *Klebsiella*, *Enterobacter* and a number of anaerobic organisms, bacteroides and actinomycetes.

Liver abscesses are clinically characterised by pain in the right upper quadrant, fever, tender hepatomegaly and sometimes jaundice. Laboratory examination reveals leucocytosis, elevated serum alkaline phosphatase, hypoalbuminaemia and a positive blood culture.

MORPHOLOGIC FEATURES *Grossly*, depending upon the cause for pyogenic liver abscess, they occur as single or multiple yellow abscesses, 1 cm or more in diameter, in an enlarged liver. A single abscess generally has a thick fibrous capsule. The abscesses are particularly common in right lobe of the liver (**Fig. 19.16**).

Microscopically, typical features of abscess are seen. There are multiple small neutrophilic abscesses with areas of extensive necrosis of the affected liver parenchyma. The adjacent viable area shows pus and blood clots in the portal vein, inflammation, congestion and proliferating fibroblasts. Direct extension from the liver may lead to subphrenic or pleuro-pulmonary suppuration or peritonitis. There may be small pyaemic abscesses elsewhere such as in the lungs, kidneys, brain and spleen.

AMOEBIC LIVER ABSCESS

Amoebic liver abscesses are less common than pyogenic liver abscesses and have many similar features. They are caused by the spread of *Entamoeba histolytica* from intestinal lesions. The trophozoite form of amoebae in the colon invade the colonic mucosa forming flask-shaped ulcers from where they are carried to the liver in the portal venous system (page 555). Amoebae multiply and block small intrahepatic portal

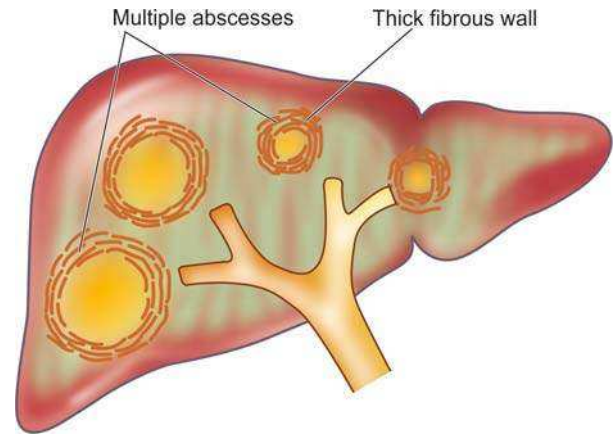

Figure 19.16 Gross appearance of pyogenic abscesses in the liver.

radicles resulting in infarction necrosis of the adjacent liver parenchyma.

The patients, generally from tropical and subtropical countries, may give history of amoebic dysentery in the past. Cysts of *E. histolytica* in stools are present in only 15% of patients of hepatic amoebiasis. Intermittent low-grade fever, pain and tenderness in the liver area are common presenting features. A positive haemagglutination test is quite sensitive and useful for diagnosis of amoebic liver abscess.

MORPHOLOGIC FEATURES *Grossly*, amoebic liver abscesses are usually solitary and more often located in the right lobe in the posterosuperior portion. Amoebic liver abscess may vary greatly in size but is generally of the size of an orange. The centre of the abscess contains large necrotic area having reddish-brown, thick pus resembling anchovy or chocolate sauce. The abscess wall consists of irregular shreds of necrotic liver tissue (**Fig. 19.17**).

Histologically, the necrotic area consists of degenerated liver cells, leucocytes, red blood cells, strands of connective tissue and debris. Amoebae are most easily found in the liver tissue at the margin of abscess. PAS-staining is employed to confirm the trophozoites of *E. histolytica*.

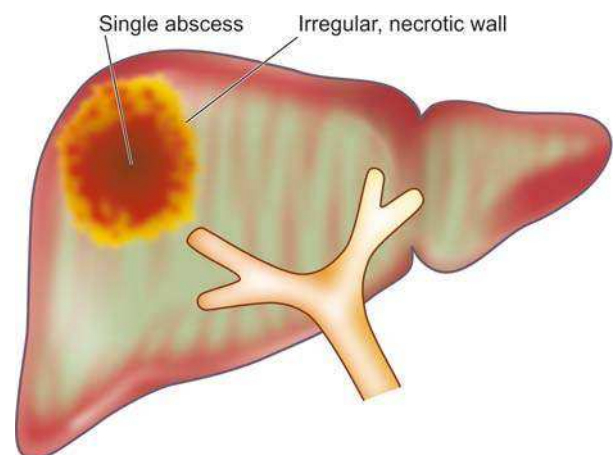

Figure 19.17 Amoebic liver abscess is commonly solitary and its wall is irregular and necrotic.

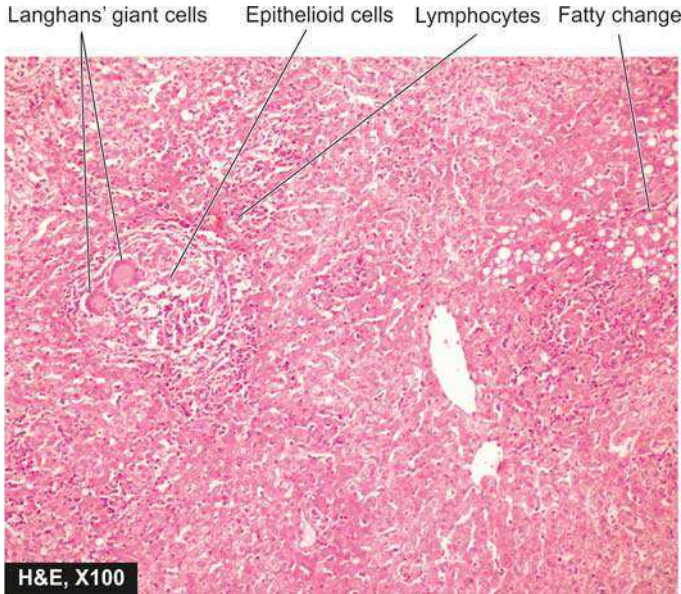

Figure 19.18 Miliary tuberculosis liver. The hepatic parenchyma shows epithelioid granulomas with small areas of central necrosis and surrounded peripherally by Langhans' giant cells and lymphocytes.

HEPATIC TUBERCULOSIS

Tuberculosis of the liver occurs as a result of miliary dissemination from primary complex or from chronic adult pulmonary tuberculosis. The diagnosis is possible by liver biopsy. The patients may have unexplained fever, jaundice, hepatomegaly or hepatosplenomegaly. There may be elevated serum alkaline phosphatase levels and hyperglobulinaemia.

MORPHOLOGIC FEATURES The basic lesion is the epithelioid cell granuloma characterised by central caseation necrosis with destruction of the reticulin framework and peripheral cuff of lymphocytes (**Fig. 19.18**). Ziehl-Neelsen staining for AFB or culture of the organism from the biopsy tissue is confirmatory. Rare lesions consist of tuberculous cholangitis and tuberculous pylephlebitis.

HYDATID DISEASE (ECHINOCOCCOSIS)

Hydatid disease occurs as a result of infection by the larval cyst stage of the tapeworm, *Echinococcus granulosus*. The dog is the common definite host, while man, sheep and cattle are the intermediate hosts. The dog is infected by eating the viscera of sheep containing hydatid cysts. The infected faeces of the dog contaminate grass and farmland from where the ova are ingested by sheep, pigs and man. Thus, man can acquire infection by handling dogs as well as by eating contaminated vegetables. The ova ingested by man are liberated from the chitinous wall by gastric juice and pass through the intestinal mucosa from where they are carried to the liver by portal venous system. These are trapped in the hepatic sinusoids where they eventually develop into hydatid cyst. About 70% of hydatid cysts develop in the liver which acts as the first filter for ova. However, ova which pass through the liver enter the right side of the heart and are caught in the pulmonary capillary bed and form pulmonary hydatid cysts. Some ova which enter the systemic circulation give rise to hydatid cysts in the brain, spleen, bone and muscles.

The disease is common in sheep-raising countries such as Australia, New Zealand and South America. The *uncomplicated hydatid cyst* of the liver may be silent or may produce dull ache in the liver area and some abdominal distension.

Complications of hydatid cyst include its rupture (e.g. into the peritoneal cavity, bile ducts and lungs), secondary infection and hydatid allergy due to sensitisation of the host with cyst fluid. The diagnosis is made by peripheral blood eosinophilia, radiologic examination and serologic tests such as indirect haemagglutination test and Casoni skin test.

MORPHOLOGIC FEATURES Hydatid cyst grows slowly and may eventually attain a size over 10 cm in diameter in about 5 years. *E. granulosus* generally causes unilocular hydatid cyst while *E. multilocularis* results in multilocular or alveolar hydatid disease in the liver.

The cyst wall is composed of 3 distinguishable zones—outer *pericyst*, intermediate characteristic *ectocyst* and inner *endocyst* (**Fig. 19.19**):

- 1. Pericyst** is the outer host inflammatory reaction consisting of fibroblastic proliferation, mononuclear cells, eosinophils and giant cells, eventually developing into dense fibrous capsule which may even calcify.
- 2. Ectocyst** is the intermediate layer composed of characteristic acellular, chitinous, laminated hyaline material (**Fig. 19.20**).
- 3. Endocyst** is the inner germinal layer bearing daughter cysts (brood-capsules) and scolices projecting into the lumen.

Hydatid sand is the grain-like material composed of numerous scolices present in the hydatid fluid. Hydatid fluid, in addition, contains antigenic proteins so that its liberation into circulation gives rise to pronounced eosinophilia or may cause anaphylaxis.

GIST BOX 19.7

Other Infections and Infestations of Liver

- Cholangitis occurring secondary to obstruction of a major extrahepatic duct causes pyogenic cholangitis.
- Pyogenic liver abscesses can occur by ascending infection, portal pyaemia, septicaemia, and direct infection.
- Amoebic liver abscesses are caused by the spread of trophozoites of *Entamoeba histolytica* from intestinal lesions.
- Tuberculosis of the liver occurs by miliary dissemination from another site, most often chronic adult pulmonary tuberculosis.
- Hydatid cyst has endocyst, ectocyst and pericyst and it occurs as a result of infection by the tapeworm larvae, *Echinococcus granulosus*.

CHEMICAL AND DRUG INJURY

HEPATIC DRUG METABOLISM The liver plays a central role in the metabolism of a large number of organic and inorganic chemicals and drugs which gain access to the body by inhalation, injection, or most commonly, via the intestinal tract. The main drug metabolising system resides in the microsomal fraction of the smooth endoplasmic reticulum of

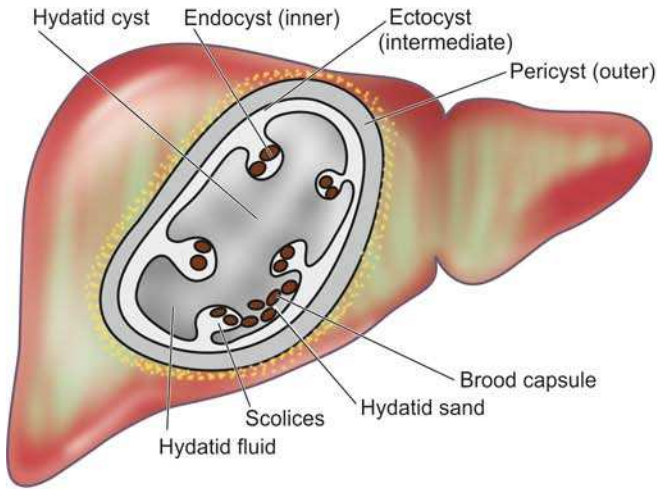

Figure 19.19 Hydatid cyst in the liver. The cyst wall is composed of whitish membrane resembling the membrane of a hard boiled egg.

the liver cells via P-450 cytochrome and cytochrome reductase enzyme systems. Other steps involved in the drug metabolism are its conjugation with an endogenous molecule, its active transport from the hepatocytes and ultimately its excretion in the bile or in urine depending upon the molecular weight of the substance. A number of risk factors predispose an individual to hepatic drug injury such as pre-existing liver disease, ageing, female sex and genetic inability to perform a particular biotransformation.

HEPATOTOXICITY Toxic liver injury produced by drugs and chemicals may virtually mimic any form of naturally-occurring liver disease. In fact, any patient presenting with liver disease or unexplained jaundice is thoroughly questioned about history of drug intake or exposure to chemicals. Hepatotoxicity from drugs and chemicals is the commonest form of iatrogenic

disease. Severity of hepatotoxicity is greatly increased if the drug is continued after symptoms develop.

Among the various *inorganic compounds* producing hepatotoxicity are arsenic, phosphorus, copper and iron. *Organic agents* include certain naturally-occurring plant toxins such as pyrrolizidine alkaloids, mycotoxins and bacterial toxins. The synthetic group of organic compounds are a large number of medicinal agents. In addition, exposure to hepatotoxic compounds may be occupational, environmental or domestic that could be accidental, homicidal or suicidal ingestion.

In general, drug reactions affecting the liver are divided into two main classes:

1. Direct or predictable, when the drug or one of its metabolites is either directly toxic to the liver or it lowers the

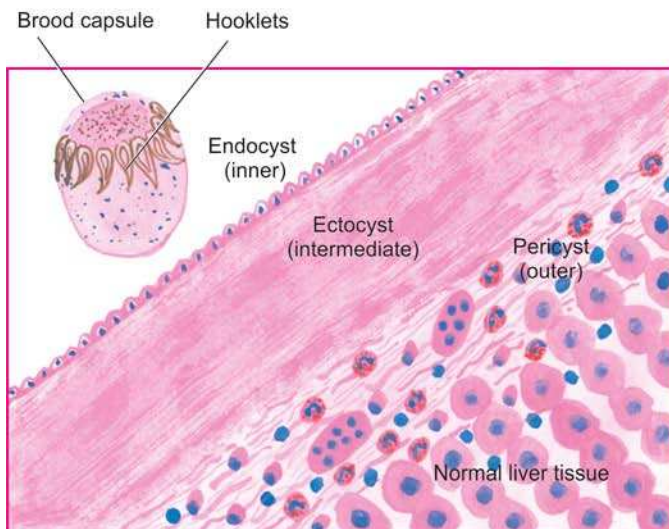

Figure 19.20 Microscopy shows three layers in the wall of hydatid cyst. Inbox in the right photomicrograph shows a scolex with a row of hooklets.

host immune defense mechanism. The adverse effects occur in most individuals who consume them and their hepatotoxicity is dose-dependent e.g. carbon tetrachloride.

2. Indirect or unpredictable or idiosyncratic, when the drug or one of its metabolites acts as a hapten and induces hypersensitivity in the host. In many instances, drug hepatotoxicity is associated with appearance of autoantibodies to liver-kidney microsomes (i.e. anti-LKM2) directed against cytochrome P450 enzyme. The hepatotoxicity by this group does not occur regularly in all individuals and the effects are usually not dose-related e.g. acetaminophen.

A simplified clinicopathologic classification of important hepatic drug reactions and the agents causing them is presented in **Table 19.8**. The changes produced by hepatotoxic agents may vary from mild, which are diagnosed only by elevated serum transaminases, to instances of massive necrosis and death. The pathologic changes by hepatotoxins include 2 large categories:

1. *Acute liver disease* characterised by cholestasis, hepatocellular necrosis, fatty change, granulomatous reaction or vascular disease.

2. *Chronic liver disease* characterised by variable degree of fibrosis, cirrhosis or neoplasia.

As such, the pathologic changes induced by hepatotoxins are indistinguishable from the respective disease states.

GIST BOX 19.8 Chemical and Drug Injury

- ☐ The liver plays a central role in the metabolism of a large number of organic and inorganic chemicals and drugs which enter the body by inhalation, injection, or via the intestinal tract.
- ☐ Toxic liver injury produced by drugs and chemicals may mimic any form of naturally-occurring liver disease.
- ☐ Drug reactions affecting the liver may be direct or predictable, and indirect or unpredictable.

CIRRHOSIS

Cirrhosis of the liver is one of the ten leading causes of death in the Western world. It represents the irreversible end-stage of several diffuse diseases causing hepatocellular injury and is characterised by the following 4 features:

1. It involves the entire liver.
2. The normal lobular architecture of hepatic parenchyma is disorganised.
3. There is formation of nodules separated from one another by irregular bands of fibrosis.
4. It occurs following hepatocellular necrosis of varying etiology so that there are alternate areas of necrosis and regenerative nodules. However, regenerative nodules are not essential for diagnosis of cirrhosis since biliary cirrhosis and cirrhosis in haemochromatosis have little regeneration.

PATHOGENESIS

Irrespective of the etiology, cirrhosis involves a combination of a few processes: hepatocellular necrosis, healing by fibrosis, formation of compensatory regenerative nodules and changes in vascular pattern of the hepatic parenchyma.

FIBROGENESIS Continued destruction of hepatocytes causes collapse of normal lobular hepatic parenchyma followed by fibrosis around necrotic liver cells. Fibrosis in the liver lobules may be portal-central, portal-portal, or both. The mechanism of fibrosis is by increased synthesis of type I and III collagen in the space of Disse. There is proliferation of fat-storing Ito cells underlying the sinusoidal epithelium which are transformed into myofibroblasts and fibrocytes. Besides collagen, two glycoproteins, fibronectin and laminin, are deposited in excessive amounts in area of liver cell damage. Stimulants for fibrosis are several growth factors (e.g. platelet-derived growth factor receptor- β , transforming growth factor- β , metalloproteinases), vasoactive factors, cytokines, lymphokines and chemokines released from lymphocytes, Kupffer cells, endothelial cells and hepatocytes.

REGENERATIVE NODULES The surviving hepatocytes act as stimulants for growth and proliferation of more hepatocytes under influence of growth factors. This compensatory proliferation of hepatocytes is restricted within fibrous nodules forming regenerative nodules.

Table 19.8 Classification of hepatic drug reactions.

| | PATHOLOGIC CHANGES | AGENTS |
|----|---------------------------------------|--|
| A. | ACUTE LIVER DISEASE | |
| 1. | <i>Zonal necrosis</i> | Carbon tetrachloride Acetaminophen Halothane |
| 2. | <i>Massive necrosis</i> | Halothane Acetaminophen Methyldopa |
| 3. | <i>Fatty change</i> | Tetracycline Salicylates Methotrexate Ethanol |
| 4. | <i>Hepatitis</i> | Methyldopa Isoniazid Halothane Ketoconazole |
| 5. | <i>Granuloma formation</i> | Sulfonamides Methyldopa Quinidine Allopurinol |
| 6. | <i>Cholestasis</i> | Sex hormones (including oral contraceptives) Chlorpromazine Nitrofurantoin |
| 7. | <i>Veno-occlusive disease</i> | Cytotoxic drugs |
| 8. | <i>Hepatic/portal vein thrombosis</i> | Oral contraceptives |
| B. | CHRONIC LIVER DISEASE | |
| 1. | <i>Fibrosis-cirrhosis</i> | Methotrexate |
| 2. | <i>Focal nodular hyperplasia</i> | Vinyl chloride Vitamin A Sex hormones |
| 3. | <i>Adenoma</i> | Sex hormones |
| 4. | <i>Hepatocellular carcinoma</i> | Sex hormones |

VASCULAR REORGANISATION Due to damaged hepatic parenchyma and formation of fibrous nodules, the new vessels formed in the fibrous septa are connected to the vessels in the portal triad (i.e. branches of hepatic artery and portal vein) and then the blood is drained into hepatic vein. This way, the blood bypasses the hepatic parenchyma. Moreover, due to fibrous proliferation in the space of Disse, gaps in the hepatic sinusoids are closed which result in development of capillaries in the sinusoids (capillarisation of sinusoids).

CLASSIFICATION

Cirrhosis can be classified on the basis of morphology and etiology (**Table 19.9**).

A. MORPHOLOGIC CLASSIFICATION There are 3 morphologic types of cirrhosis—micronodular, macronodular and mixed. Each of these forms may have an active and inactive form.

◆ An *active form* is characterised by continuing hepatocellular necrosis and inflammatory reaction, a process that closely resembles chronic hepatitis.

◆ An *inactive form*, on the other hand, has no evidence of continuing hepatocellular necrosis and has sharply-defined nodules of surviving hepatic parenchyma without any significant inflammation.

1. Micronodular cirrhosis In micronodular cirrhosis, the nodules are usually regular and small, *less than 3 mm* in diameter. There is diffuse involvement of all the hepatic lobules forming nodules by thick fibrous septa which may be portal-portal, portal-central, or both. The micronodular cirrhosis includes etiologic type of alcoholic cirrhosis (or nutritional cirrhosis or Laennec's cirrhosis) and represents impaired capacity for regrowth as seen in alcoholism, malnutrition, severe anaemia and old age.

2. Macronodular cirrhosis In this type, the nodules are of variable size and are generally *larger than 3 mm* in

diameter. The pattern of involvement is more irregular than in micronodular cirrhosis, sparing some portal tracts and central veins, and more marked evidence of regeneration. Macronodular cirrhosis corresponds to post-necrotic (or post-hepatitis) cirrhosis of the etiologic classification.

3. Mixed cirrhosis In mixed type, some parts of the liver show micronodular appearance while other parts show macronodular pattern. All the portal tracts and central veins are not involved by fibrosis but instead some of them are spared. Mixed pattern is a kind of incomplete expression of micronodular cirrhosis.

B. ETIOLOGIC CLASSIFICATION Based on the etiologic agent for cirrhosis, various categories of cirrhosis are described as given in **Table 19.9**.

SPECIFIC TYPES OF CIRRHOSIS

Alcoholic Liver Disease and Cirrhosis

Alcoholic liver disease is the term used to describe the spectrum of liver injury associated with acute and chronic alcoholism. There are three sequential stages in alcoholic liver disease: *alcoholic steatosis (fatty liver)*, *alcoholic hepatitis* and *alcoholic cirrhosis*.

Before discussing the features of alcoholic liver disease and cirrhosis, a brief outline of ethanol metabolism is outlined below and is discussed earlier in Chapter 8 (page 234).

ETHANOL METABOLISM One gram of alcohol gives 7 calories. But alcohol cannot be stored in the body and must undergo obligatory oxidation, chiefly in the liver. Thus, these empty calories make no contribution to nutrition other than to give energy.

Ethanol after ingestion and absorption from the small bowel circulates through the liver where about 90% of it is oxidised to acetate by a *two-step enzymatic process* involving two enzymes: *alcohol dehydrogenase (ADH)* present in the cytosol, and *acetaldehyde dehydrogenase (ALDH)* in the mitochondria of hepatocytes (**Fig. 19.21**). The remaining 10% of ethanol is oxidised elsewhere in the body.

First step: Ethanol is catabolised to acetaldehyde in the liver by the following three pathways, one major and two minor:

i) *In the cytosol*, by the major rate-limiting pathway of alcohol dehydrogenase (ADH).

ii) *In the smooth endoplasmic reticulum*, via microsomal P-450 oxidases (also called microsomal ethanol oxidising system, MEOS), where only part of ethanol is metabolised.

iii) *In the peroxisomes*, minor pathway via catalase such as H_2O_2 .

Acetaldehyde is toxic and may cause membrane damage and cell necrosis. Simultaneously, the cofactor nicotinamide-adenine dinucleotide (NAD) which is a hydrogen acceptor, is reduced to NADH.

Second step: The second step occurs in the mitochondria where acetaldehyde is converted to acetate with ALDH acting as a co-enzyme. Most of the acetate on leaving the liver is finally oxidised to carbon dioxide and water, or converted by the citric acid cycle to other compounds including fatty acids. Simultaneously, the same cofactor, NAD, is reduced to NADH resulting in *increased NADH: NAD redox ratio* which

Table 19.9 Classification of cirrhosis.

| A. MORPHOLOGIC | B. ETIOLOGIC |
|---|---|
| I. Micronodular (nodules less than 3 mm) | 1. Alcoholic cirrhosis (the most common, 60-70%) |
| II. Macronodular (nodules more than 3 mm) | 2. Post-necrotic cirrhosis (10%) |
| III. Mixed | 3. Biliary cirrhosis (5-10%) |
| | 4. Pigment cirrhosis in haemochromatosis (5%) |
| | 5. Cirrhosis in Wilson's disease |
| | 6. Cirrhosis in α -1-antitrypsin deficiency |
| | 7. Cardiac cirrhosis |
| | 8. Indian childhood cirrhosis (ICC) |
| | 9. Cirrhosis in autoimmune hepatitis |
| | 10. Cirrhosis in non-alcoholic steatohepatitis |
| | 11. Miscellaneous forms of cirrhosis (metabolic, infectious, GI, infiltrative) diseases |
| | 12. Cryptogenic cirrhosis |

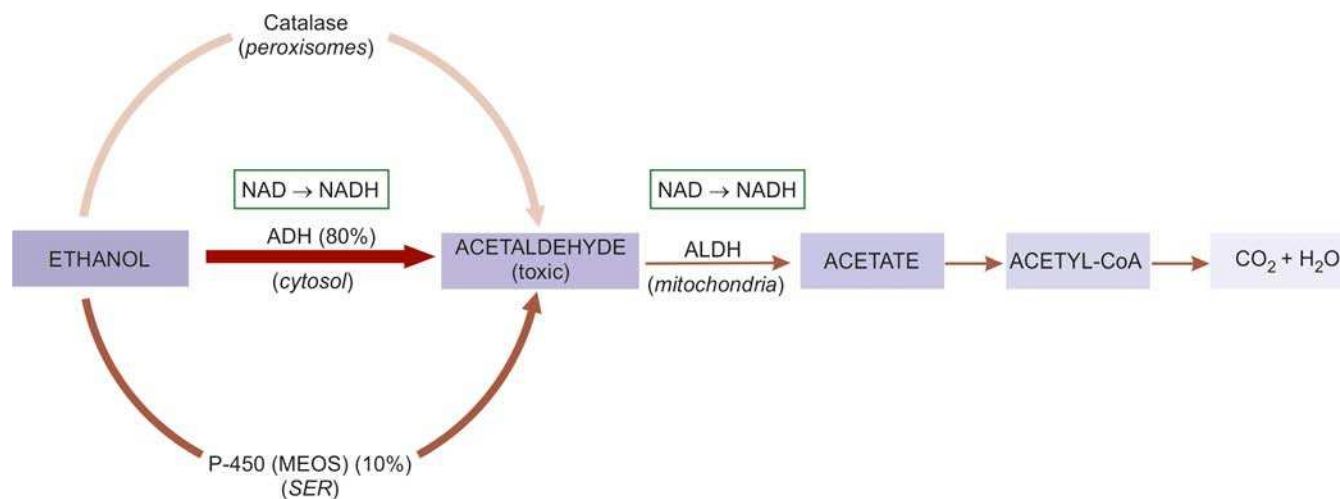

Figure 19.21 Metabolism of ethanol in the liver. Thickness and intensity of colour of arrows on left side of figure corresponds to extent of metabolic pathway followed (ADH = alcohol dehydrogenase; ALDH or ACDH = hepatic acetaldehyde dehydrogenase; NAD = nicotinamide adenine dinucleotide; NADH = reduced NAD).

is the basic biochemical alteration occurring during ethanol metabolism. A close estimate of NADH:NAD ratio is measured by the ratio of its oxidised and reduced metabolites in the form of *lactate-pyruvate ratio* and *β-hydroxy butyrate-acetoacetate ratio*.

RISK FACTORS FOR ALCOHOLIC LIVER DISEASE All those who indulge in alcohol abuse do not develop liver damage. The incidence of cirrhosis among alcoholics at autopsy is about 10-15%. Why some individuals are predisposed to alcoholic cirrhosis is not clearly known, but a few risk factors have been implicated. These are as under:

1. Drinking patterns Most epidemiologic studies have attributed alcoholic cirrhosis to chronic alcoholism. Available evidence suggests that chronic and excessive consumption of alcohol invariably leads to fatty liver in >90% of chronic alcoholics, progression to alcoholic hepatitis in 10-20% cases, and eventually to alcoholic cirrhosis in more than 10 years. It is generally agreed that continued daily imbibing of 60-80 gm of ethanol in any type of alcoholic beverage for at least 10 years is likely to result in alcoholic cirrhosis. Liver injury is related to the quantity of ethanol contained in alcoholic beverage consumed and its duration, but not related to the type of alcoholic beverage consumed. Ethanol content in an alcoholic beverage is given on the label of the container, but in general, it is about 4-6% in beer, 10-12% in wine, and about 40-50% in brandy, whisky and scotch. Intermittent drinking for long duration is less harmful since the liver is given chance to recover.

2. Gender Women have increased susceptibility to develop advanced alcoholic liver disease with much lesser alcohol intake (20-40 g/day). This gender difference in disease progression is unclear but is probably linked to effects of oestrogen.

3. Malnutrition Absolute or relative malnutrition of proteins and vitamins is regarded as a contributory factor in the evolution of cirrhosis. The combination of chronic alcohol ingestion and impaired nutrition leads to alcoholic liver disease and not malnutrition *per se*. It appears that calories derived from alcohol displace other nutrients leading to malnutrition

and deficiency of vitamins in alcoholics. Additional factors contributing to malnutrition in alcoholics are chronic gastritis and pancreatitis. The evidence in favour of synergistic effect of malnutrition in chronic alcoholism comes from clinical and morphologic improvement in cases of alcoholic cirrhosis on treatment with protein-rich diets.

4. Infections Intercurrent bacterial infections are common in cirrhotic patients and may accelerate the course of the disease. Lesions similar to alcoholic cirrhosis may develop in non-alcoholic patients who have had viral infections in the past.

5. Genetic factors The rate of ethanol metabolism is under genetic control. It is chiefly related to altered rates of elimination of ethanol due to genetic polymorphism for the two main enzyme systems, MEOS (microsomal P-450 oxidases) and alcohol dehydrogenase (ADH). Various HLA histocompatibility types have been associated with susceptibility of different populations to alcoholic liver damage but no single genotype has been identified yet.

6. Hepatitis B and C infection Concurrent infection with either HBV or HCV is an important risk factor for progression of alcoholic liver disease. HBV or HCV infection in chronic alcoholic leads to development of alcoholic liver disease with much less alcohol consumption (20-50 g/day), disease progression at a younger age, having greater severity, and increased risk to develop cirrhosis and hepatocellular carcinoma, and overall poorer survival.

PATHOGENESIS Exact pathogenesis of alcoholic liver injury is yet unclear as to why only some chronic alcoholics develop the complete sequence of changes in the liver while others don't. However, knowledge and understanding of the ethanol metabolism has resulted in discarding the old concept of liver injury due to malnutrition. Instead, it is now known that ethanol and its metabolites are responsible for ill-effects on the liver in a susceptible chronic alcoholic having above-mentioned risk factors. Briefly, the biomedical and cellular pathogenesis due to chronic alcohol consumption culminating in morphologic lesions of alcoholic steatosis (fatty liver),

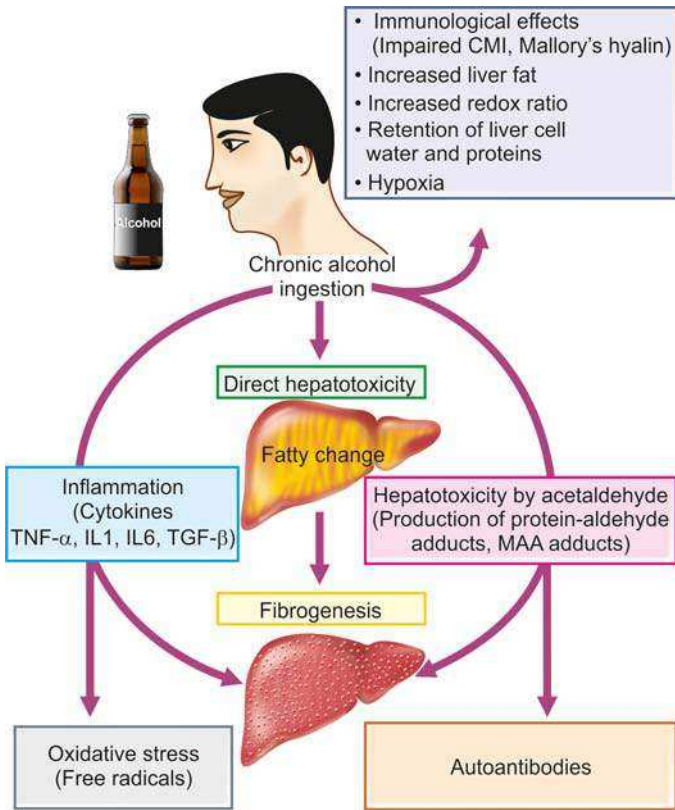

Figure 19.22 Pathogenesis of alcoholic liver disease.

alcoholic hepatitis and alcoholic cirrhosis can be explained as under and is schematically illustrated in **Fig. 19.22**:

1. Direct hepatotoxicity by ethanol There is evidence to suggest that ethanol ingestion for a period of 8-10 days regularly may cause direct hepatotoxic effect on the liver and produce fatty change. Ethanol is directly toxic to microtubules, mitochondria and membrane of hepatocytes.

2. Hepatotoxicity by ethanol metabolites The major hepatotoxic effects of ethanol are exerted by its metabolites, chiefly acetaldehyde. Acetaldehyde levels in blood are elevated in chronic alcoholics. Acetaldehyde produces hepatotoxicity by formation of two adducts:

- Production of protein-aldehyde adducts* which are extremely toxic and can cause cytoskeletal and membrane damage and bring about hepatocellular necrosis.
- Formation of malon-di-aldehyde-acetaldehyde (MAA) adducts* which produce autoantibodies and initiate auto-immune response. These adducts have also a role in hepatic fibrogenesis due to peroxisome proliferator-activated receptor (PPAR)- γ on hepatocytes.

3. Oxidative stress Oxidation of ethanol by the cytochrome-450 oxidases (MEOS) leads to generation of free radicals which causes oxidative damage to the membranes and proteins.

4. Immunological mechanism Cell-mediated immunity is impaired in alcoholic liver disease. Ethanol causes direct immunologic attack on hepatocytes. In a proportion of cases, alcohol-related liver cell injury continues unabated despite cessation of alcohol consumption which is attributed to immunologic mechanisms. Immunological mechanism may also explain the genesis of Mallory's alcoholic hyalin though more favoured hypothesis for its origin is the aggregation

of intermediate filaments of prekeratin type due to alcohol-induced disorganisation of cytoskeleton.

5. Inflammation Chronic ethanol ingestion is not only injurious to hepatocytes but also damages the intestinal cells. The injured intestinal cells elaborate endotoxins which release proinflammatory cytokines, chiefly tumour necrosis factor- α , IL-1, IL-6 and TGF- β . These cytokines and endotoxaemia produce apoptosis and necrosis of hepatocytes and initiate inflammatory reaction in the alcohol-damaged liver.

6. Fibrogenesis Main event facilitating hepatic fibrogenesis is activation of stellate cells by various stimuli:

- by damaged hepatocytes,
- by malon-di-aldehyde-acetaldehyde adducts,
- by activated Kupffer cells, and
- direct stimulation by acetaldehyde.

All forms of collagen are increased and there is increased transformation of fat-storing Ito cells into myofibroblasts and fibrocytes.

7. Increased redox ratio Marked increase in the NADH:NAD redox ratio in the hepatocytes results in increased redox ratio of lactate-pyruvate, leading to lactic acidosis. This altered redox potential has been implicated in a number of metabolic consequences such as in fatty liver, collagen formation, occurrence of gout, impaired gluconeogenesis and altered steroid metabolism.

8. Retention of liver cell water and proteins Alcohol is inhibitory to secretion of newly-synthesised proteins by the liver leading to their retention in the hepatocytes. Water is simultaneously retained in the cell in proportion to the protein and results in swelling of hepatocytes resulting in hepatomegaly in alcoholics.

9. Hypoxia Chronic ingestion of alcohol results in increased oxygen demand by the liver resulting in a hypoxic state which causes hepatocellular necrosis in centrilobular zone (zone 3). Redox changes are also more marked in zone 3.

10. Increased liver fat The origin of fat in the body was discussed in Chapter 2 (page 19). In chronic alcoholism, there is rise in the amount of fat available to the liver which could be from exogenous (dietary) sources, excess mobilisation from adipose tissue or increased lipid synthesis by the liver itself. This may account for lipid accumulation in the hepatocytes.

MORPHOLOGIC FEATURES Three types of morphologic lesions are described in alcoholic liver disease—alcoholic steatosis (fatty liver), alcoholic hepatitis and alcoholic cirrhosis.

1. ALCOHOLIC STEATOSIS (FATTY LIVER) The morphologic changes in fatty change in liver have already been described on page 19 and are briefly considered here.

Grossly, the liver is enlarged, yellow, greasy and firm with a smooth and glistening capsule.

Microscopically, the features consist of initial *microvesicular* droplets of fat in the hepatocyte cytoplasm followed by more common and pronounced feature of *macrovesicular* large droplets of fat displacing the nucleus to the periphery (**Fig. 19.23**). *Fat cysts* may develop due to coalescence and rupture of fat-containing hepatocytes. Less often, *lipogranulomas* consisting of collection of lymphocytes, macrophages and some multinucleate giant cells may be found.

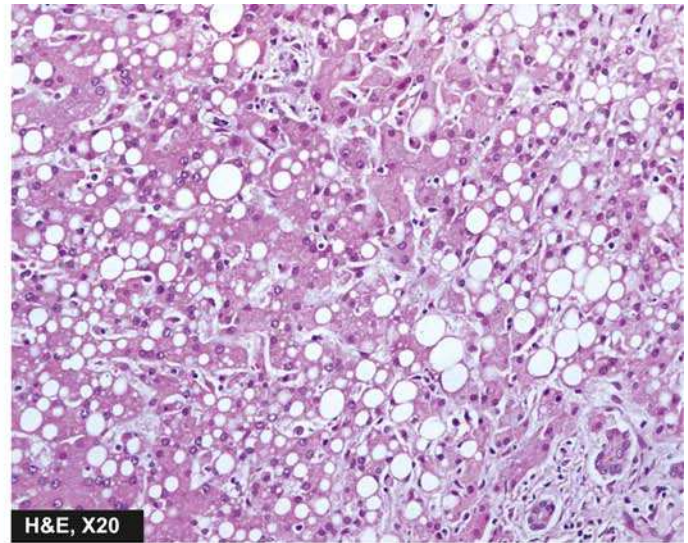

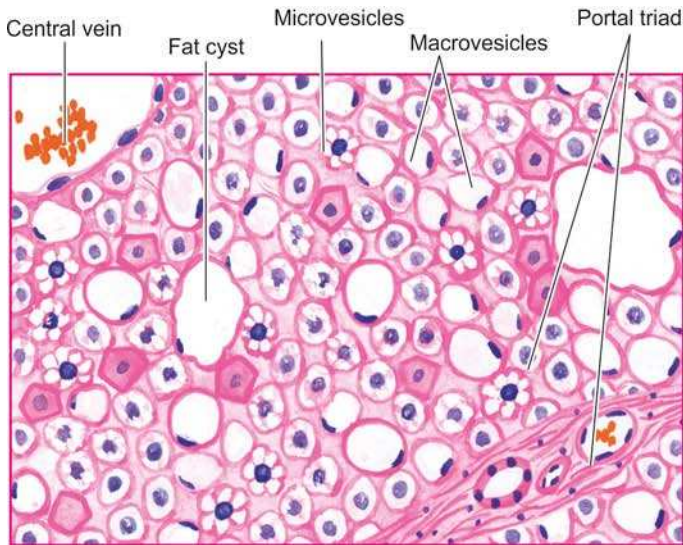

Figure 19.23 Fatty liver (alcoholic steatosis). Most of the hepatocytes are distended with large lipid vacuoles with peripherally displaced nuclei.

2. ALCOHOLIC HEPATITIS Alcoholic hepatitis develops acutely, usually following a bout of heavy drinking. Repeated episodes of alcoholic hepatitis superimposed on pre-existing fatty liver are almost certainly a forerunner of alcoholic cirrhosis.

Histologically, the features of alcoholic hepatitis are as follows (**Fig. 19.24**):

i) Hepatocellular necrosis: Single or small clusters of hepatocytes, especially in the centrilobular area (zone 3), undergo ballooning degeneration and necrosis.

ii) Mallory bodies or alcoholic hyalin: These are eosinophilic, intracytoplasmic inclusions seen in perinuclear location within swollen and ballooned hepatocytes. They represent aggregates of cytoskeletal intermediate filaments (prekeratin). They can be best visualised with connective tissue stains like Masson's trichrome and chromophobe aniline blue, or by the use of immunoperoxidase methods. Mallory bodies are highly suggestive of, but not specific for,

alcoholic hepatitis since Mallory bodies are also found in certain other conditions such as: primary biliary cirrhosis, Indian childhood cirrhosis, cholestatic syndromes, Wilson's disease, intestinal bypass surgery, focal nodular hyperplasia and hepatocellular carcinoma.

iii) Inflammatory response: The areas of hepatocellular necrosis and regions of Mallory bodies are associated with an inflammatory infiltrate, chiefly consisting of polymorphs and some scattered mononuclear cells. In more extensive necrosis, the inflammatory infiltrate is more widespread and may involve the entire lobule.

iv) Fibrosis: Most cases of alcoholic hepatitis are accompanied by pericellular and perivenular fibrosis, producing a web-like or chickenwire-like appearance. This is also termed as *creeping collagenosis*.

3. ALCOHOLIC CIRRHOSIS Alcoholic cirrhosis is the most common form of lesion, constituting 60-70% of all cases of cirrhosis. Several terms have been used for this

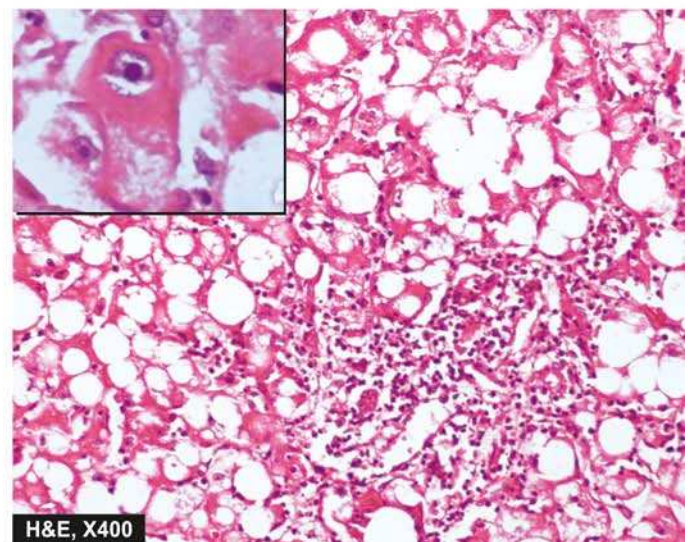

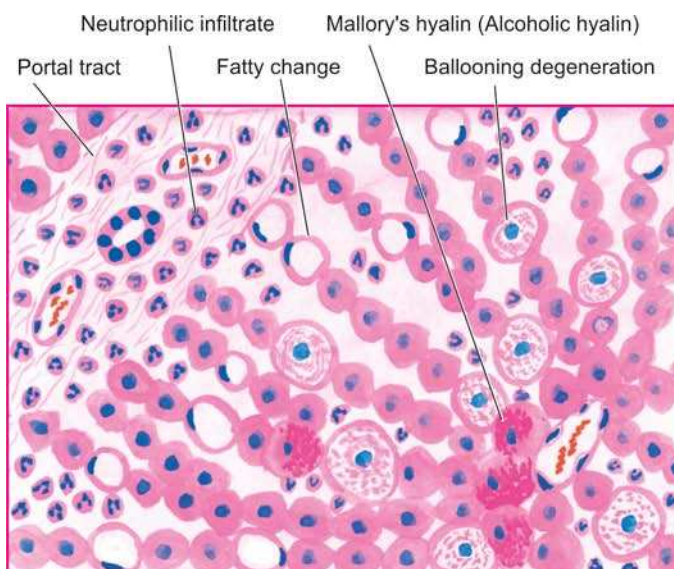

Figure 19.24 Alcoholic hepatitis. Liver cells show ballooning degeneration and necrosis with some containing Mallory's hyalin (Inbox). Fatty change and clusters of neutrophils are also present.

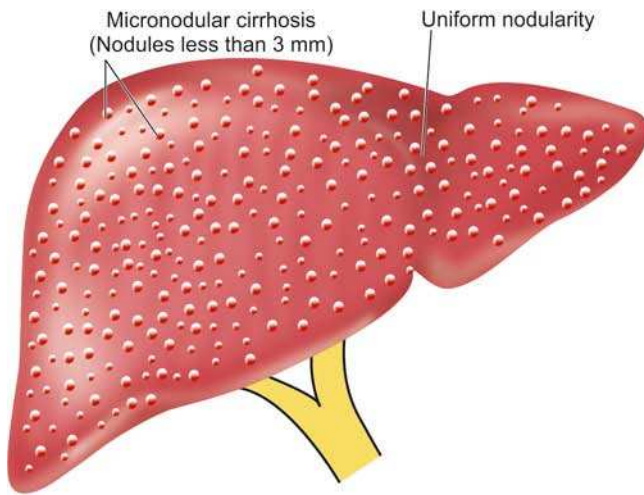

Figure 19.25 Alcoholic cirrhosis, showing the typical micronodular pattern in gross specimen. There is diffuse nodularity (nodules less than 3 mm diameter) on sectioned surface of the liver.

type of cirrhosis such as *Laennec's cirrhosis*, *portal cirrhosis*, *hobnail cirrhosis*, *nutritional cirrhosis*, *diffuse cirrhosis* and *micronodular cirrhosis*.

Grossly, alcoholic cirrhosis classically begins as micronodular cirrhosis (nodules less than 3 mm diameter), the liver being large, fatty and weighing usually above 2 kg (**Fig. 19.25**). Eventually over a span of years, the liver shrinks to less than 1 kg in weight, becomes non-fatty, having macronodular cirrhosis (nodules larger than 3 mm in diameter), resembling post-necrotic cirrhosis. The nodules of the liver due to their fat content are tawny-yellow, on the basis of which Laennec in 1818 introduced the term *cirrhosis* first of all (from Greek *kirrhos* = tawny). The surface of liver in alcoholic cirrhosis is studded with diffuse nodules which vary little in size, producing hobnail liver (because of the resemblance of the surface with the sole of an old-fashioned

shoe having short nails with heavy heads). On cut section, spheroidal or angular nodules of fibrous septa are seen.

Microscopically, alcoholic cirrhosis is a progressive alcoholic liver disease. Its features include the following (**Fig. 19.26**):

- i) Nodular pattern:** Normal lobular architecture is effaced in which central veins are hard to find and is replaced with nodule formation.
- ii) Fibrous septa:** The fibrous septa that divide the hepatic parenchyma into nodules are initially delicate and extend from central vein to portal regions, or portal tract to portal tract, or both. As the fibrous scarring increases with time, the fibrous septa become dense and more confluent.
- iii) Hepatic parenchyma:** The hepatocytes in the islands of surviving parenchyma undergo slow proliferation

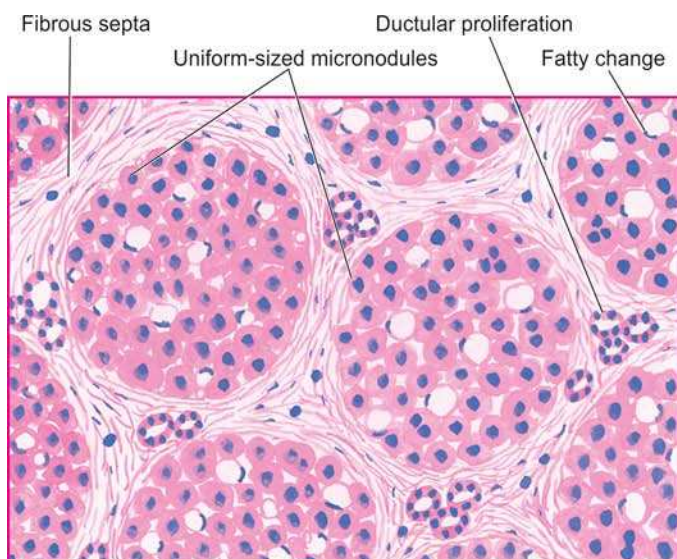

Figure 19.26 Alcoholic cirrhosis, microscopic appearance. It shows nearly uniform-sized micronodules, devoid of central veins and having thick fibrous septa dividing them. There is minimal inflammation and some reactive bile duct proliferation in the septa.

forming regenerative nodules having disorganised masses of hepatocytes. The hepatic parenchyma within the nodules shows extensive fatty change early in the disease. But as the fibrous septa become more thick, the amount of fat in hepatocytes is reduced. Thus, there is an inverse relationship between the amount of fat and the amount of fibrous scarring in the nodules.

iv) Necrosis, inflammation and bile duct proliferation: The etiologic clue to diagnosis in the form of Mallory bodies is hard to find in a fully-developed alcoholic cirrhosis. The fibrous septa usually contain sparse infiltrate of mononuclear cells with some bile duct proliferation. Bile stasis and increased cytoplasmic haemosiderin deposits due to enhanced iron absorption in alcoholic cirrhosis are some other noticeable findings.

LABORATORY DIAGNOSIS The clinical manifestations and complications of cirrhosis in general are described on page 614. The laboratory findings in the course of alcoholic liver disease may be quite variable and liver biopsy is necessary in doubtful cases. Progressive form of the disease, however, generally presents the following biochemical and haematological alterations:

1. Elevated transaminases; increase in SGOT (AST) is more than that of SGPT (ALT).
2. Rise in serum γ -glutamyl transpeptidase (γ -GT).
3. Elevation in serum alkaline phosphatase.
4. Hyperbilirubinaemia.
5. Hypoproteinaemia with reversal of albumin-globulin ratio.
6. Prolonged prothrombin time and partial thromboplastin time.
7. Anaemia.
8. Neutrophilic leucocytosis in alcoholic hepatitis and in secondary infections.

Post-necrotic Cirrhosis

Post-necrotic cirrhosis, also termed *post-hepatitic cirrhosis*, *macronodular cirrhosis* and *coarsely nodular cirrhosis*, is characterised by large and irregular nodules with broad bands of connective tissue and occurring most commonly after previous viral hepatitis.

ETIOLOGY Based on epidemiologic and serologic studies, the following factors have been implicated in the etiology of post-necrotic cirrhosis.

1. **Viral hepatitis** About 25% of patients give history of recent or remote attacks of acute viral hepatitis followed by chronic viral hepatitis. Most common association is with hepatitis B and C; hepatitis A is not known to evolve into cirrhosis. It is estimated that about 20% cases of HBV chronic hepatitis and about 20-30% cases of HCV chronic hepatitis progress to cirrhosis over 20-30 years.
2. **Drugs and chemical hepatotoxins** A small percentage of cases may have origin from toxicity due to chemicals and drugs such as phosphorus, carbon tetrachloride, mushroom poisoning, acetaminophen and α -methyl dopa.
3. **Others** Certain infections (e.g. brucellosis), parasitic infestations (e.g. clonorchiasis), metabolic diseases (e.g. Wilson's disease or hepatolenticular degeneration) and

advanced alcoholic liver disease may produce a picture of post-necrotic cirrhosis.

4. Idiopathic After all these causes have been excluded, a group of cases remain in which the etiology is unknown.

MORPHOLOGIC FEATURES Typically, post-necrotic cirrhosis is macronodular type.

Grossly, the liver is usually small, weighing less than 1 kg, having distorted shape with irregular and coarse scars and nodules of varying size (Fig. 19.27). Sectioned surface shows scars and nodules varying in diameter from 3 mm to a few centimeters.

Microscopically, the features are as follows (Fig. 19.28):

1. **Nodular pattern:** The normal lobular architecture of hepatic parenchyma is mostly lost and is replaced by nodules larger than those in alcoholic cirrhosis. However, uninvolved portal tracts and central veins in the hepatic lobules can still be seen in some parts of surviving parenchyma.
2. **Fibrous septa:** The fibrous septa dividing the variable-sized nodules are generally thick.
3. **Necrosis, inflammation and bile duct proliferation:** Active liver cell necrosis is usually inconspicuous. Fibrous septa contain prominent mononuclear inflammatory cell infiltrate which may even form follicles, especially in cases following HCV chronic hepatitis. Often there is extensive proliferation of bile ductules derived from collapsed liver lobules.
4. **Hepatic parenchyma:** Liver cells vary considerably in size and multiple large nuclei are common in regenerative nodules. Fatty change may or may not be present in the hepatocytes.

CLINICAL FEATURES Besides the general clinical features described on page 614, post-necrotic cirrhosis is seen as frequent in women as in men, especially in the younger age group. Like in alcoholic cirrhosis, the patients may remain asymptomatic or may present with prominent signs and symptoms of chronic hepatitis (page 596). Splenomegaly and hypersplenism are other prominent features. The results of haematologic and liver function test are similar to those of alcoholic cirrhosis. Out of the various types of cirrhosis, post-necrotic cirrhosis, especially when related to hepatitis B and C virus infection in early life, is more frequently associated with development of hepatocellular carcinoma later.

Biliary Cirrhosis

Biliary cirrhosis is defined as a chronic disorder characterised by clinical, biochemical and morphological features of long-continued cholestasis of intrahepatic or extrahepatic origin. Biliary cirrhosis is of following types:

- A. **Primary biliary cirrhosis** in which the destructive process of unknown etiology affects intrahepatic bile ducts.
- B. **Secondary biliary cirrhosis** resulting from prolonged mechanical obstruction of the extrahepatic biliary passages.
- C. **Primary sclerosing cholangitis and autoimmune cholangiopathy** causing biliary cirrhosis.

ETIOLOGY The etiology of these forms of biliary cirrhosis is distinctive:

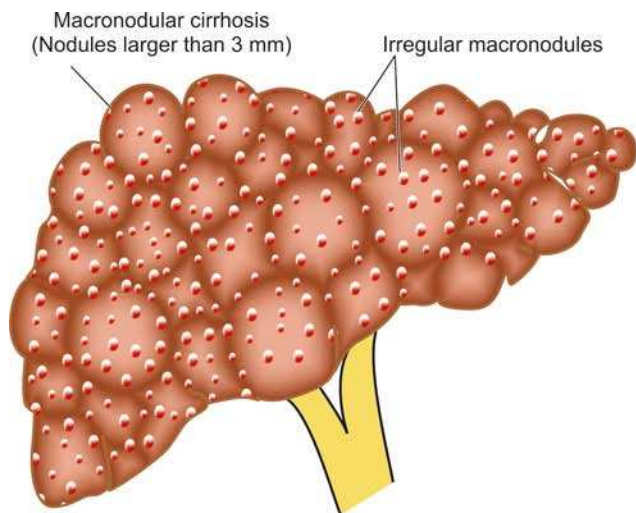

Figure 19.27 Post-necrotic cirrhosis, showing the typical irregular macronodular pattern (nodules larger than 3 mm diameter). Externally the liver is small, distorted and irregularly scarred.

A. Primary biliary cirrhosis The etiology of this type remains unknown. However, a few factors have been implicated:

1. The condition is predominant in middle-aged women (male: female ratio = 1:9) and has led to the suggestion of a possible *endocrine origin*.

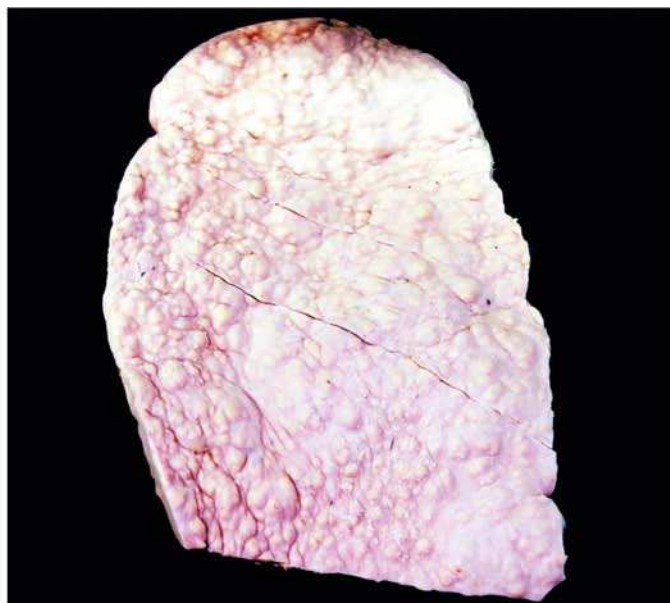

2. *Familial incidence* has been observed suggesting the role of some genetic influence and certain HLA types.

3. There is *elevated cholesterol* level with appearance of xanthoma and xanthelasma. Hepatomegaly and chronic liver disease are late features of the disease.

4. However, presently the most widely accepted hypothesis is *autoimmune origin* of the disease. In support are the following observations:

i) increased incidence of associated autoimmune diseases (e.g. scleroderma, Sjögren's syndrome, CREST syndrome, and autoimmune thyroiditis),

ii) circulating anti-mitochondrial antibody of IgG class detected in more than 90% cases;

iii) elevated levels of immunoglobulins, particularly of IgM;
iv) increased levels of circulating immune complexes;
v) decreased number of circulating T-cells; and
vi) accumulation of T cells around bile ducts.

B. Secondary biliary cirrhosis Most cases of secondary biliary cirrhosis result from prolonged obstruction of extra-hepatic biliary passages (page 584). These causes include the following:

1. Extrahepatic gallstone formation, most common
2. Biliary atresia
3. Cancer of biliary tree and of head of pancreas
4. Postoperative strictures with superimposed ascending cholangitis.

C. Cirrhosis due to primary sclerosing cholangitis Primary or idiopathic sclerosing cholangitis is a chronic cholestatic syndrome of unknown etiology. It is characterised by progressive, inflammatory, sclerosing and obliterative process

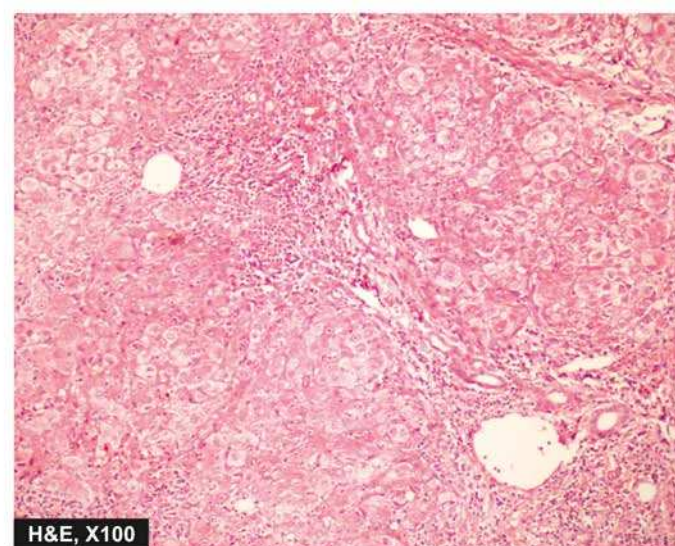

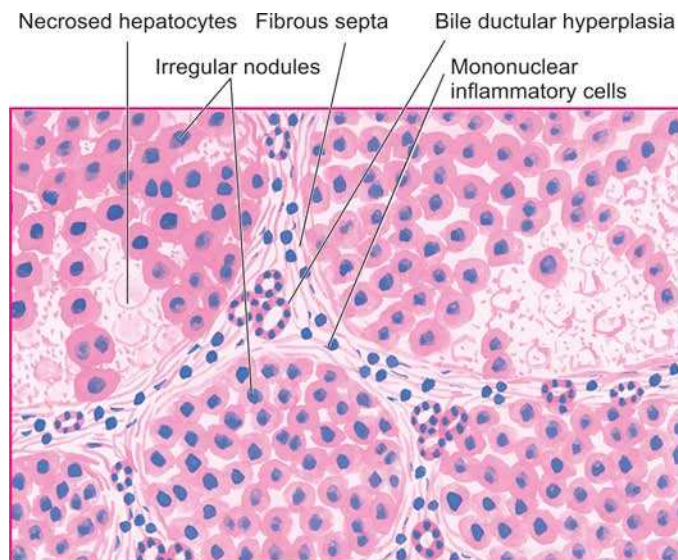

Figure 19.28 Post-necrotic cirrhosis. Fibrous septa dividing the hepatic parenchyma into nodules are thick and contain prominent mononuclear inflammatory cell infiltrate and bile ductular hyperplasia. A few intact hepatic lobules remain.

affecting the entire biliary passages, both extra-hepatic and intrahepatic ducts. Although etiology remains unknown, various mechanisms have been postulated which include viral and bacterial infections, immunologic injury, toxins, and genetic predisposition.

MORPHOLOGIC FEATURES *Grossly*, in biliary cirrhosis of all types, the liver is initially enlarged and characteristically *greenish* in appearance, but later becomes smaller, firmer and coarsely micronodular. In cirrhosis due to primary sclerosing cholangitis, there is characteristic beading of intra- and extrahepatic bile ducts due to irregular strictures and dilatation.

Microscopically, the features of intra- and extrahepatic cholestasis correspond to primary and secondary biliary cirrhosis respectively discussed on page 584. The salient features of various forms of biliary cirrhosis are as under:

A. Primary biliary cirrhosis: The diagnostic histologic feature is a chronic, non-suppurative, destructive cholangitis involving intrahepatic bile ducts. The disease evolves through the following 4 histologic states:

Stage I: There are *florid bile duct lesions* confined to portal tracts. The changes in the affected area consist of destruction of bile ducts, presence of bile plugs, infiltration with acute and chronic inflammatory cells and sometimes formation of granulomas and lymphoid follicles.

Stage II: There is *ductular proliferation*. The ductal involvement is quite widespread with very few normal bile ducts. The inflammatory infiltrate too extends beyond the portal tracts into surrounding hepatic parenchyma. Periportal Mallory bodies may be present.

Stage III: This stage is characterised by *fibrous scarring* interconnecting the portal areas. There is diminished inflammatory infiltrate and reduced number of bile ducts.

Stage IV: Well-formed *micronodular pattern* of cirrhosis develops in a period of a few years (**Fig. 19.29**).

B. Secondary biliary cirrhosis: Prolonged obstruction of extrahepatic bile ducts may produce the following histologic changes:

1. *Bile stasis*, degeneration and focal areas of centrilobular necrosis of hepatocytes.
2. Proliferation, dilatation and rupture of bile ductules in the portal area with formation of *bile lakes*.
3. *Cholangitis*, sterile or pyogenic, with accumulation of polymorphs around the bile ducts.
4. *Progressive expansion* of the portal tract by fibrosis and evolution into micronodular cirrhosis.

C. Cirrhosis due to primary sclerosing cholangitis: Following changes are seen:

1. *Fibrosing cholangitis* with lymphocytic infiltrate around bile ducts with segmental involvement.
2. *Periductal fibrosis* with eventual obliteration of lumen of affected bile ducts.
3. *Intervening bile ducts* are dilated, tortuous and inflamed.
4. Late cases show *cholestasis* and full-blown picture of biliary cirrhosis.

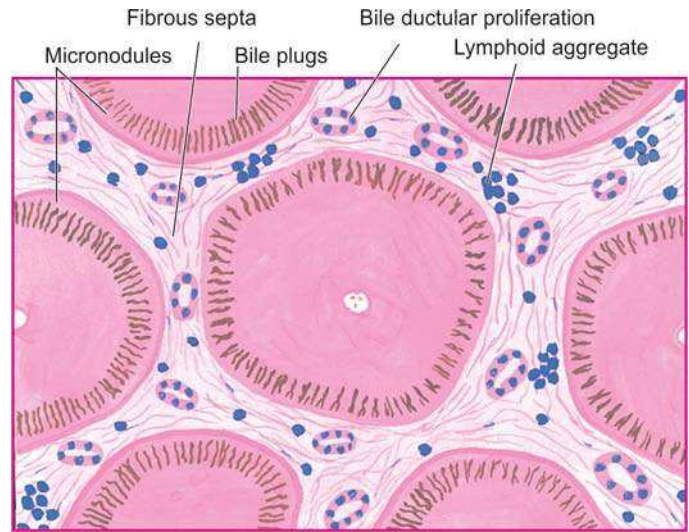

Figure 19.29 Primary biliary cirrhosis, diagrammatic representation. There are fibrous scars dividing the hepatic parenchyma into the micronodules. The fibrous septa contain prominent lymphoid infiltrate and proliferated bile ducts. Many of the hepatocytes contain elongated bile plugs.

CLINICAL FEATURES Clinical features of the three types of biliary cirrhosis are variable:

◆ **Primary biliary cirrhosis** may remain asymptomatic for months to years. Symptoms develop insidiously. Basically, it is a cholestatic disorder. The patients present with persistent pruritus, dark urine, pale stools, steatorrhoea, jaundice and skin pigmentation. The earliest laboratory finding is a markedly elevated serum alkaline phosphatase level. Elevation of serum lipids is accompanied by appearance of periorbital xanthelasma and xanthomas over joints. Death usually results from hepatic failure, variceal bleeding, intercurrent infections and concomitant development of cancers of liver and breast.

◆ The diagnosis of **secondary biliary cirrhosis** is considered in patients with previous history of gallstones, biliary tract surgery or clinical features of ascending cholangitis.

◆ The patients of **primary sclerosing cholangitis** may remain asymptomatic or may show features of cholestatic jaundice (raised alkaline phosphatase, pruritus, fatigue). Late cases show manifestations of chronic liver disease. The disease occurs in 3rd to 5th decade of life with two fold preponderance in males.

The contrasting features of three main types of intrahepatic disorders leading to biliary cirrhosis are summarised in **Table 19.10**.

Pigment Cirrhosis in Haemochromatosis

Haemochromatosis is an iron-storage disorder in which there is excessive accumulation of iron in parenchymal cells with eventual tissue damage and functional insufficiency of organs such as the liver, pancreas, heart and pituitary gland. The condition is characterised by a triad of features—*micronodular pigment cirrhosis*, *diabetes mellitus* and *skin pigmentation*. On the basis of the last two features, the disease has also come to be termed as '*bronze diabetes*.' Males predominate and manifest earlier since women have physiologic iron loss delaying the

Table 19.10 Contrasting features of major forms of biliary cirrhosis.

| FEATURE | PRIMARY BILIARY CIRRHOSIS | SECONDARY BILIARY CIRRHOSIS | PRIMARY SCLEROSING CHOLANGITIS |
|------------------------------|--|--|---|
| 1. <i>Etiology</i> | Possibly autoimmune; association with other autoimmune diseases | Extrahepatic biliary obstruction; biliary atresia | Possibly autoimmune; association with inflammatory bowel disease |
| 2. <i>Age and sex</i> | Middle-aged women Male: Female = 1:9 | Any age and either sex | Middle age Male: Female = 2:1 |
| 3. <i>Laboratory tests</i> | ↑ Alkaline phosphatase ↑ Conjugated bilirubin Autoantibodies present | ↑ Alkaline phosphatase ↑ Conjugated bilirubin | ↑ Alkaline phosphatase ↑ Conjugated bilirubin Hypergammaglobulinaemia |
| 4. <i>Pathologic changes</i> | Chronic destructive; cholangitis of intrahepatic bile ducts | Bile stasis in bile ducts, and sterile or pyogenic cholangitis | Fibrosing cholangitis with periductal fibrosis |

effects of excessive accumulation of iron. Haemochromatosis exists in 2 main forms:

1. *Idiopathic (primary, genetic) haemochromatosis* is an autosomal recessive disorder of excessive accumulation of iron. It is associated with overexpression of HFE gene located on chromosome 6 close to the HLA gene locus, and normally regulates intestinal absorption of iron. Mutated (overexpressed) HFE gene complexes with transferrin receptor on intestinal crypt epithelial cells and results in excessive absorption of dietary iron throughout life.

2. *Secondary (acquired) haemochromatosis* is gross iron overload with tissue injury arising secondary to other diseases such as thalassaemia, sideroblastic anaemias, alcoholic cirrhosis or multiple transfusions.

ETIOPATHOGENESIS A general discussion of iron metabolism and iron excess states is given on page 23.

Normally, the body iron content is 3-4 gm which is maintained in such a way that intestinal mucosal absorption of iron is equal to its loss. This amount is approximately 1 mg/day in men and 1.5 mg/day in menstruating women. In haemochromatosis, however, this amount goes up to 4 mg/day or more, as evidenced by elevated serum iron (normal about 125 mg/dl) and increased serum transferrin saturation (normal 30%).

◆ In **idiopathic or hereditary haemochromatosis**, the primary mechanism of disease appears to be the genetic basis in which the defect may either lie at the intestinal mucosal level causing excessive iron absorption, or at the post-absorption excretion level leading to excessive accumulation of iron. The excess iron in primary haemochromatosis is deposited mainly in the cytoplasm of parenchymal cells of organs such as the liver, pancreas, spleen, heart and endocrine glands. Tissue injury results from iron-laden lysosomes of parenchymal cells and lipid peroxidation of cell organelles by excess iron.

◆ In **secondary or acquired haemochromatosis**, there is excessive accumulation of iron due to acquired causes like ineffective erythropoiesis, defective haemoglobin synthesis, multiple blood transfusions and enhanced absorption of iron due to alcohol consumption. The last-named phenomenon is observed in *African or Bantu siderosis* affecting South African Bantu tribals who consume large quantities of home-brew prepared in iron vessels. Cases of secondary haemochromatosis have increased iron storage within the reticuloendothelial system and liver. However, the magnitude of the iron excess in

secondary haemochromatosis is generally insufficient to cause tissue damage.

MORPHOLOGIC FEATURES Excessive deposition of iron in organs and tissues is ferritin and haemosiderin, both of which appear as golden-yellow pigment granules in the cytoplasm of affected parenchymal cells and haemosiderin stains positively with Prussian blue reaction. The organs most frequently affected are the liver and pancreas, and to a lesser extent, the heart, endocrine glands, skin, synovium and testis.

◆ In the **liver**, excess of pigment accumulates in the hepatocytes, and less often Kupffer cells and in bile duct epithelium. The deposits in the initial stage may be prominent in the periportal liver cells along with increased fibrosis in the portal zone. Eventually, micronodular cirrhosis develops. The deposits may produce grossly chocolate-brown colour of the liver and nodular surface.

◆ In the **pancreas**, pigmentation is less intense and is found in the acinar and islet cells. The deposits in pancreas produce diffuse interstitial fibrosis and atrophy of parenchymal cells leading to occurrence of diabetes mellitus.

CLINICAL FEATURES The major clinical manifestations of haemochromatosis include skin pigmentation, diabetes mellitus, hepatic and cardiac dysfunction, arthropathy and hypogonadism. Characteristic bronze pigmentation is the presenting feature in about 90% of cases. Demonstration of excessive parenchymal iron stores is possible by measurement of serum iron, determination of percent saturation of transferrin, measurement of serum ferritin concentration, estimation of chelatable iron stores using chelating agent (e.g. desferrioxamine), and finally, by liver biopsy. Occurrence of hepatocellular carcinoma is a late complication of haemochromatosis-induced cirrhosis.

Cirrhosis in Wilson's Disease

Wilson's disease, also termed by a more descriptive designation of *hepatolenticular degeneration*, is an autosomal recessive inherited disease of copper metabolism, characterised by toxic accumulation of copper in many tissues, chiefly the liver, brain and eye. These accumulations lead to the *triad* of features:

1. Cirrhosis of the liver.
2. Bilateral degeneration of the basal ganglia of the brain.

3. Greenish-brown pigmented rings in the periphery of the cornea (Kayser-Fleischer rings).

The disease manifests predominantly in children and young adults (5-30 years). Initially, the clinical manifestations are referable to liver involvement such as jaundice and hepatomegaly (*hepatic form*) but later progressive *neuropsychiatric changes* and *Kayser-Fleischer rings* in the cornea appear.

PATHOGENESIS The pathogenesis of Wilson's disease is best understood when compared with normal copper metabolism.

◆ **Normally**, dietary copper is more than body's requirement. Excess copper so absorbed through the stomach and duodenum is transported to the liver where it is incorporated into α_2 -globulin to form ceruloplasmin, which is excreted by the liver via bile normally. Most of the plasma copper circulates as ceruloplasmin. Only minute amount of copper is excreted in the urine normally.

◆ **In Wilson's disease**, the initial steps of dietary absorption and transport of copper to the liver are normal but copper accumulates in the liver rather than being excreted by the liver. The underlying defect in chromosome 13 is a mutation in ATP7B gene, the normal hepatic copper-excreting gene. Eventually, capacity of hepatocytes to store copper is exceeded and copper is released into circulation which then gets deposited in extrahepatic tissues such as the brain, eyes and others. However, increased copper in the kidney does not produce any serious renal dysfunction.

Biochemical abnormalities in Wilson's disease include the following:

1. *Decreased serum ceruloplasmin* (due to impaired synthesis of apoceruloplasmin in damaged liver and defective mobilisation of copper from hepatocellular lysosomes).
2. *Increased hepatic copper* in liver biopsy (due to excessive accumulation of copper in the liver).
3. *Increased urinary excretion* of copper.
4. However, *serum copper level* estimation is of no diagnostic help and may vary from low-to-normal-to-high depending upon the stage of disease.

MORPHOLOGIC FEATURES The **liver** shows varying grades of changes that include fatty change, acute and chronic active hepatitis, submassive liver necrosis and macronodular cirrhosis. Mallory bodies are present in some cases. Copper is usually deposited in the periportal hepatocytes in the form of reddish granules in the cytoplasm or as reddish cytoplasmic coloration, stainable by rubanic acid or rhodamine stains for copper.

Involvement of basal ganglia in the **brain** is seen in the form of toxic injury to neurons, in the **cornea** as greenish-brown deposits of copper in Descemet's membrane, and in the **kidney** as fatty and hydropic change.

Cirrhosis in α -1-Antitrypsin Deficiency

Alpha-1-antitrypsin deficiency is an autosomal codominant condition in which the homozygous state produces liver disease (cirrhosis), pulmonary disease (emphysema), or both (page 460). α -1-antitrypsin is a glycoprotein normally synthesised in the rough endoplasmic reticulum of the hepatocytes and is the most potent protease inhibitor (Pi). A single autosomal dominant gene coding for α -1-antitrypsin is located on long

arm of chromosome 14 that codes for immunoglobulin light chains too. Out of 24 different alleles labelled alphabetically, PiMM is the most common normal phenotype, while the most frequent abnormal phenotype in α -1-antitrypsin deficiency leading to liver and/or lung disease is PiZZ in homozygote form. Other phenotypes in which liver disease occurs are PiSS and Pi-null in which serum α -1-antitrypsin value is nearly totally deficient. Intermediate phenotypes, PiMZ and PiSZ persons are predisposed to develop hepatocellular carcinoma.

The patients may present with respiratory disease due to the development of emphysema, or may develop liver dysfunction, or both. At birth or in neonates, the features of cholestatic jaundice of varying severity may appear. In adolescence, the condition may evolve into hepatitis or cirrhosis which is usually well compensated.

MORPHOLOGIC FEATURES Pulmonary changes in α -1-antitrypsin deficiency in the form of emphysema are described in page 460. The hepatic changes vary according to the age at which the deficiency becomes apparent. At birth or in neonates, the histologic features consist of neonatal hepatitis that may be acute or 'pure' cholestasis. Micronodular or macronodular cirrhosis may appear in childhood or in adolescence in which the diagnostic feature is the presence of intracellular, acidophilic, PAS-positive globules in the periportal hepatocytes. Ultrastructurally, these globules consist of dilated rough endoplasmic reticulum.

Cardiac Cirrhosis

Cardiac cirrhosis is an uncommon complication of severe right-sided congestive heart failure of long-standing duration (page 399). The common causes culminating in cardiac cirrhosis are cor pulmonale, tricuspid insufficiency or constrictive pericarditis. The pressure in the right ventricle is elevated which is transmitted to the liver via the inferior vena cava and hepatic veins. The patients generally have enlarged and tender liver with mild liver dysfunction. Splenomegaly occurs due to simple passive congestion.

MORPHOLOGIC FEATURES *Grossly*, the liver is enlarged and firm with stretched Glisson's capsule.

Histologically, in acute stage, the hepatic sinusoids are dilated and congested with haemorrhagic necrosis of centrilobular hepatocytes (*central haemorrhagic necrosis*). Severe and more prolonged heart failure results in delicate fibrous strands radiating from the central veins. These fibrous strands may form interconnections leading to cardiac cirrhosis and regenerative nodules.

Indian Childhood Cirrhosis

Indian childhood cirrhosis (ICC) is an unusual form of cirrhosis seen in children between the age of 6 months and 3 years in rural, middle class, Hindus in India and in parts of South-East Asia and in the Middle-East. There is no role of viral infection in its etiology. Instead, a combination of some common toxic effects and inherited abnormality of copper metabolism has been suggested. Death occurs due to hepatic failure within a year of diagnosis.

MORPHOLOGIC FEATURES Five histologic types of ICC have been distinguished of which type II is the most common. This form is characterised by the following features:

- i) Liver cell injury ranging from ballooning degeneration to significant damage to hepatocytes.
- ii) Prominent Mallory bodies in some hepatocytes without fatty change.
- iii) Neutrophilic and sometimes along with lymphocytic infiltrate.
- iv) Creeping pericellular fibrosis which may eventually lead to fine micro-macro-nodular cirrhosis.
- v) There is significant deposition of copper and copper-associated proteins in hepatocytes, often more than what is seen in Wilson's disease.

Thus, the picture resembles acute alcoholic hepatitis but without the fatty change and with greatly impaired regeneration. There is marked increase in hepatic copper since the milk consumed by such infants is often boiled and stored in copper vessels in India. The condition has to be distinguished from Wilson's disease.

Cirrhosis in Autoimmune Hepatitis

Autoimmune hepatitis (also called lupoid hepatitis) is a form of chronic hepatitis characterised by continued hepatocellular injury, inflammation and fibrosis which may progress to cirrhosis. The condition may run a variable natural history ranging from indolent to severe rapid course. This form of hepatitis has prominent autoimmune etiology is supported by immunologic abnormalities and a few other characteristic diagnostic criteria as under:

1. Female gender predisposition.
2. Predominant elevation of aminotransferases (AST and ALT).
3. Hyperglobulinaemia (elevated IgG and γ -globulin).
4. High serum titres of nuclear (ANA), smooth muscle (SMA), and liver-kidney microsomal (LKM1) autoantibodies, and absence of antimitochondrial antibodies.
5. Concurrent presence of other autoimmune diseases.
6. Presence of HLA DR3 or HLA DR4 markers.
7. Lack of prominent elevation of alkaline phosphatase.
8. Exclusion of chronic hepatitis of other known etiologies (viral, toxic, genetic etc).

MORPHOLOGIC FEATURES Autoimmune hepatitis is morphologically indistinguishable from chronic hepatitis of viral etiology. Patients who survive active disease develop cirrhosis. There are features of burnt out chronic autoimmune hepatitis accompanied with cirrhosis.

Cirrhosis in Non-alcoholic Steatohepatitis

Non-alcoholic steatohepatitis (NASH) or non-alcoholic fatty liver disease (NAFLD) is a form of hepatitis resembling alcoholic liver disease but seen in nondrinkers of alcohol. The condition is seen more commonly in affluent western societies, has a strong association with obesity, dyslipidaemia and type 2 diabetes mellitus. It is seen in younger patients with equal gender prevalence. Patients are generally asymptomatic and are diagnosed by routine biochemical tests.

MORPHOLOGIC FEATURES The condition is a form of chronic hepatitis after known causes have been excluded. About 10-30% cases of NASH progress to increased fibrosis and develop cirrhosis.

Miscellaneous Forms of Cirrhosis

In addition to the various types of cirrhosis just described, a few other uncommon types associated with different diseases are sometimes distinguished. These include the following:

1. **Metabolic disorders** e.g. in galactosaemia, hereditary fructose intolerance, glycogen storage diseases.
2. **Infectious diseases** e.g. in brucellosis, schistosomiasis, syphilis (hepar lobatum) and toxoplasma infection.
3. **Gastrointestinal disorders** e.g. in inflammatory bowel disease, cystic fibrosis of the pancreas and intestinal bypass surgery for obesity.
4. **Infiltrative diseases** e.g. in sarcoidosis.

Cryptogenic Cirrhosis

Finally, when all the known etiologic types of cirrhosis have been excluded, there remain patients with cirrhosis in whom the cause is unknown. These cases are grouped under a waste-basket diagnosis of cryptogenic cirrhosis (*crypto* = concealed).

NON-CIRRHOTIC PORTAL FIBROSIS

Non-cirrhotic portal fibrosis (NCPF) is a group of congenital and acquired diseases in which there is localised or generalised hepatic fibrosis without nodular regenerative activity and there is absence of clinical and functional evidence of cirrhosis. Besides, the patients of NCPF are relatively young as compared to those of cirrhosis and develop repeated bouts of haematemesis in the course of disease. Similar condition described from Japan has been named as *idiopathic (primary) portal hypertension with splenomegaly*.

The type common in India, particularly in young males, is related to following etiologic factors:

1. Exposure to trace elements, particularly chronic arsenic ingestion in drinking water.
2. Intake of orthodox medicines.
3. Infections, particularly of umbilical cord, infective diarrhoea and sepsis, causing infection in portal circulation and leading to thrombophlebitis.
4. Familial aggregation of disease and its relationship to HLA-DR3.

MORPHOLOGIC FEATURES *Grossly*, the liver is small, fibrous and shows prominent fibrous septa on both external as well as on cut surface forming irregular islands in the liver.

Histologically, the salient features are as under:

- i) Standing out of portal tracts due to their increased amount of fibrous tissue in triad without significant inflammation.
- ii) Obliterative sclerosis of portal vein branches in the portal tracts (obliterative portovenopathy).

CLINICAL MANIFESTATIONS AND COMPLICATIONS OF CIRRHOSIS

The range of clinical features in cirrhosis varies widely, from an asymptomatic state to progressive liver failure and death. The

onset of disease is insidious. In general, the features of cirrhosis are more marked in the alcoholic form than in other varieties. These include weakness, fatigability, weight loss, anorexia, muscle wasting, and low-grade fever due to hepatocellular necrosis or some latent infection. Advanced cases develop a number of complications which are as follows:

1. *Portal hypertension* and its major effects such as ascites, splenomegaly and development of collaterals (e.g. oesophageal varices, spider naevi etc) as discussed below.
2. *Progressive hepatic failure* and its manifestations as described already (page 587).
3. Development of *hepatocellular carcinoma*, more often in post-necrotic cirrhosis (HBV and HCV more often) than following alcoholic cirrhosis (page 618).
4. *Chronic relapsing pancreatitis*, especially in alcoholic liver disease (page 632).
5. *Steatorrhea* due to reduced hepatic bile secretion.
6. *Gallstones* usually of pigment type, are seen twice more frequently in patients with cirrhosis than in general population.
7. *Infections* are more frequent in patients with cirrhosis due to impaired phagocytic activity of reticuloendothelial system.
8. *Haematologic derangements* such as bleeding disorders and anaemia due to impaired hepatic synthesis of coagulation factors and hypoalbuminaemia are present.
9. *Cardiovascular complications* such as atherosclerosis of coronaries and aorta and myocardial infarction are more frequent in cirrhotic patients.
10. *Musculoskeletal abnormalities* like digital clubbing, hypertrophic osteoarthropathy and Dupuytren's contracture are more common in cirrhotic patients.
11. *Endocrine disorders* In males these consist of feminisation such as gynaecomastia, changes in pubic hair pattern, testicular atrophy and impotence, whereas in cirrhotic women amenorrhoea is a frequent abnormality.
12. *Hepatorenal syndrome* leading to renal failure may occur in late stages of cirrhosis.

The ultimate *causes of death* are hepatic coma, massive gastrointestinal haemorrhage from oesophageal varices (complication of portal hypertension), intercurrent infections, hepatorenal syndrome and development of hepatocellular carcinoma.

GIST BOX 19.9 Cirrhosis

- ▣ Cirrhosis is a diffuse liver disease characterised by effacement of normal lobular architecture, formation of nodules separated by fibrous septa and alternate areas of hepatocellular necrosis and regenerative nodules.
- ▣ There are 3 morphologic types of cirrhosis—micronodular, macronodular and mixed.
- ▣ Based on etiology, major forms are alcoholic, postnecrotic, biliary, and in haemochromatosis.
- ▣ Alcoholic cirrhosis evolves through preceding sequential stages of steatosis and alcoholic hepatitis.
- ▣ Most common etiologic factor for postnecrotic cirrhosis is preceding viral hepatitis with hepatitis B or C.
- ▣ A few variant forms are non-alcoholic fatty liver disease, cirrhosis in autoimmune hepatitis, non-cirrhotic portal fibrosis etc.
- ▣ Advanced cases of cirrhosis develop portal hypertension and its sequelae.

PORTAL HYPERTENSION

Increase in pressure in the portal system usually follows obstruction to the portal blood flow anywhere along its course. Portal veins have no valves and thus obstruction anywhere in the portal system raises pressure in all the veins proximal to the obstruction. However, unless proved otherwise, portal hypertension means obstruction to the portal blood flow by cirrhosis of the liver. The normal portal venous pressure is quite low (10–15 mm saline). Portal hypertension occurs when the portal pressure is above 30 mm saline. Measurement of *intrasplenic pressure* reflects pressure in the splenic vein; the *percutaneous transhepatic pressure* provides a measure of pressure in the main portal vein; and wedged hepatic *venous pressure* represents sinusoidal pressure. Measurement of these pressures helps in localising the site of obstruction and classifying the portal hypertension.

CLASSIFICATION Based on the site of obstruction to portal venous blood flow, portal hypertension is categorised into 3 main types—*intrahepatic*, *posthepatic* and *prehepatic* (Table 19.11). Rare cases of idiopathic portal hypertension showing non-cirrhotic portal fibrosis are encountered as discussed above.

1. Intrahepatic portal hypertension Cirrhosis is by far the commonest cause of portal hypertension. Other less frequent intrahepatic causes are metastatic tumours, non-cirrhotic nodular regenerative conditions, hepatic venous obstruction (Budd-Chiari syndrome), veno-occlusive disease, schistosomiasis, diffuse granulomatous diseases and extensive fatty change. In cirrhosis and other conditions, there is obstruction to the portal venous flow by fibrosis, thrombosis and pressure by regenerative nodules. About 30–60% patients of cirrhosis develop significant portal hypertension.

2. Posthepatic portal hypertension This is uncommon and results from obstruction to the blood flow through hepatic vein into inferior vena cava. The causes are neoplastic occlusion and thrombosis of the hepatic vein or of the inferior vena cava (including Budd-Chiari syndrome). Prolonged congestive heart failure and constrictive pericarditis may also cause portal hypertension by transmitting the elevated pressure through the hepatic vessels into the portal vein.

3. Prehepatic portal hypertension Blockage of portal flow before portal blood reaches the hepatic sinusoids results in prehepatic portal hypertension. Such conditions are thrombosis and neoplastic obstruction of the portal vein before it ramifies in the liver, myelofibrosis, and congenital absence of portal vein.

MAJOR SEQUELAE OF PORTAL HYPERTENSION Irrespective of the mechanisms involved in the pathogenesis of portal hypertension, there are 4 major clinical consequences—*ascites*, *varices* (collateral channels or portosystemic shunts), *splenomegaly* and *hepatic encephalopathy* (Fig. 19.30).

1. Ascites Ascites is the accumulation of excessive volume of fluid within the peritoneal cavity. It frequently accompanies cirrhosis and other diffuse liver diseases. The development of ascites is associated with haemodilution, oedema and decreased urinary output. Ascitic fluid is generally transudate with specific gravity of 1.010, protein content below 3 gm/dl and electrolyte concentrations like those of other extracellular fluids. It may contain a few mesothelial cells and

 2. Constrictive pericarditis
 3. Hepatic veno-occlusive disease
 4. Budd-Chiari syndrome
- C. PREHEPATIC
1. Portal vein thrombosis
 2. Neoplastic obstruction of portal vein
 3. Myelofibrosis
 4. Congenital absence of portal vein

mononuclear cells. Presence of neutrophils is suggestive of secondary infection and red blood cells in ascitic fluid points to disseminated intra-abdominal cancer. However, some cases of ascites may develop serious complication of *spontaneous bacterial peritonitis* characterised by spontaneous infection of the ascitic fluid without any intra-abdominal infection.

Pathogenesis The ascites becomes clinically detectable when more than 500 ml of fluid has accumulated in the peritoneal cavity. The mechanisms involved in its formation were discussed on page 87. Briefly, the systemic and local factors favouring ascites formation are as under (Fig. 19.31):

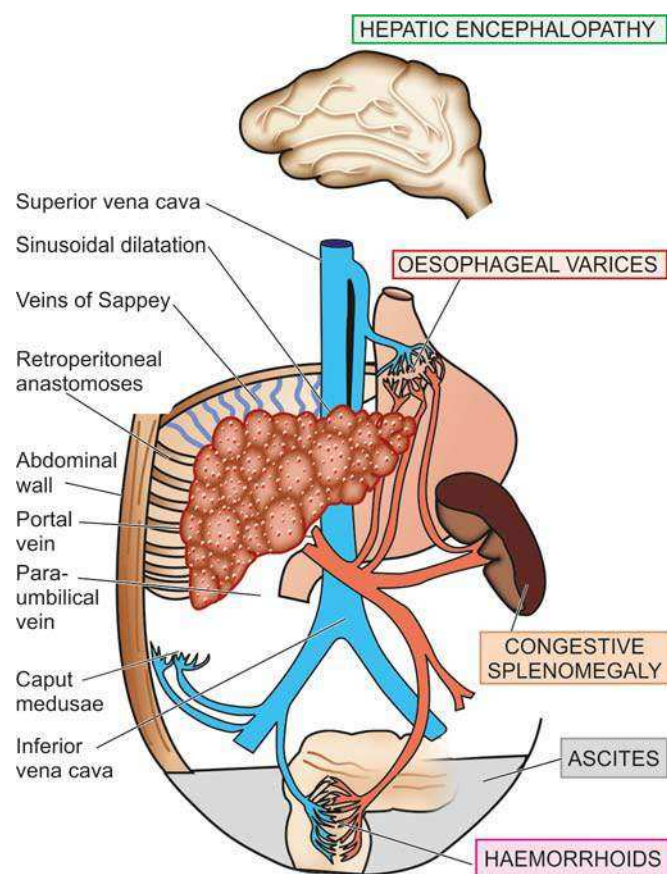

Figure 19.30 Major clinical consequences of portal hypertension.

A. Systemic Factors:

i) *Decreased plasma colloid oncotic pressure* There is hypoalbuminaemia from impaired hepatic synthesis of plasma proteins including albumin, as well as from loss of

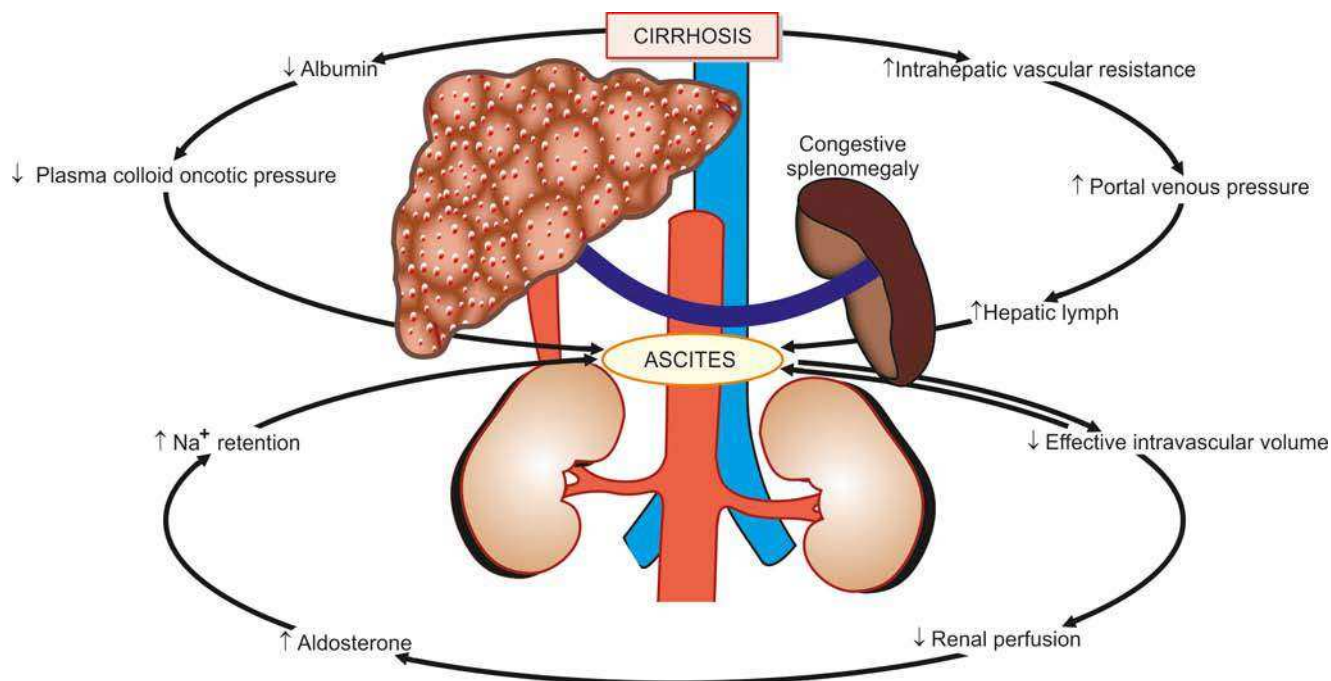

Figure 19.31 Mechanisms of ascites formation in cirrhosis.

albumin from the blood plasma into the peritoneal cavity. Hypoalbuminaemia, in turn, causes reduced plasma oncotic pressure and leads to loss of water into extravascular space.

ii) *Hyperaldosteronism* In cirrhosis, there is increased aldosterone secretion by the adrenal gland, probably due to reduced renal blood flow, and impaired hepatic metabolism and excretion of aldosterone.

iii) *Impaired renal excretion* Reduced renal blood flow and excessive release of antidiuretic hormone results in renal retention of sodium and water and impaired renal excretion.

B. Local Factors:

i) *Increased portal pressure* Portal venous pressure is not directly related to ascites formation but portal hypertension in combination with other factors contributes to the formation and localisation of the fluid retention in the peritoneal cavity.

ii) *Increased hepatic lymph formation* Obstruction of hepatic vein such as in Budd-Chiari syndrome and increased intra-sinusoidal pressure found in cirrhotic patients stimulates hepatic lymph formation that oozes through the surface of the liver.

2. Varices (Collateral channels or Porto-systemic shunts)

As a result of rise in portal venous pressure and obstruction in the portal circulation within or outside the liver, the blood tends to bypass the liver and return to the heart by development of porto-systemic collateral channels (or shunts or varices). These varices develop at sites where the systemic and portal circulations have common capillary beds. The principal sites are as under:

i) *Oesophageal varices*: The development of oesophago-gastric varices which is frequently manifested by massive haematemesis is the most important consequence of portal hypertension (page 522).

ii) *Haemorrhoids*: Development of collaterals between the superior, middle and inferior haemorrhoidal veins resulting in haemorrhoids is another common accompaniment. Bleeding from haemorrhoids is usually not as serious a complication as haematemesis from oesophageal varices.

iii) *Caput medusae*: Anastomoses between the portal and systemic veins may develop between the hilum of the liver and the umbilicus along the paraumbilical plexus of veins resulting in abdominal wall collaterals. These appear as dilated subcutaneous veins radiating from the umbilicus and are termed caput medusae (named after the snake-haired Medusa).

iv) *Retroperitoneal anastomoses*: In the retroperitoneum, portocaval anastomoses may be established through the veins of Retzius and the veins of Sappey.

3. Splenomegaly The enlargement of the spleen in prolonged portal hypertension is called congestive splenomegaly (page 92). The spleen may weigh 500-1000 gm and is easily palpable. The spleen is larger in young people and in macronodular cirrhosis than in micronodular cirrhosis.

4. Hepatic encephalopathy Porto-systemic venous shunting may result in a complex metabolic and organic syndrome of the brain characterised by disturbed consciousness, neurologic signs and flapping tremors. Hepatic encephalopathy is particularly associated with advanced hepatocellular disease such as in cirrhosis.

GIST BOX 19.10 Portal Hypertension

- Portal hypertension occurs when the portal pressure is above 30 mm saline (normal 10-15 mm saline).
- Based on the site of obstruction to portal venous blood flow, portal hypertension is categorised into intrahepatic (e.g. cirrhosis), posthepatic (e.g. CHF) and prehepatic (e.g. portal vein thrombosis).
- Major clinical consequences of portal hypertension are ascites, varices (collateral channels or portosystemic shunts), splenomegaly and hepatic encephalopathy.

HEPATIC TUMOURS AND TUMOUR-LIKE LESIONS

The liver is the site for benign tumours, tumour-like lesions, and both primary and metastatic malignant tumours. However, metastatic tumours are much more common than primary tumours and tumour-like lesions. Primary hepatic tumours may arise from *hepatic cells, bile duct epithelium, or mesodermal structures (Table 19.12)*.

TUMOUR-LIKE LESIONS

These include cysts in the liver and focal nodular hyperplasia.

Hepatic Cysts

Cysts in the liver may be single or multiple. These cysts are mainly of 3 types—congenital, simple (nonparasitic) and hydatid (*Echinococcus*) cysts.

1. CONGENITAL CYSTS These are uncommon. They are usually small (less than 1 cm in diameter) and are lined by biliary epithelium. They may be single, or occur as polycystic liver disease, often associated with polycystic kidney. On occasions, these cysts have abundant connective tissue and numerous ducts, warranting the designation of *congenital hepatic fibrosis*.

2. SIMPLE (NON-PARASITIC) CYSTS Simple cysts are solitary non-parasitic cysts seen more frequently in middle-aged women. The cyst is usually large (up to 20 cm in diameter), lying underneath the Glisson's capsule and filled with serous fluid. The cyst produces a palpable mass and may be associated with jaundice.

Table 19.12 Classification of primary hepatic tumours.

| | BENIGN | MALIGNANT |
|----------------------------------|-------------------------------------|--|
| A. <i>Hepatocellular tumours</i> | Hepatocellular (liver cell) adenoma | Hepatocellular (liver cell) carcinoma Hepatoblastoma (Embryoma) |
| B. <i>Biliary tumours</i> | Bile duct adenoma (Cholangioma) | Cholangiocarcinoma Combined hepatocellular and cholangiocarcinoma Cystadenocarcinoma |
| C. <i>Mesodermal tumours</i> | Haemangioma | Angiosarcoma Embryonal sarcoma |

Histologically, the cyst wall is composed of compact fibrous tissue and is lined by low columnar to cuboid epithelium and occasionally by squamous lining.

3. HYDATID (ECHINOCOCCUS) CYSTS Hydatid cyst has already been discussed on page 601.

Focal Nodular Hyperplasia

The *etiology* of focal nodular hyperplasia is not known but these lesions are more common in women taking oral contraceptives.

Grossly, Focal nodular hyperplasia is a well-demarcated tumour-like nodule occurring underneath the Glisson's capsule. The nodules may be single or multiple, measuring about 5 cm in diameter. It may be tan-yellow or bile-stained. The sectioned surface shows a central fibrous scar.

Histologically, it is composed of collagenous septa radiating from the central fibrous scar which separate nodules of normal hepatocytes without portal triads or central hepatic veins. The fibrous septa contain prominent lymphocytic infiltrate.

BENIGN HEPATIC TUMOURS

These are uncommon and some of them are incidental autopsy findings. These include hepatocellular (liver cell) adenoma, bile duct adenoma (cholangioma) and haemangioma.

Hepatocellular (Liver Cell) Adenoma

Adenomas arising from hepatocytes are rare and are reported in women in reproductive age group in association with use of oral contraceptives, sex hormone therapy and with pregnancy. The tumour presents as intrahepatic mass that may be mistaken for hepatocellular carcinoma and may rupture causing severe intraperitoneal haemorrhage.

MORPHOLOGIC FEATURES **Grossly**, the tumour usually occurs singly but about 10% are multiple. It is partly or completely encapsulated and slightly lighter in colour than adjacent liver or may be bile-stained. The tumours vary from a few centimetres up to 30 cm in diameter. On cut section, many of the tumours have varying degree of infarction and haemorrhage.

Histologically, liver cell adenomas are composed of sheets and cords of hepatocytes which may be normal-looking or may show slight variation in size and shape but no mitoses. The hepatocytes in adenomas contain greater amount of glycogen than the surrounding liver cells and may sometimes show fatty change. Hepatocellular adenomas lack portal tracts and bile ducts but bile canaliculi containing bile-plugs may be present. Numerous blood vessels are generally present in the tumour which may be thrombosed. Thrombosis leads to infarction and may result in rupture with intraperitoneal haemorrhage.

Bile Duct Adenoma (Cholangioma)

Intrahepatic or extrahepatic bile duct adenoma is a rare benign tumour. The tumour may be small, composed of acini lined by biliary epithelium and separated by variable amount of

connective tissue, or are larger cystadenomas having loculi lined by biliary epithelium.

Haemangioma

Haemangioma is the commonest benign tumour of the liver. Majority of them are asymptomatic and discovered incidentally. Rarely, a haemangioma may rupture into the peritoneal cavity.

MORPHOLOGIC FEATURES **Grossly**, haemangiomas appear as solitary or multiple, circumscribed, red-purple lesions, commonly subcapsular and varying from a few millimetres to a few centimetres in diameter. They are commonly cavernous type giving the sectioned surface a spongy appearance.

Histologically, haemangioma of the liver shows characteristic large, cavernous, blood-filled spaces, lined by a single layer of endothelium and separated by connective tissue (**Fig. 19.32**). Some haemangiomas may undergo progressive fibrosis and may later get calcified.

MALIGNANT HEPATIC TUMOURS

Among the primary malignant tumours of the liver, hepatocellular (liver cell) carcinoma accounts for approximately 85% of all primary malignant tumours, cholangiocarcinoma for about 5-10%, and infrequently mixed pattern is seen. The remainder are rare tumours that include hepatoblastoma, haemangiosarcoma (angiosarcoma) and embryonal sarcoma. Hepatic haemangiosarcoma and embryonal sarcoma resemble in morphology with their counterparts elsewhere in the body.

Hepatocellular Carcinoma

Hepatocellular carcinoma (HCC) or liver cell carcinoma, also termed as hepatoma, is the most common primary malignant tumour of the liver. The tumour shows marked geographic variations in incidence which is closely related to HBV and HCV infection in the region. Whereas the prevalence of HCC is less than 1% of all autopsies in the United States and Europe, the incidence in sub-Saharan Africa and South-East Asia (particularly China) is high (2-8%). Liver cell cancer is more common in males than in females in the ratio of 4:1. The peak incidence occurs in 5th to 6th decades of life but in high incidence areas where HBV and HCV infection is prevalent, it occurs a decade or two earlier. The tumour supervenes on cirrhosis in 70-80% of cases.

ETIOPATHOGENESIS A number of etiologic factors are implicated in the etiology of HCC, most important being *HBV and HCV infection, and association with cirrhosis*.

1. Relation to HBV infection Genesis of HCC is linked to prolonged infection with HBV. The evidence in support is both epidemiologic and direct.

i) The incidence of HBsAg positivity is higher in HCC patients. For example, in Taiwan, HBsAg-positive carriers have more than 200 times greater risk of developing HCC than HBsAg-negative patients, particularly when the infection is acquired in early life.

ii) In African and Asian patients, 95% cases of HCC have anti-HBc.

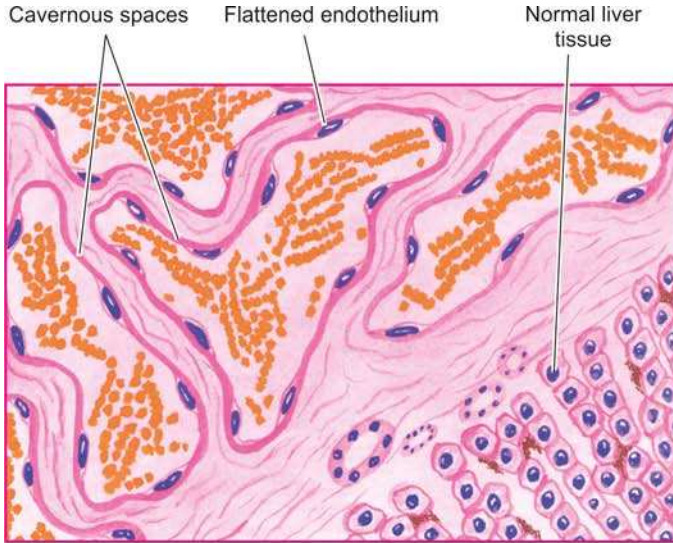

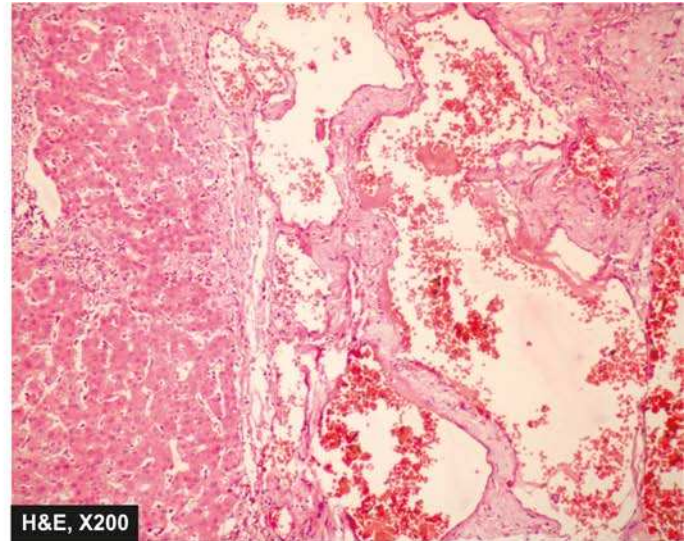

Figure 19.32 Cavernous haemangioma of the liver.

iii) There is more direct evidence of integration of HBV-DNA genome in the genome of tumour cells of HCC.

2. Relation to HCV infection Long-standing HCV infection has emerged as a major factor in the etiology of HCC, generally after more than 30 years of infection. The evidences in support are as under:

- i) In developed countries where higher incidence of HCC was earlier attributed to endemic HBV infection (e.g. in Japan) has shown a remarkable shift to HCV infection. However, in developing countries HBV is still the predominant etiologic factor in the pathogenesis of HCC.
- ii) The patients having anti-HCV and anti-HBc antibodies together have three times higher risk of developing HCC than in those with either antibody alone.
- iii) HCV infection after a long interval produces cirrhosis more often prior to development of HCC, while in HCC following HBV infection half the cases have cirrhosis and remainder have chronic hepatitis.
- iv) It is also possible that HBV and HCV infection may act synergistically to predispose to HCC.

3. Relation to cirrhosis Cirrhosis of all etiologic types is more commonly associated with HCC but the most frequent association is with macronodular post-necrotic cirrhosis. The mechanism of progression to HCC appears to be chronic regenerative activity in cirrhosis, or that the damaged liver in cirrhosis is rendered vulnerable to carcinogenic influences. *Liver cell dysplasia* identified by cellular enlargement, nuclear hyperchromatism and multinucleate cells, is found in 60% of cirrhotic livers with HCC and in only 10% of non-cirrhotic livers.

4. Relation to alcohol It has been observed that alcoholics have about four-fold increased risk of developing HCC. It is possible that alcohol may act as co-carcinogen with HBV or HCV infection, but alcohol does not appear to be a hepatic carcinogen *per se*.

5. Mycotoxins An important mycotoxin, aflatoxin B₁, produced by a mould *Aspergillus flavus*, can contaminate poorly stored wheat grains or groundnuts, in hot and humid

palces. This is responsible for higher incidence of HCC in some developing countries of Asia and Africa. Aflatoxin B₁ is carcinogenic; it may act as a co-carcinogen with hepatitis B or may suppress the cellular immune response.

6. Chemical carcinogens A number of chemical carcinogens can induce liver cancer in experimental animals. These include:

- i) Butter-yellow, saffrole and nitrosamines used as common food additives.
- ii) Bush trees containing pyrrolizidine, tannin acid.
- iii) Pollutants such as pesticides and insecticides.

7. Miscellaneous factors Limited role of various other factors in HCC has been observed. These include the following:

- i) Haemochromatosis
- ii) α -1-antitrypsin deficiency
- iii) Prolonged immunosuppressive therapy in renal transplant patients
- iv) Other types of viral hepatitis
- v) Non-alcoholic steatohepatitis (NASH)
- vi) Tobacco smoking
- vii) Parasitic infestations such as clonorchiasis and schistosomiasis
- viii) Glycogen storage diseases.

Molecular pathogenesis of HCC can be explained on the basis of genetic mutations induced by one or more of the above major etiologic factors which damage the DNA of hepatocyte and results in neoplastic transformation. These mutated genes are as under:

- i) Inactivation of tumour suppressor oncogene *p53* by HBV.
- ii) Binding of X-protein (HBxAg) generated from X-gene of HBV to *p53*.
- iii) Mutations of oncogenes such as KRAS
- iv) Mutations in receptors for hepatocyte growth factors e.g. c-MYC, c-MET.
- v) Activation of WNT and AKT pathways.

MORPHOLOGIC FEATURES *Grossly*, HCC may form one of the following 3 patterns of growth, in decreasing order of frequency (**Fig. 19.33**):

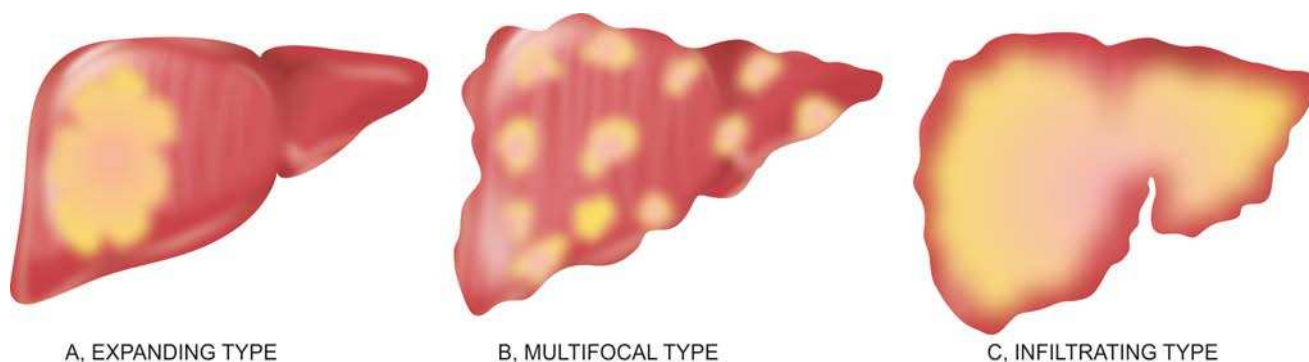

Figure 19.33 Macroscopic patterns of hepatocellular carcinoma.

- i) *Expanding type*: Most frequently, it forms a *single, yellow-brown, large mass*, most often in the right lobe of the liver with central necrosis, haemorrhage and occasional bile-staining (**Fig. 19.34**). It may be deceptively encapsulated.
- ii) *Multifocal type*: Less often, *multifocal, multiple masses*, 3-5 cm in diameter, scattered throughout the liver are seen.
- iii) *Infiltrating (Spreading) type*: Rarely, the HCC forms diffusely infiltrating tumour mass.

Microscopically, the tumour cells in the typical HCC resemble hepatocytes but vary with the degree of differentiation, ranging from well-differentiated to highly anaplastic lesions. Most of the HCC have trabecular growth pattern. The tumour cells have a tendency to invade and grow along blood vessels. Thus important diagnostic features are the *patterns of tumour cells* and their *cytologic features*:

1. Histologic patterns: These include the following:

- i) *Trabecular or sinusoidal pattern* is the most common. The trabeculae are made up of 2-8 cell wide layers of tumour cells separated by vascular spaces or sinusoids which are endothelium-lined (**Fig. 19.35**).
- ii) *Pseudoglandular or acinar pattern* is seen sometimes. The tumour cells are disposed around central cystic space formed by degeneration and breakdown in solid trabeculae.
- iii) *Compact pattern* resembles trabecular pattern but the tumour cells form large solid masses with inconspicuous sinusoids.
- iv) *Scirrhou pattern* is characterised by more abundant fibrous stroma.

2. Cytologic features: The typical cytologic features in the HCC consist of cells resembling hepatocytes having vesicular nuclei with prominent nucleoli. The cytoplasm is granular and eosinophilic but becomes increasingly basophilic with increasing malignancy. Aside from these features, a few other cellular features are: pleomorphism, bizarre giant cell formation, spindle-shaped cells, tumour cells with clear cytoplasm, presence of bile within dilated canaliculi, and intracytoplasmic Mallory's hyalin.

Immunohistochemically, hepatocellular carcinoma cells stain positively with AFP, EMA, keratin etc.

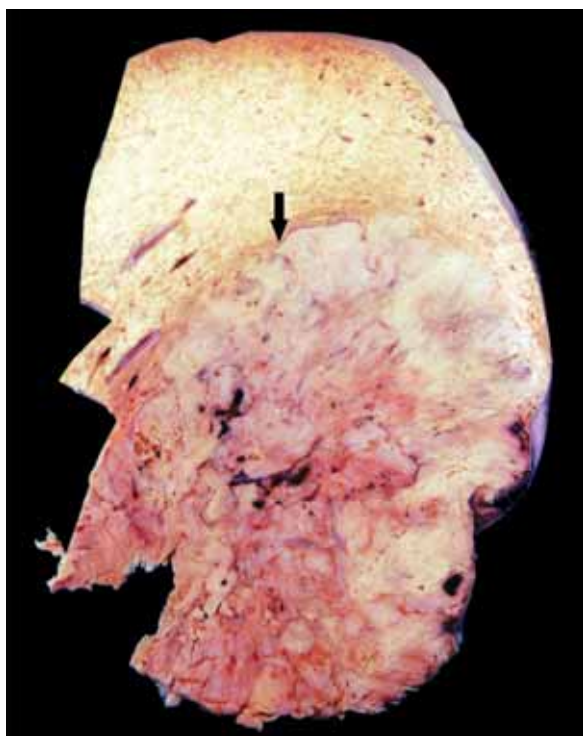

Figure 19.34 Hepatocellular carcinoma. Sectioned surface shows a single, large mass (arrow) with irregular borders and having central areas of necrosis, while rest of the hepatic parenchyma in the upper part of the picture shows many nodules of variable sizes owing to co-existent macronodular cirrhosis.

FIBROLAMELLAR CARCINOMA A clinicopathologic variant of the HCC is fibrolamellar carcinoma of the liver found in young people of both sexes. The tumour forms a single large mass which may be encapsulated and occurs in the absence of cirrhosis.

Histologically, the tumour is composed of eosinophilic polygonal cells (oncocytes) forming cords and nests which are separated by bands of fibrous stroma (**Fig. 19.36**).

The prognosis of fibrolamellar carcinoma is better than other forms of HCC.

CLINICAL FEATURES Hepatic cancer may remain undetected initially because it often occurs in patients with underlying cirrhosis. The usual features consist of hepatomegaly with palpable mass in the liver, right upper quadrant pain or tenderness, and less often, jaundice, fever and haemorrhage from oesophageal varices. Ascites with RBCs and malignant cells is found in about half the patients. Rarely, systemic endocrine manifestations due to paraneoplastic

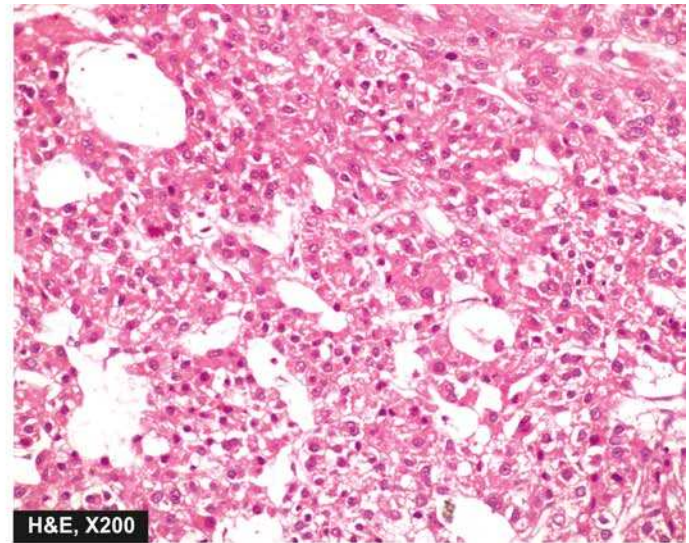

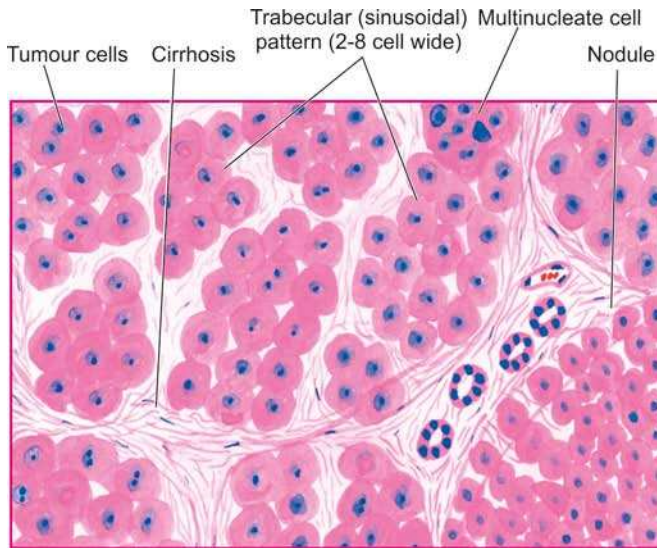

Figure 19.35 Hepatocellular carcinoma, typical microscopic pattern. The tumour cells resembling hepatocytes show pleomorphism and are seen forming 2-8 cell wide trabeculae which are separated by endothelium-lined sinusoidal spaces.

plastic syndrome are observed such as hypercalcaemia, hypoglycaemia, gynaecomastia and acquired porphyria.

Laboratory findings yield nonspecific results like anaemia, markedly elevated serum alkaline phosphatase as found in cirrhosis, and high serum alpha-foetoprotein (AFP). Elevated AFP level is quite specific; very high levels of AFP (above 500 ng/ml) are observed in 70-80% cases of HCC but lacks sensitivity since AFP is also found elevated in yolk sac tumour, cirrhosis, chronic hepatitis, massive liver necrosis and normal pregnancy. Ultrasound of the liver has been reported to be more sensitive than elevated AFP level. An abnormal type of prothrombin, des- γ -carboxy prothrombin, is also elevated and correlates well with AFP levels.

SPREAD The HCC can have both intrahepatic and extrahepatic spread which faithfully reproduces the structure of the primary tumour:

◆ **Intrahepatic spread** occurs by haematogenous route and forms multiple metastases in the liver.

◆ **Extrahepatic spread** occurs via hepatic or portal veins to different sites, chiefly to lungs and bones, and by lymphatic route to regional lymph nodes at the porta hepatis and to mediastinal and cervical lymph nodes.

The causes of death from the HCC are cachexia, massive bleeding from oesophageal varices, and liver failure with hepatic coma. Usually, survival after diagnosis of HCC is less than 2 years.

Cholangiocarcinoma

Cholangiocarcinoma is the designation used for carcinoma arising from bile duct epithelium within the liver (*peripheral cholangiocarcinoma*). Carcinomas arising from the large hilar ducts (*hilar cholangiocarcinoma*) and from extrahepatic ducts are termed *bile duct carcinomas* (page 630). None of the etiologic factors related to HCC have any role in the genesis of cholangiocarcinoma. However, the etiological factors involved in it are exposure to radio-opaque dye thorotrast, anabolic steroids, clonorchiasis and fibrocystic disease. The tumour affects older people and the clinical features are those of HCC but with prominence of jaundice.

MORPHOLOGIC FEATURES **Grossly**, the tumour is firm to hard and whitish.

Microscopically, the tumour has glandular structure. The tumour cells resemble biliary epithelium but without bile secretion. They form various patterns such as tubular, ductular or papillary. The stroma consists of fibrous tissue with little or no capillary formation. Occasionally, mucinous, signet-ring and adenosquamous type of patterns are found. An uncommon variant is combined hepatocellular-cholangiocarcinoma.

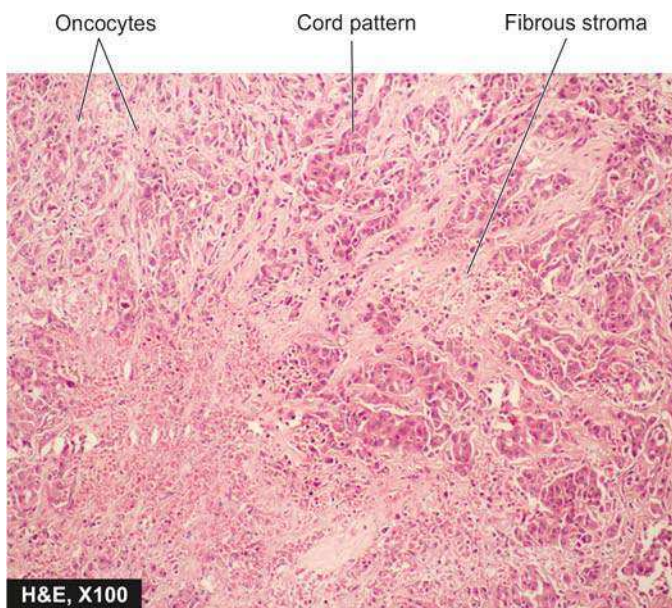

Figure 19.36 Fibrolamellar carcinoma liver.

Hepatoblastoma (Embryoma)

Hepatoblastoma is a rare malignant tumour arising from primitive hepatic parenchymal cells. It presents before the age

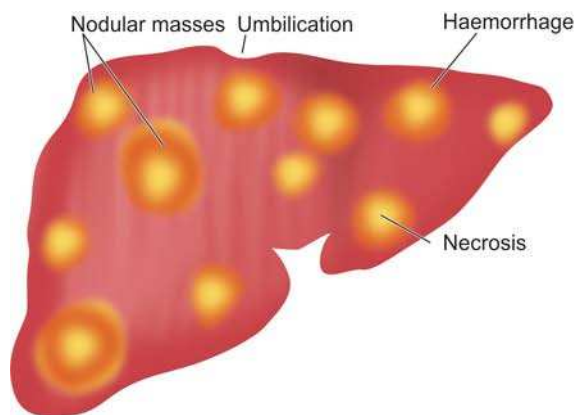

Figure 19.37 Metastatic tumour deposits in the liver as seen on sectioned surface. Characteristic features include multiple, variable-sized, nodular masses, often under the capsule, producing umbilication on the surface.

of 2 years as progressive abdominal distension with anorexia, failure to thrive, fever and jaundice. It is more common in boys. The concentration of serum AFP is high. The tumour grows rapidly and causes death by haemorrhage, hepatic failure or widespread metastases.

MORPHOLOGIC FEATURES *Grossly*, the tumour is circumscribed and lobulated mass measuring 5-25 cm in size, having areas of cystic degeneration, haemorrhage and necrosis.

Microscopically, hepatoblastoma consists of 2 components:

i) **Epithelial component** contains 2 types of cells—‘embryonal’ hepatocytes are small with dark-staining, hyperchromatic nuclei and scanty cytoplasm, while ‘foetal’ hepatocytes are larger with more cytoplasm that may be granular or clear. The epithelial cells are organised in trabeculae, ribbons or rosettes.

ii) **Mesenchymal component** includes fibrous connective tissue, cartilage and osteoid of variable degree of maturation. Extramedullary haematopoiesis is a frequent accompaniment.

Secondary Hepatic Tumours

Metastatic tumours in the liver are more common than the primary hepatic tumours. Most frequently, they are blood-borne metastases, irrespective of whether the primary tumour is drained by portal vein or systemic veins. Most frequent primary tumours metastasising to the liver, in descending order of frequency, are those of stomach, breast, lungs, colon, oesophagus, pancreas, malignant melanoma and haematopoietic malignancies. Sarcomas rarely metastasise to the liver. Occasionally, metastatic involvement may be present in the absence of obvious evidence of primary tumour. Aside from general features of disseminated malignancy such as anorexia, cachexia and anaemia, the patients have hepatomegaly with nodular free margin. There is little hepatic dysfunction until late in the course of hepatic metastatic disease.

MORPHOLOGIC FEATURES *Grossly*, most metastatic carcinomas form multiple, spherical, nodular masses

which are of variable size. Liver is enlarged and heavy, weighing 5 kg or more. The tumour deposits are white, well-demarcated, soft or haemorrhagic. The surface of the liver shows characteristic umbilication due to central necrosis of nodular masses (Fig. 19.37).

Histologically, the metastatic tumours generally reproduce the structure of the primary lesions (Fig. 19.38).

GIST BOX 19.11

Hepatic Tumours and Tumour-like Lesions

- ☐ Tumour-like lesions include cysts in the liver (e.g. congenital, simple parasitic) and focal nodular hyperplasia.
- ☐ Benign hepatic tumours are uncommon and include hepatocellular (liver cell) adenoma, bile duct adenoma (cholangioma) and haemangioma.

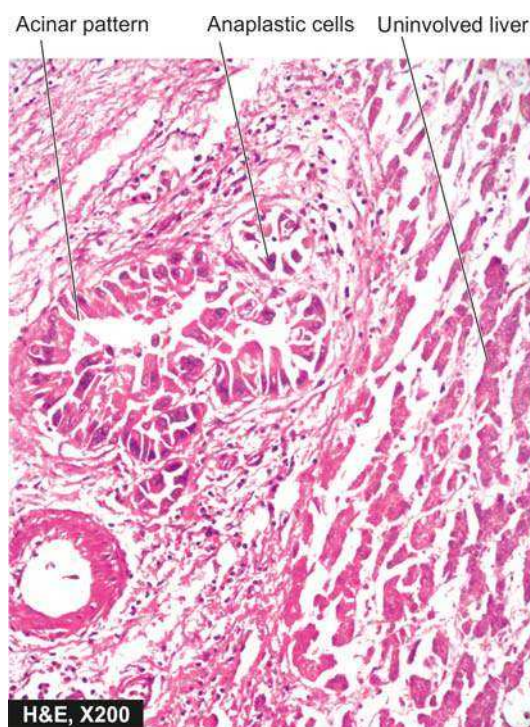

Figure 19.38 Metastatic deposits from adenocarcinoma in the liver.

- ▣ Hepatocellular carcinoma or hepatoma is the most common primary malignant tumour of the liver. The tumour supervenes on cirrhosis in 70-80% of cases. HCC has poor prognosis while a variant, fibrolamellar carcinoma, occurring in younger age group has better prognosis.
- ▣ Hepatoblastoma is a rare malignant tumour presenting before the age of 2 years.
- ▣ Metastatic tumours in the liver are more common than the primary hepatic tumours and most frequently, they are blood-borne metastases from various primary sites.

BILIARY TRACT

NORMAL STRUCTURE

ANATOMY The gallbladder is a pear-shaped organ, 9 cm in length and has a capacity of approximately 50 ml. It consists of the *fundus*, *body* and *neck* that tapers into the cystic duct. The two hepatic ducts from right and left lobes of the liver unite at the porta hepatis to form the common hepatic duct which is joined by the cystic duct from the gallbladder to form the common bile duct. The common bile duct enters the second part of the duodenum posteriorly. In about 70% of cases, it is joined by the main pancreatic duct to form the combined opening in the duodenum (*ampulla of Vater*). In 30% cases, the common bile duct and the pancreatic duct open separately into the duodenum (see Fig. 19.1). The common bile duct in its duodenal portion is surrounded by longitudinal and circular muscles derived from the duodenum forming *sphincter of Oddi*.

HISTOLOGY Histologically, the gallbladder, unlike the rest of gastrointestinal tract, lacks the muscularis mucosae and submucosa. The wall of the gallbladder is composed of the following 4 layers:

- 1. Mucosal layer:** It has a single layer of tall columnar epithelium which is thrown into permanent folds that are larger and more numerous in the neck of the gallbladder. Beneath the epithelium is delicate lamina propria that contains capillaries, and in the region of the neck, a few acinar glands are present.
- 2. Smooth muscle layer:** External to the lamina propria are smooth muscle bundles in layers—inner longitudinal, middle oblique, and outer circular.
- 3. Perimuscular layer:** Outer to the muscle layer is a zone of fibrous connective tissue with some interspersed fat cells.
- 4. Serosal layer:** The perimuscular layer is covered by serosa on the peritoneal surface of the gallbladder. The peritoneum covers the gallbladder except in the region of gallbladder fossa where it is embedded in the liver.

The *extrahepatic bile ducts* are also lined by tall columnar epithelium that overlies the lamina propria. It is surrounded by dense layer of fibromuscular tissue. The ducts which lie between the lobules of the liver and receive bile from the canaliculi are lined by cuboidal or flattened cells.

FUNCTIONS The main function of the gallbladder is to store and concentrate the bile secreted by the liver and then deliver it into the intestine for digestion and absorption of fat. The concentrating ability of the gallbladder is due to its absorptive mucosal surface that has numerous folds. Normally,

the liver secretes approximately 500 ml of bile per day and the gallbladder concentrates it 5-10 times. The motility, concentration and relaxation of the gallbladder are under the influence of a peptide hormone, cholecystokinin, released from neuroendocrine cells of the duodenum and jejunum.

CONGENITAL ANOMALIES

Several uncommon congenital anomalies of the biliary system have been described. These include: agenesis, duplication and heterotopic tissue. However, *congenital cystic lesions* of the bile ducts (as also of the liver) are more frequently diagnosed. These conditions include: congenital intrahepatic biliary dilatation (Caroli's disease), choledochal cysts, polycystic liver disease and congenital hepatic fibrosis. They are found in various combinations and are usually inherited. All of them may be complicated by malignant change.

CHOLELITHIASIS (GALLSTONES)

Gallstones are formed from constituents of the bile (viz. cholesterol, bile pigments and calcium salts) along with other organic components. Accordingly, the gallstones commonly contain cholesterol, bile pigment and calcium salts in varying proportions. They are usually formed in the gallbladder, but sometimes may develop within extrahepatic biliary passages, and rarely in the larger intrahepatic bile duct.

RISK FACTORS

The incidence of gallstones varies markedly in different geographic areas, age, gender, diet and various other risk factors. These factors which largely pertain to cholesterol stones can be summed up in the old saying that gallstones are common in 4F's acronym for—'*fat, female, fertile (multipara) and forty*.' Some of the risk factors in lithogenesis are explained below:

- 1. Geography** Gallstones are quite prevalent in almost the entire Western world. American Indians have the highest known prevalence. Black Africans and populations in the Eastern world are relatively free of cholelithiasis.
- 2. Genetic factors** There is increased frequency of gallstones in first-degree relatives of patients with cholelithiasis. Patients of gallstones disease have increased secretion of dietary cholesterol in bile than in non-gallstone patients in spite of high-cholesterol diet. Recently, mutation in *CYP7A1* gene has been found that results in deficiency of enzyme, cholesterol 7-hydroxylase, which has a role in bile acid synthesis. This mutation is associated with hypercholesterolaemia and gallstones.
- 3. Age** There is steady increase in the prevalence of gallstones with advancing age which may be related to increased cholesterol content in the bile. The incidence increases above the age of 40 and presentation of disease is usually in the 50s and 60s.
- 4. Sex** Gallstones are twice more frequent in women than in men. In the United States, autopsy series have shown gallstones in about 20% of women and 8% of men above the age of 40. The incidence is higher in multiparous women than in nulliparous women.
- 5. Drugs** Women on oestrogen therapy or on birth control pills have higher incidence of gallstones. This is considered

to be due to production of more lithogenic bile as a result of cholestatic effect of oestrogen. Similar is the influence of certain drugs used for lowering blood cholesterol such as clofibrate.

6. Obesity Obesity is associated with increased cholesterol synthesis and its excretion resulting in higher incidence of gallstones in obese patients.

7. Diet Deficiency of dietary fibre content is linked to higher prevalence of gallstones. A moderate consumption of alcohol, however, seems to protect against gallstones.

8. Gastrointestinal diseases Certain gastrointestinal disorders such as Crohn's disease, ileal resection, ileal bypass surgery etc are associated with interruption in enterohepatic circulation followed by gallstone formation.

9. Factors in pigment gallstones All the above factors apply largely to cholesterol stones. Pigment stones, whether pure or mixed type, are more frequently associated with haemolytic anaemias which lead to increased content of unconjugated bilirubin in the bile. Pigment stones are also more frequent in cirrhosis and hepatocellular disease.

PATHOGENESIS

The mechanism of gallstone formation (i.e. lithogenesis) is explained separately below under 2 headings: *firstly* for cholesterol, mixed gallstones and biliary sludge; and, *secondly* for pigment gallstones as under:

Pathogenesis of Cholesterol, Mixed Gallstones and Biliary Sludge

Cholesterol is essentially insoluble in water and can be solubilised by another lipid. Normally, cholesterol and phospholipids (lecithin) are secreted into bile as 'bilayered vesicles' but are converted into 'mixed micelles' by addition of bile acids, the third constituent. If there is excess of cholesterol compared to the other two constituents, unstable cholesterol-rich vesicles remain behind which aggregate and form cholesterol crystals. Formation of such lithogenic (stone-forming) bile is explained by the following mechanisms (Fig. 19.39):

1. Supersaturation of bile Several etiologic factors listed above favour increased secretion of cholesterol in the presence of normal bile acids and lecithin in the bile as the major mechanism for initiation of gallstone formation. These factors cause enhanced activity of enzyme, HMG-CoA reductase, that normally regulates cholesterol synthesis and its hepatic uptake. Two other disturbances which may contribute to supersaturation of the bile with cholesterol are as under:

i) *Reduced bile acid pool*: This causes rapid loss of the available bile acids into the small intestine and then into the colon, resulting in supersaturation of the bile with cholesterol.

ii) *Increased conversion of cholic acid to deoxycholic acid*: This causes increased secretion of deoxycholate in the bile which is associated with hypersecretion of cholesterol into the bile.

Mutation in *MDR3* gene has been found that causes defect in phospholipid secretion from bile, resulting in cholesterol supersaturation of bile and cholesterol gallstone formation. Although supersaturation of the bile with cholesterol is an important pre-requisite for lithogenesis, this in itself is not sufficient for cholesterol precipitation.

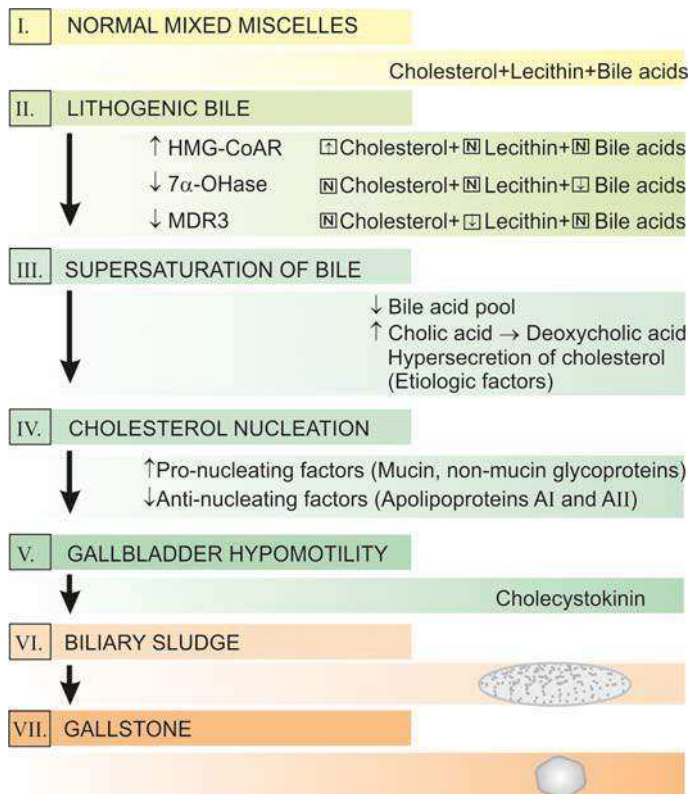

Figure 19.39 Schematic pathogenesis of gallstone formation. (HMG-CoAR = hydroxy methyl glutaryl-coenzyme A reductase; 7 α -OHase = cholesterol 7 α -OHase hydroxylase; MDR3 = multidrug resistance-associated protein 3).

2. Cholesterol nucleation Initiation of cholesterol stones occurs by nucleation of cholesterol monohydrate crystals. Accelerated nucleation of cholesterol monohydrate may occur either from pro-nucleating factors or from deficiency of anti-nucleating factors:

- Pro-nucleating factors* are mucin and non-mucin glycoproteins secreted by epithelial cells of the gallbladder.
- Anti-nucleating factors* are apolipoproteins AI and AII, and some glycoproteins.

Cholesterol monohydrate nucleation probably occurs in the mucin gel layer of the gallbladder followed by continued addition and precipitation of more crystals resulting in solid state crystals.

3. Gallbladder hypomotility Normally, the gallbladder is capable of emptying and clearing any sludge or debris which might initiate stone formation. This takes place under the influence of *cholecystokinin* secreted from small intestine. However, the motility of gallbladder may be impaired due to decrease in cholecystokinin receptors in the gallbladder resulting in stasis of biliary sludge and lithogenesis. A defect in gallbladder emptying has been found to play a role in recurrence of gallstone formation in patients who undergo biliary lithotripsy.

Pathogenesis of Pigment Gallstones

The mechanism of pigment stone formation is explained on the basis of following factors:

- Chronic haemolysis resulting in increased level of unconjugated bilirubin in the bile.

- ii) Alcoholic cirrhosis.
- iii) Chronic biliary tract infection e.g. by parasitic infestations of the biliary tract such as by *Clonorchis sinensis* and *Ascaris lumbricoides*.
- iv) Demographic and genetic factors e.g. in rural setting and prevalence in Asian countries.

TYPES OF GALLSTONES

As stated before, gallstones contain cholesterol, bile pigment and calcium carbonate, either in pure form or in various combinations. Accordingly, gallstones are of 3 major types—*pure gallstones*, *mixed gallstones* and *combined gallstones*. Mixed gallstones are the most common (80%) while pure and combined gallstones comprise 10% each. In general, gallstones are formed most frequently in the gallbladder but may occur in extrahepatic as well as intrahepatic biliary passages. Gallbladder containing pure stones shows no significant inflammatory reaction, whereas chronic cholecystitis is invariably present in gallbladder with either mixed or combined gallstones. Presence of calcium salts renders gallstones radio-opaque, while cholesterol stones appear as radiolucent filling defects in the gallbladder.

The salient features of various types of gallstones are summarised in **Table 19.13** and presented here:

1. PURE GALLSTONES They constitute about 10% of all gallstones. They are further divided into 3 types according to the component of bile forming them. These are as under (**Fig. 19.40**):

i) Pure cholesterol gallstones: They are usually solitary, oval and fairly large (3 cm or more) filling the gallbladder. Their surface is hard, smooth, whitish-yellow and glistening. On cut section, the pure cholesterol stone shows radiating glistening crystals. It may result in deposition of cholesterol within the mucosal macrophages of the gallbladder producing *cholesterolosis* which is an asymptomatic condition (**Fig. 19.41**). Pure cholesterol stones are radiolucent but 10-20% of them have calcium carbonate in them which renders them opaque.

ii) Pure pigment gallstones: These stones composed primarily of bile pigment, calcium bilirubinate, and contain less than 20% cholesterol. They are generally multiple, jet-black and small (less than 1 cm in diameter). They have mulberry like external surface. They are soft and can be easily crushed. The gallbladder usually appears uninvolved.

iii) Pure calcium carbonate gallstones: They are rare. Calcium carbonate gallstones are usually multiple, grey-white, small (less than 1 cm in diameter), faceted and fairly hard due to calcium content. They, too, do not produce any change in the gallbladder wall.

2. MIXED GALLSTONES Mixed gallstones are the most common (80%) and contain more than 50% cholesterol monohydrate plus an admixture of calcium salts, bile pigments and fatty acids. They are always multiple, multifaceted so that they fit together and vary in size from as tiny as sand-grain to 1 cm or more in diameter. On section, they have distinct laminated structure with alternating dark pigment layer and pale-white layer revealing different combinations of cholesterol, bilirubin pigment and calcium carbonate, laid down in layers at different times (**Fig. 19.42, A**).

Mixed gallstones are invariably accompanied by chronic cholecystitis.

3. COMBINED GALLSTONES They comprise about 10% of all gallstones. Combined gallstones are usually solitary, large and smooth-surfaced. It has a *pure gallstone nucleus* (cholesterol, bile pigment or calcium carbonate) and outer shell of mixed gallstone; or a *mixed gallstone nucleus* with pure gallstone shell (**Fig. 19.42, B**).

Combined gallstones, too, are associated with chronic cholecystitis.

CLINICAL MANIFESTATIONS AND COMPLICATIONS

In about 50% cases, gallstones cause no symptoms and may be diagnosed by chance during investigations for some other condition (*silent gallstones*). The future course in such asymptomatic silent cases is controversial, most surgeons advocating cholecystectomy while physicians advising watchful waiting. Follow-up studies, however, show that only about 10% of such cases develop symptoms. Symptomatic gallstone disease appears only when complications develop. These are as under (**Fig. 19.43**):

1. Cholecystitis The relationship between cholelithiasis and cholecystitis is well known but it is not certain which of the two comes first. The patients with gallstones develop symptoms due to cholecystitis which include typical biliary colic precipitated by fatty meal, nausea, vomiting, fever alongwith leucocytosis and high serum bilirubin.

2. Choledocholithiasis Gallstones may pass down into the extrahepatic biliary passages and the small bowel, or less often they may be formed in the biliary tree. Patients with gallstone in the common bile duct frequently develop pain and obstructive jaundice. Fever may develop due to bacterial ascending cholangitis.

3. Mucocele and empyema Mucocele or hydrops of the gallbladder is distension of the gallbladder by clear, watery mucinous secretion resulting from impacted stones in the neck of the gallbladder. When it gets infected empyema is formed.

4. Biliary fistula An uncommon complication of cholelithiasis is formation of fistulae between one part of the biliary system and the bowel, and rarely between the gallbladder and the skin.

5. Gallstone ileus A gallstone in the intestine may be passed in the faeces without causing symptoms. Occasionally, however, gallstones in the intestine may cause intestinal obstruction called gallstone ileus.

6. Pancreatitis Obstructive cholecystasis may result in acute pancreatitis.

7. Gallbladder cancer There is a small and doubtful risk of development of cancer of the gallbladder in cases with cholelithiasis (page 629).

GIST BOX 19.12 Cholelithiasis (Gallstones)

- ☐ Gallstones are formed from constituents of the bile (viz. cholesterol, bile pigments and calcium salts) along with other organic components.
- ☐ Gallstones are of 3 major types—pure gallstones (cholesterol, bile and calcium containing), mixed gallstones and combined gallstones.

Table 19.13 Features of Gallstones.

| TYPE | FREQUENCY | COMPOSITION | GALLBLADDER CHANGES | APPEARANCE |
|-------------------------------|-----------|---|---|---|
| 1. <i>Pure gallstones</i> | 10% | i) Cholesterol ii) Bile pigment iii) Calcium carbonate | Cholesterolosis No change No change | Solitary, oval, large, smooth, yellow-white; on C/S radiating glistening crystals Multiple, small, jet-black, mulberry-shaped; on C/S soft black Multiple, small, grey-white, faceted; C/S hard |
| 2. <i>Mixed gallstones</i> | 80% | Cholesterol, bile pigment and calcium carbonate in varying combination | Chronic cholecystitis | Multiple, multifaceted, variable size, on C/S laminated alternating dark-pigment layer and pale-white layer |
| 3. <i>Combined gallstones</i> | 10% | Pure gallstone nucleus with mixed gallstone shell, or mixed gallstone nucleus with pure gallstone shell | Chronic cholecystitis | Solitary, large, smooth; on C/S central nucleus of pure gallstone with mixed shell or vice versa |

- ▣ Mixed gallstones are the most common (80%) while pure and combined gallstones comprise 10% each.
- ▣ Major complications of gallstones are cholecystiasis, choledocholithiasis, mucocele, empyema, biliary fistula, ileus, pancreatitis and gallbladder cancer.

CHOLECYSTITIS

Cholecystitis or inflammation of the gallbladder may be acute, chronic, or acute superimposed on chronic. Though chronic cholecystitis is more common, acute cholecystitis is a surgical emergency.

ACUTE CHOLECYSTITIS

In many ways, acute cholecystitis is similar to acute appendicitis. The condition usually begins with obstruction, followed by infection later.

ETIOPATHOGENESIS Based on the initiating mechanisms, acute cholecystitis occurs in two types of situations—*acute calculous* and *acute acalculous cholecystitis*.

◆ **Acute calculous cholecystitis** In 90% of cases, acute cholecystitis is caused by obstruction in the neck of the gallbladder or in the cystic duct by a gallstone. The commonest location of impaction of a gallstone is in Hartmann's pouch. Obstruction results in distension of the gallbladder followed by acute inflammation which is initially due to chemical irritation. Later, however, secondary bacterial infection, chiefly by *E. coli* and *Streptococcus faecalis*, supervenes.

◆ **Acute acalculous cholecystitis** The remaining 10% cases of acute cholecystitis do not contain gallstones. In such cases, a variety of causes have been assigned such as previous nonbiliary surgery, multiple injuries, burns, recent childbirth, severe sepsis, dehydration, torsion of the gallbladder and diabetes mellitus. Rare causes include primary bacterial infection like salmonellosis and cholera and parasitic infestations.

MORPHOLOGIC FEATURES Except for the presence or absence of calculi, the two forms of acute cholecystitis are morphologically similar.

Grossly, the gallbladder is distended and tense. The serosal surface is coated with fibrinous exudate with congestion and haemorrhages. The mucosa is bright red. The lumen is filled with pus mixed with green bile. In calculous cholecystitis, a stone may get impacted in the neck or in the cystic duct. When obstruction of the cystic duct is complete, the lumen is filled with purulent exudate and the condition is known as *empyema of the gallbladder*.

Microscopically, wall of the gallbladder shows marked inflammatory oedema, congestion and neutrophilic exudate. There may be frank abscesses in the wall and gangrenous necrosis with rupture into the peritoneal cavity (*gangrenous cholecystitis*).

CLINICAL FEATURES The patients of acute cholecystitis of either type have similar clinical features. They present with severe pain in the upper abdomen with features of peritoneal irritation such as guarding and hyperaesthesia. The gallbladder is tender and may be palpable. Fever, leucocytosis with neutrophilia and slight jaundice are generally present. Early cholecystectomy within the first three days has a mortality of less than 0.5% and risk of complications such as perforation, biliary fistula, recurrent attacks and adhesions is avoided. However, medical treatment brings about resolution in a fairly large proportion of cases though chances of recurrence of attack persist.

CHRONIC CHOLECYSTITIS

Chronic cholecystitis is the commonest type of clinical gallbladder disease. There is almost constant association of chronic cholecystitis with cholelithiasis.

ETIOPATHOGENESIS The association of chronic cholecystitis with mixed and combined gallstones is virtually always present. However, it is not known what initiates the inflammatory response in the gallbladder wall. Possibly, supersaturation of the bile with cholesterol predisposes to both gallstone formation and inflammation. In some patients, repeated attacks of mild acute cholecystitis result in chronic cholecystitis.

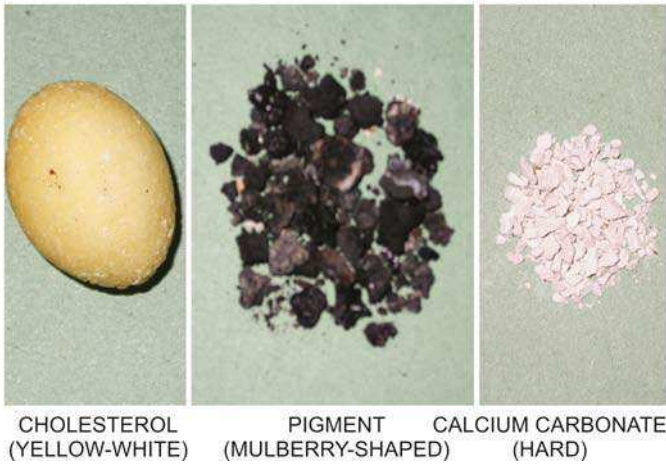

Figure 19.40 Pure gallstones of various types.

MORPHOLOGIC FEATURES Grossly, the gallbladder is generally contracted but may be normal or enlarged (Fig. 19.44). The wall of the gallbladder is thickened which on cut section is grey-white due to dense fibrosis or may be even calcified. The mucosal folds may be intact, thickened, or flattened and atrophied. The lumen commonly contains multiple mixed stones or a combined stone.

Histologically, the features are as under (Fig. 19.45):

1. Thickened and congested mucosa but occasionally mucosa may be totally destroyed.
2. Penetration of the mucosa deep into the wall of the gallbladder up to muscularis layer to form *Rokitansky-Aschoff's sinuses*.
3. Variable degree of chronic inflammatory reaction, consisting of lymphocytes, plasma cells and macrophages, present in the lamina propria and subserosal layer.
4. Variable degree of fibrosis in the subserosal and subepithelial layers.

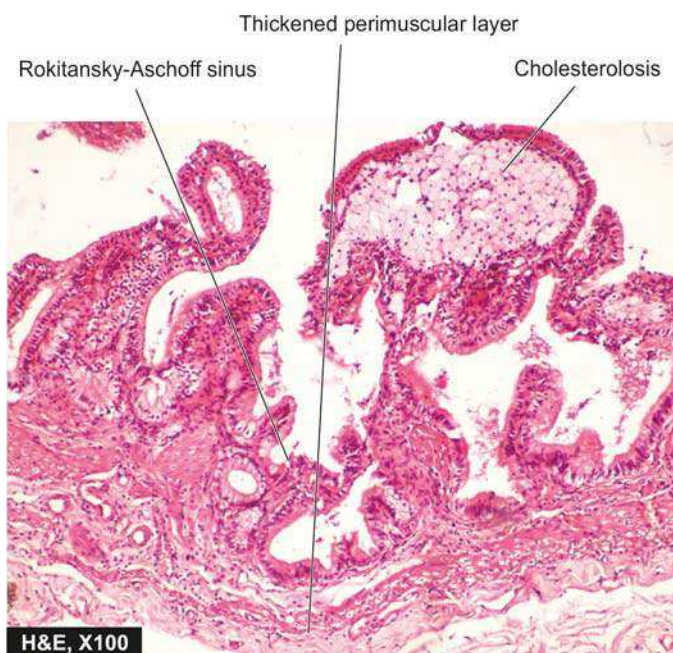

Figure 19.41 Cholesterosis of the gallbladder. The lamina propria of the mucosa shows foamy macrophages.

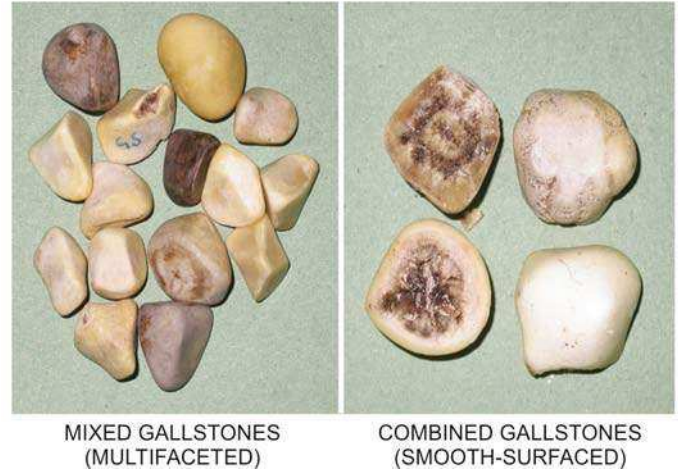

Figure 19.42 Mixed and combined gallstones.

A few morphologic variants of chronic cholecystitis are considered below:

- ◆ **Cholecystitis glandularis**, when the mucosal folds fuse together due to inflammation and result in formation of crypts of epithelium buried in the gallbladder wall.
- ◆ **Porcelain gallbladder** is the pattern when the gallbladder wall is calcified and cracks like an egg-shell.
- ◆ **Acute on chronic cholecystitis** is the term used for the morphologic changes of acute cholecystitis superimposed on changes of chronic cholecystitis.

CLINICAL FEATURES Chronic cholecystitis has ill-defined and vague symptoms. Generally, the patient—a *fat, fertile, female of forty or fifty*, presents with abdominal distension or epigastric discomfort, especially after a fatty meal. There is a constant dull ache in the right hypochondrium and epigastrium and tenderness over the right upper abdomen. Nausea and flatulence are common. Biliary colic may occasionally occur due to passage of stone into the bile ducts. Cholecystography usually allows radiologic visualisation of the gallstones.

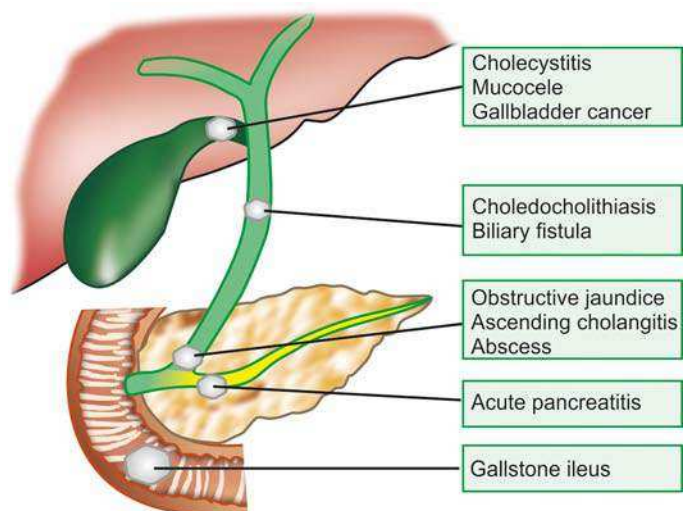

Figure 19.43 Major clinical effects and complications of gallstones.

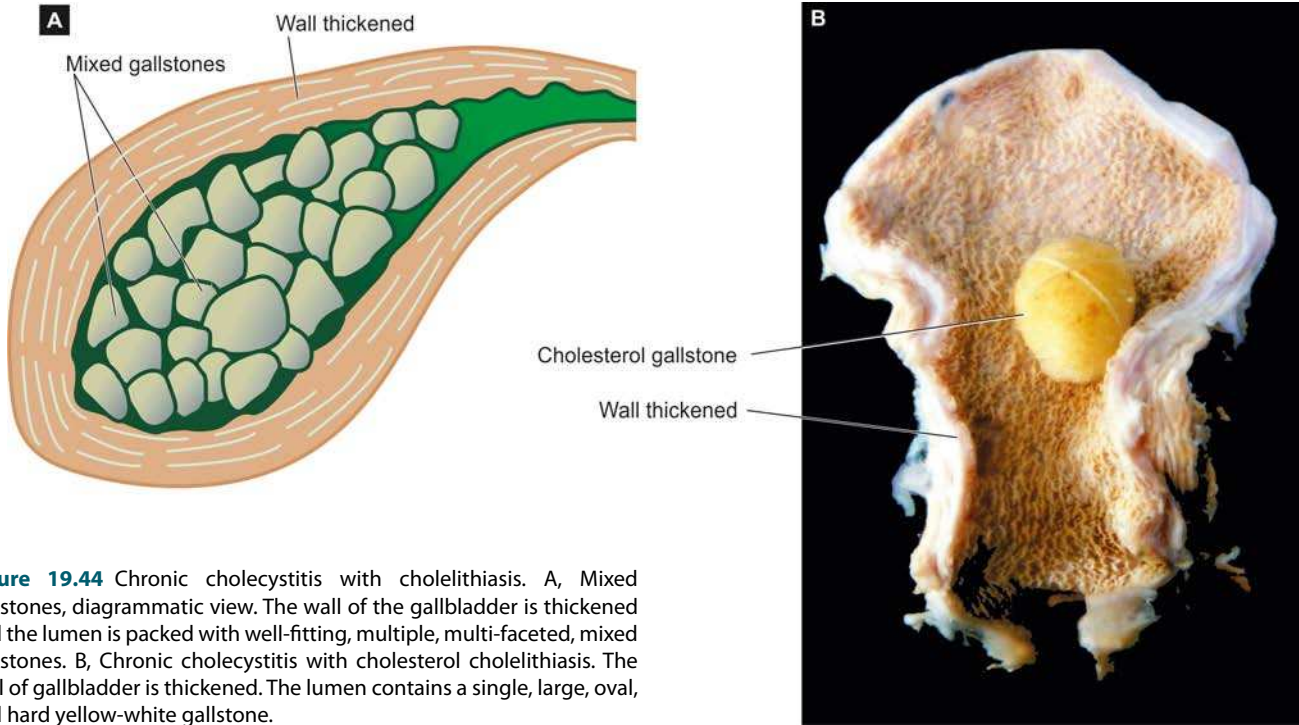

Figure 19.44 Chronic cholecystitis with cholelithiasis. A, Mixed gallstones, diagrammatic view. The wall of the gallbladder is thickened and the lumen is packed with well-fitting, multiple, multi-faceted, mixed gallstones. B, Chronic cholecystitis with cholesterol cholelithiasis. The wall of gallbladder is thickened. The lumen contains a single, large, oval, and hard yellow-white gallstone.

GIST BOX 19.13 Cholecystitis

- ▣ Acute cholecystitis is clinically similar to acute appendicitis. It usually begins with obstruction, followed by infection later.
- ▣ Chronic cholecystitis is invariably associated with mixed and combined gallstones.
- ▣ Generally, the patients of chronic cholecystitis are fat, fertile, female of forty or fifty, presenting with abdominal distension or epigastric discomfort.

TUMOURS OF BILIARY TRACT

BENIGN TUMOURS

Benign tumours such as papilloma, adenoma, adenomyoma, fibroma, lipoma, myxoma, and haemangioma have been described in the biliary tract but all of them are exceedingly rare. *Adenomyoma* is more common benign tumour than the rest. All these tumours resemble their counterparts in morphology elsewhere in the body.

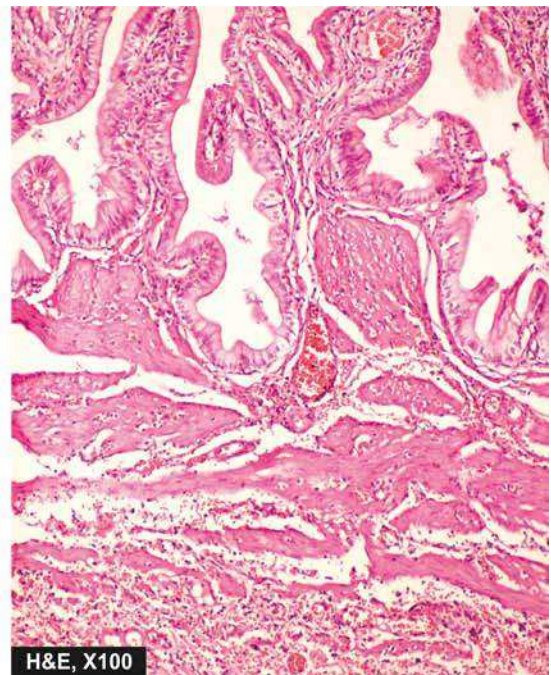

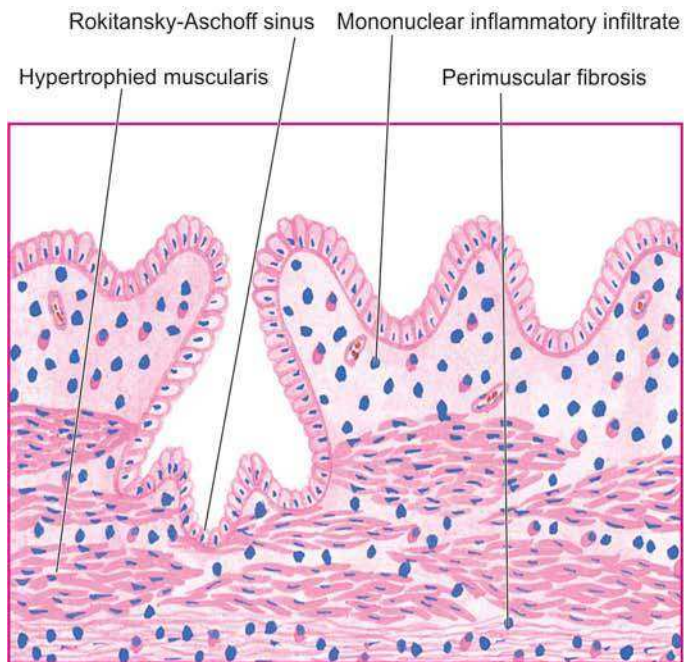

Figure 19.45 Chronic cholecystitis, microscopic appearance. There is penetration of epithelium-lined spaces into the gallbladder wall (Rokitansky-Aschoff sinus) in an area. There is subepithelial and subserosal fibrosis and hypertrophy of muscularis. Mononuclear inflammatory cell infiltrate is present in subepithelial and perimuscular layers.

MALIGNANT TUMOURS

Carcinoma of the gallbladder and carcinoma of the bile ducts and ampulla of Vater are among the more frequent malignant tumours of the biliary tract.

Carcinoma of the Gallbladder

Primary carcinoma of the gallbladder is more prevalent than other cancers of the extrahepatic biliary tract. Like cholelithiasis and cholecystitis, it is more frequent in women than in men (ratio 4:1) with a peak incidence in 7th decade of life. It may remain undetected until the time it is widely spread and rendered inoperable.

ETIOLOGY A number of etiologic factors have been implicated.

1. Cholelithiasis and cholecystitis The most significant association of cancer of the gallbladder is with cholelithiasis and cholecystitis, though there is no definite evidence of causal relationship. Cholelithiasis and cholecystitis are present in about 75% cases of gallbladder cancer. On the other hand, incidence of documented gallbladder cancer in the presence of cholelithiasis and cholecystitis is about 0.5% only. Porcelain gallbladder is particularly likely to become cancerous.

2. Chemical carcinogens A number of chemical carcinogens structurally similar to naturally-occurring bile acids have been considered to induce gallbladder cancer. These include methyl cholanthrene, various nitrosamines and pesticides. Workers engaged in rubber industry have higher incidence of gallbladder cancer.

3. Genetic factors There is higher incidence of cancer of the gallbladder in certain populations living in the same geographic region suggesting a strong genetic component in the disease. Japanese immigrants and Native Americans of the South-Western America have increased frequency while American Indians and Mexicans have lower incidence.

4. Miscellaneous Patients who have undergone previous surgery on the biliary tract have higher incidence of subsequent gallbladder cancer. Patients with inflammatory bowel disease (ulcerative colitis and Crohn's disease) have high incidence of gallbladder cancer.

MORPHOLOGIC FEATURES The commonest site is the fundus, followed next in frequency by the neck of the gallbladder (Fig. 19.46).

Grossly, cancer of the gallbladder is of 2 types—infiltrating and fungating type (Fig. 19.47):

1. Infiltrating type appears as an irregular area of diffuse thickening and induration of the gallbladder wall. It may have deep ulceration causing direct invasion of the gallbladder wall and liver bed. On section, the gallbladder wall is firm due to scirrhous growth.

2. Fungating type grows like an irregular, friable, papillary or cauliflower-like growth into the lumen as well as into the wall of the gallbladder and beyond.

Histologically, the following patterns are observed:

1. Most gallbladder cancers are *adenocarcinomas* (90%). They may be papillary or infiltrative, well-differentiated or poorly-differentiated. Most are non-mucin secreting but some are colloid carcinomas forming mucus pools.

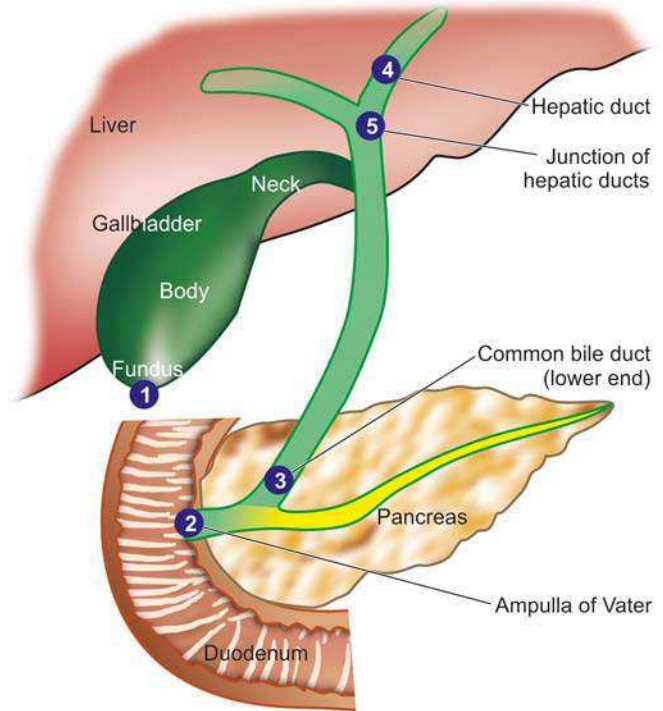

Figure 19.46 Frequency of cancer in the biliary system.

2. About 5% of gallbladder cancers are *squamous cell carcinomas* arising from squamous metaplastic epithelium.
3. A few cases show both squamous and adenocarcinoma pattern of growth called *adenosquamous carcinoma*.

CLINICAL FEATURES Carcinoma of the gallbladder is slow-growing and causes symptoms late in the course of disease.

Figure 19.47 Carcinoma gallbladder. The lumen of the gallbladder contains irregular, friable papillary growth arising from mucosa (arrow). Two multi-faceted gallstones (mixed) are also present in the lumen.

Quite often, the diagnosis is made when gallbladder is removed for cholelithiasis. The symptomatic cases have pain, jaundice, noticeable mass, anorexia and weight loss. In such case, the growth has usually invaded the liver and other adjacent organs and has metastasised to regional lymph nodes and more distant sites such as the lung, peritoneum and gastrointestinal tract.

Carcinoma of Ampulla of Vater and Extrahepatic Bile Ducts

In its pure form, the term *ampullary carcinoma* is used for adenocarcinoma located in the ampulla of Vater, and often its origin from pre-existing villous or tubulovillous adenoma of the ampulla may be demonstrable. However, when the tumour is advanced, it is indistinguishable from 3 other cancers in the vicinity:

- i) cancer of adjacent duodenal mucosa with secondary involvement of ampulla;
- ii) cancer of terminal third of bile duct infiltrating in the ampulla; and
- iii) carcinoma of the head of pancreas merging into the ampulla.

Therefore, in advanced cancer involving the ampulla, the term *periampullary carcinoma* is used that encompasses cancer from all 4 anatomic sites: i) ampulla of Vater, ii) duodenum, iii) terminal part of common bile duct, and iv) the head of pancreas.

Unlike other diseases of the biliary passages, this cancer is more common in males with peak incidence in 6th decade of life.

ETIOLOGY Ampullary carcinoma frequently arises from pre-existing polyp in the ampulla, or may be a part of familial adenomatous polyposis, or neurofibromatosis type 1.

There is no association between carcinoma of common bile duct and gallstones. Bile duct cancers are associated with a number of other conditions such as ulcerative colitis, sclerosing cholangitis, parasitic infestations of the bile ducts with *Fasciola hepatica* (liver fluke), *Ascaris lumbricoides* and *Clonorchis sinensis*.

MORPHOLOGIC FEATURES Ampullary carcinoma may be centered on the ampulla bulging into the duodenum (*intraampullary carcinoma*) or may form circumferential growth around the ampulla (*periampullary carcinoma*). Extrahepatic bile duct carcinoma may arise anywhere in the biliary tree but the most frequent sites, in descending order of frequency, are: the ampulla of Vater, lower end of common bile duct, hepatic ducts, and the junction of hepatic ducts to form common bile duct (see Fig. 19.46).

Grossly, ampullary carcinoma projects into the duodenal lumen and has a papillary surface. Bile duct carcinoma is usually small, extending for 1-2 cm along the duct, producing thickening of the affected duct.

Histologically, the tumour is usually adenocarcinoma varying from well-differentiated to poorly differentiated and may or may not be mucin-secreting. Perineural invasion is frequently present.

CLINICAL FEATURES Obstructive jaundice is the usual presenting feature which is characterised by intense pruritus. Pain, steatorrhoea, weight loss and weakness may be present. The tumour usually metastasises to the regional lymph

nodes. Prognosis of ampullary carcinoma is better than than pancreatic cancer and bile duct carcinoma.

GIST BOX 19.14 Tumours of Biliary Tract

- ☐ Primary carcinoma of the gallbladder is more prevalent than other cancers of the extrahepatic biliary tract and are usually adenocarcinoma.
- ☐ Extrahepatic bile duct carcinoma and carcinoma of Ampulla of Vater is less frequent and has varying grades of differentiation.

EXOCRINE PANCREAS

NORMAL STRUCTURE

The human pancreas, though anatomically a single organ, histologically and physiologically has 2 distinct parts—the *exocrine* and *endocrine parts*. The endocrine part of the gland is dealt with in Chapter 25 while the exocrine gland is considered here. The whole of pancreas, exocrine and endocrine, is embryologically derived from the foregut endoderm.

ANATOMY The pancreas lies obliquely in the concavity of the duodenum as an elongated structure about 15 cm in length and 100 gm in weight (see Fig. 19.1). It is subdivided into 3 topographic zones:

1. The *head* lying in the concavity of the duodenum and the *uncinate process* projecting from the head.
2. The *body* comprises the main part of the gland.
3. The *tail* is the thin, tapering part of the gland towards the hilum of the spleen.

HISTOLOGY The exocrine pancreas constitutes 80 to 85% of the total gland, while the endocrine pancreas comprises the remaining part.

The exocrine part is divided into rhomboid lobules separated by thin fibrous tissue septa containing blood vessels, lymphatics, nerves and ducts. Each lobule is composed of numerous acini. The acini are lined by pyramid-shaped columnar epithelial cells. These secretory epithelial cells have microvilli projecting into the lumen from their surface. The apical portions of these cells contain zymogen granules in their cytoplasm, while the basal region is deeply basophilic and free of zymogen granules. The zymogen granules are membrane-bound sacs which fuse with the plasma membrane and are then released into the lumina of the acini. The secretions are carried from the acini by fine ductal branches into the small ducts in the lobules and eventually into the main pancreatic duct. The main pancreatic duct is formed by fusion of the ventral duct with the dorsal duct; the latter also called the *duct of Wirsung*, provides the main drainage for pancreatic secretions into the duodenum. The pancreatic secretions are delivered into the second part of the duodenum either by a combined opening of the pancreatic and bile ducts in the ampulla of Vater, or less often both open separately into the duodenum. Occasionally, the proximal part of the dorsal duct persists as the *duct of Santorini*.

FUNCTIONS The main functions of the exocrine pancreas is the alkaline secretion of digestive enzymes prominent among which are trypsin, chymotrypsin, elastase, amylase, lipase and phospholipase.

DEVELOPMENTAL ANOMALIES

The significant developmental anomalies of the pancreas are ectopic or aberrant pancreatic tissue in Meckel's diverticulum (page 544), anomalies of the ducts, and cystic fibrosis. Only the last named is discussed here.

Cystic Fibrosis

Cystic fibrosis of the pancreas or fibrocystic disease is a hereditary disorder characterised by viscid mucous secretions in all the exocrine glands of the body (*mucoviscidosis*) and is associated with increased concentrations of electrolytes in the eccrine glands. The terms 'cystic fibrosis' and 'fibrocystic disease' are preferable over 'mucoviscidosis' in view of the main pathologic change of fibrosis produced as a result of obstruction of the passages by viscid mucous secretions.

The disease has an *autosomal recessive inheritance* but clinical features are apparent in homozygotes only with apparent clinical features in homozygotes only. The defect is a genetic mutation in *CFTR* gene, acronym for coding protein for *cystic fibrosis transmembrane conductance regulator* located on chromosome 7. It is quite common in the whites (1 per 2000 livebirths). The clinical manifestations may appear at birth or later in adolescence and pertain to multiple organs and systems such as pancreatic insufficiency, intestinal obstruction, steatorrhoea, malnutrition, hepatic cirrhosis and respiratory complications.

MORPHOLOGIC FEATURES Depending upon the severity of involvement and the organs affected, the pathologic changes are variable. Most of the changes are produced as a result of obstruction by viscid mucous.

1. Pancreas The pancreas is almost invariably involved in cystic fibrosis.

Grossly, pancreatic lobules are ovoid rather than rhomboid. Fatty replacement of the pancreas and grossly visible cysts may be seen.

Microscopically, the lobular architecture of pancreatic parenchyma is maintained. There is increased interlobular fibrosis. The acini are atrophic and many of the acinar ducts contain laminated, eosinophilic concretions. Rarely, inflammation, fat necrosis and cyst formation may be seen. The islet tissue (endocrine pancreas) generally remains intact. Atrophy of the exocrine pancreas may cause impaired fat absorption, steatorrhoea, intestinal obstruction and avitaminosis A.

2. Liver The bile canaliculi are plugged by viscid mucous which may cause diffuse fatty change, portal fibrosis and ductular proliferation. More severe involvement may cause biliary cirrhosis (page 609).

3. Respiratory tract Changes in the respiratory passages are seen in almost all typical cases of cystic fibrosis. The viscid mucous secretions of the submucosal glands of the respiratory tract cause obstruction, dilatation and infection of the airways. The changes include chronic bronchitis, bronchiectasis, bronchiolitis, bronchiolectasis, peribronchiolar pneumonia and inflammatory nasal polyps.

4. Salivary glands Pathologic changes in the salivary glands are similar to those in pancreas and include obstruction of the ducts, dilatation, fibrosis and glandular atrophy.

5. Sweat glands Hypersecretion of sodium and chloride in the sweat observed in these patients may be reflected pathologically by diminished vacuolation of the cells of eccrine glands.

GIST BOX 19.15 Cystic Fibrosis of Pancreas

- ☐ Cystic fibrosis of pancreas is a hereditary condition having viscid mucous secretions in all the exocrine glands of the body (*mucoviscidosis*).
- ☐ The disease has an autosomal recessive inheritance but clinical features are apparent in homozygotes only.

PANCREATITIS

Pancreatitis is inflammation of the pancreas with acinic cell injury. It is classified into acute and chronic forms both of which are distinct entities.

ACUTE PANCREATITIS

Acute pancreatitis is an acute inflammation of the pancreas presenting clinically with 'acute abdomen'. The severe form of the disease associated with macroscopic haemorrhages and fat necrosis in and around the pancreas is termed *acute haemorrhagic pancreatitis* or *acute pancreatic necrosis*. The condition occurs in adults between the age of 40 and 70 years and is commoner in females than in males.

The onset of acute pancreatitis is sudden, occurring after a bout of alcohol or a heavy meal. The patient presents with abdominal pain, vomiting and collapse and the condition must be differentiated from other diseases producing acute abdomen such as acute appendicitis, perforated peptic ulcer, acute cholecystitis, and infarction of the intestine following sudden occlusion of the mesenteric vessels. Characteristically, there is elevation of *serum amylase* level within the first 24 hours and elevated *serum lipase* level after 3 to 4 days, the latter being more specific for pancreatic disease. Glucosuria occurs in 10% of cases.

ETIOLOGY The two leading causes associated with acute pancreatitis are *alcoholism* and *cholelithiasis*, both of which are implicated in more than 80% of cases. Less common causes of acute pancreatitis include trauma, ischaemia, shock, extension of inflammation from the adjacent tissues, blood-borne bacterial infection, viral infections, certain drugs (e.g. thiazides, sulfonamides, oral contraceptives), hypothermia, hyperlipoproteinaemia and hypercalcaemia from hyperparathyroidism. Rarely, *familial pancreatitis* is encountered. In a proportion of cases of acute pancreatitis, the etiology remains unknown (*idiopathic pancreatitis*).

PATHOGENESIS The destructive changes in the pancreas are attributed to the liberation and activation of pancreatic enzymes. Though more than 20 enzymes are secreted by exocrine pancreas, 3 main groups of enzymes which bring about destructive effects on the pancreas are as under:

1. **Proteases** such as trypsin and chymotrypsin play the most important role in causing proteolysis. Trypsin also activates the kinin system by converting prekallikrein to kallikrein, and thereby the clotting and complement systems are activated.

This results in inflammation, thrombosis, tissue damage and haemorrhages found in acute haemorrhagic pancreatitis.

2. *Lipases and phospholipases* degrade lipids and membrane phospholipids.
3. *Elastases* cause destruction of the elastic tissue of the blood vessels.

The activation and release of these enzymes is brought about by one of the following mechanisms:

- i) *Acinic cell damage* caused by the etiologic factors such as alcohol, viruses, drugs, ischaemia and trauma result in release of intracellular enzymes.
- ii) *Duct obstruction* caused by cholelithiasis, chronic alcoholism and other obstructing lesions is followed by leakage of pancreatic enzymes from the ductules into the interstitial tissue.
- iii) *Block in exocytosis* of pancreatic enzymes occurring from nutritional causes results in activation of these intracellular enzymes by pancreatic lysosomal hydrolases.

MORPHOLOGIC FEATURES *Grossly*, in the early stage, the pancreas is swollen and oedematous. Subsequently, in a day or two, characteristic variegated appearance of grey-white pancreatic necrosis, chalky-white fat necrosis and blue-black haemorrhages are seen. In typical case, the peritoneal cavity contains blood-stained ascitic fluid and white flecks of fat necrosis in the omentum, mesentery and peripancreatic tissue. The resolved lesions show areas of fibrosis, calcification and ductal dilatation.

Microscopically, the following features in varying grades are noticeable:

1. Necrosis of pancreatic lobules and ducts.
2. Necrosis of the arteries and arterioles with areas of haemorrhages.
3. Fat necrosis.
4. Inflammatory reaction, chiefly by polymorphs, around the areas of necrosis and haemorrhages.

COMPLICATIONS A patient of acute pancreatitis who survives may develop a variety of systemic and local complications.

Systemic complications:

1. Chemical and bacterial peritonitis.
2. Endotoxic shock.
3. Acute renal failure.

Local sequelae:

1. Pancreatic abscess.
2. Pancreatic pseudocyst.
3. Duodenal obstruction.

Mortality in acute pancreatitis is high (20-30%). Patients succumb to hypotensive shock, infection, acute renal failure, and DIC.

CHRONIC PANCREATITIS

Chronic pancreatitis or *chronic relapsing pancreatitis* is the progressive destruction of the pancreas due to repeated mild and subclinical attacks of acute pancreatitis. Most patients present with recurrent attacks of severe abdominal pain at intervals of months to years. Weight loss and jaundice are often associated. Later manifestations include associated diabetes mellitus and steatorrhoea. Abdominal radiographs

show calcification in the region of pancreas and presence of pancreatic calculi in the ducts.

ETIOLOGY Most cases of chronic pancreatitis are caused by the same factors as for acute pancreatitis. Thus, most commonly, chronic pancreatitis is related to *chronic alcoholism* with protein-rich diet, and less often to *biliary tract disease*. *Familial hereditary pancreatitis*, though uncommon, is more frequently chronic than the acute form. Other rare causes of chronic pancreatitis are hypercalcaemia, hyperlipidaemia and developmental failure of fusion of dorsal and ventral pancreatic ducts.

PATHOGENESIS Acute haemorrhagic pancreatitis seldom develops into chronic pancreatitis, but instead develops pancreatic pseudocysts following recovery. Pathogenesis of alcoholic and non-alcoholic chronic pancreatitis is explained by different mechanisms:

1. Chronic pancreatitis due to *chronic alcoholism* accompanied by a high-protein diet results in increase in protein concentration in the pancreatic juice which obstructs the ducts and causes damage.
2. *Non-alcoholic cases* of chronic pancreatitis seen in tropical countries (tropical chronic pancreatitis) result from protein-calorie malnutrition. Genetic factors play a role in some cases of chronic pancreatitis.

MORPHOLOGIC FEATURES *Grossly*, the pancreas is enlarged, firm and nodular. The cut surface shows a smooth grey appearance with loss of normal lobulation. Foci of calcification and tiny pancreatic concretions to larger visible stones are frequently found. Pseudocysts may be present.

Microscopically, depending upon the stage of development, the following changes are seen (**Fig. 19.48**):

1. Obstruction of the ducts by fibrosis in the wall and protein plugs or stones in the lumina.

Figure 19.48 Chronic pancreatitis. There is destruction of acinar tissue and presence of dystrophic calcification. The necrotic tissue is surrounded by mixed inflammatory infiltrate with granulation tissue formation.

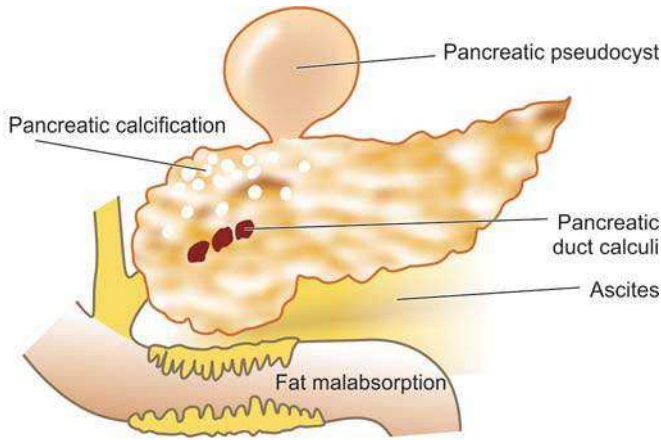

Figure 19.49 Complications of chronic pancreatitis.

2. Squamous metaplasia and dilatation of some inter- and intralobular ducts.
3. Chronic inflammatory infiltrate around the lobules as well as the ducts.
4. Atrophy of the acinar tissue with marked increase in interlobular fibrous tissue.
5. Islet tissue is involved in late stage only.

COMPLICATIONS Late stage of chronic pancreatitis may be complicated by diabetes mellitus, pancreatic insufficiency with steatorrhoea and malabsorption and formation of pancreatic pseudocysts (Fig. 19.49).

GIST BOX 19.16 Pancreatitis

- ▣ Acute pancreatitis presents clinically with 'acute abdomen'.
- ▣ The two leading causes associated with acute pancreatitis are alcoholism and cholelithiasis.
- ▣ Chronic pancreatitis is the progressive destruction of the pancreas due to repeated mild and subclinical attacks of acute pancreatitis.
- ▣ Chronic pancreatitis may be complicated by diabetes mellitus, steatorrhoea and pancreatic pseudocysts.

TUMOURS AND TUMOUR-LIKE LESIONS

Tumour-like masses of the exocrine pancreas include *congenital cystic disease* (involving the pancreas, liver and kidney) and *pancreatic pseudocysts*. True pancreatic tumours are classified into *benign* (e.g. serous cystadenoma, fibroma, lipoma and adenoma) and *malignant* (i.e. carcinoma of the pancreas). Out of all these, only two pancreatic lesions—pseudocyst and carcinoma of the pancreas, are common and are discussed below.

PANCREATIC PSEUDOCYST

Pancreatic pseudocyst is a localised collection of pancreatic juice, necrotic debris and haemorrhages. It develops following either acute pancreatitis or trauma. The patients generally present with abdominal mass producing pain, intraperitoneal haemorrhage and generalised peritonitis.

MORPHOLOGIC FEATURES *Grossly*, the pseudocyst may be present within or adjacent to the pancreas. Usually it is solitary, unilocular, measuring up to 10 cm in diameter with thin or thick wall (Fig. 19.49).

Microscopically, the cyst wall is composed of dense fibrous tissue with marked inflammatory reaction. There is evidence of preceding haemorrhage and necrosis in the form of deposits of haemosiderin pigment, calcium and cholesterol crystals. The lumen of the cyst contains serous or turbid fluid. The cyst does not show any epithelial lining.

CARCINOMA OF PANCREAS

Pancreatic cancer is the term used for cancer of the exocrine pancreas. It is one of the common cancers, particularly in the Western countries and Japan. In the United States, cancer of the pancreas is the second most common cancer of the alimentary tract after colorectal cancer, is more common in African Americans and accounts for 5% of all cancer deaths in that country. It is commoner in males than in females and the incidence increases progressively after the age of 50 years.

ETIOLOGY A significant increase in the incidence of pancreatic cancer has been observed in the UK and US during the last 50 years. Little is known about etiology of pancreatic cancer. However, following factors have been implicated in its etiology:

1. *Smoking*: Heavy cigarette smokers have higher incidence than the non-smokers. However, it is not known whether tobacco metabolites have a direct carcinogenic effect on the pancreas or by some other unknown mechanism.
2. *Diet and obesity*: Diet with high total caloric value and high consumption of animal proteins and fats is related to higher incidence of pancreatic cancer. Obesity is a risk factor for pancreatic cancer.
3. *Chemical carcinogens*: Individuals exposed to β -naphthylamine, benzidine and nitrosamines have higher incidence of cancer of the pancreas.
4. *Diabetes mellitus*: Patients of long-standing diabetes mellitus have a higher incidence.
5. *Chronic pancreatitis* patients are at increased risk.
6. *H. pylori infection* has been reported to have association with pancreatic cancer.
7. *Genetic factors* have been found to have association with pancreatic cancer e.g. its occurrence in first-degree relatives in 10% cases, occurrence in certain hereditary syndromes (Lynch, FPC, HNPCC).

However, excessive consumption of alcohol or coffee, and cholelithiasis are not risk factors for pancreatic cancer. A combination of mutations in *K-RAS* gene and *CDKN2A* gene have been found in almost all cases of cancer of the pancreas.

MORPHOLOGIC FEATURES The most common location of pancreatic cancer is the head of pancreas (70%), followed in decreasing frequency, by the body and the tail of pancreas (Fig. 19.50).

Grossly, carcinoma of the head of pancreas is generally small, homogeneous, poorly-defined, grey-white mass without any sharp demarcation between the tumour and

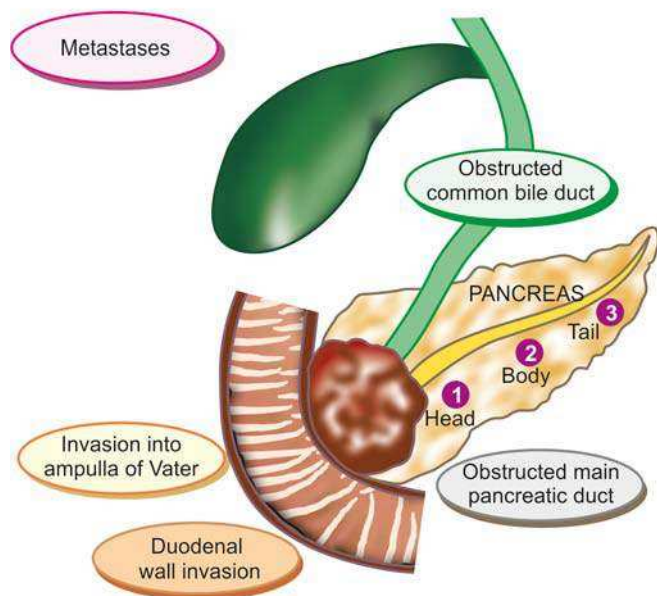

Figure 19.50 Distribution of carcinoma of the pancreas (numbered serially) and its major effects.

the surrounding pancreatic parenchyma. The tumour of the head extends into the ampulla of Vater, common bile duct and duodenum, producing obstructive biliary symptoms and jaundice early in the course of illness. Carcinomas of the body and tail of the pancreas, on the other hand, are fairly large and irregular masses and frequently infiltrate the transverse colon, stomach, liver, spleen and regional lymph nodes.

Microscopically, most pancreatic carcinomas arise from the ductal epithelium which normally comprises less than 4% of total pancreatic cells, whereas carcinoma of the acini constitutes less than 1% of pancreatic cancers. The following histologic patterns of pancreatic carcinoma are seen:

1. *Well-differentiated adenocarcinoma*, both mucinous and non-mucin secreting type, is the most common pattern. Perineural invasion is commonly present and is diagnostic of malignancy.
2. *Adenoacanthoma* consisting of glandular carcinoma and benign squamous elements is seen in a proportion of cases.
3. Rarely, peculiar *tumour giant cell formation* is seen with marked anaplasia, pleomorphism and numerous mitoses.
4. *Acinar cell carcinoma* occurs rarely and reproduces the pattern of acini in normal pancreas.

CLINICAL FEATURES Clinical symptoms depend upon the site of origin of the tumour. Generally, the following features are present:

1. **Obstructive jaundice** More often and early in the course of disease in cases with carcinoma head of the pancreas (80%), and less often in cancer of the body and tail of the pancreas. It is characterised by: dark urine, clay-like stools, pruritus, and very high serum alkaline phosphatase.
2. **Other features** These include: abdominal pain, anorexia, weight loss, cachexia, weakness and malaise, nausea and vomiting, and migratory thrombophlebitis (Trousseau's syndrome), GI bleeding and splenomegaly.

The prognosis of pancreatic cancer is dismal: median survival is 6 months from the time of diagnosis. Approximately 10% patients survive 1 year and the 5-year survival is poor 1 to 2%.

GIST BOX 19.17 Tumours and Tumour-like Lesions of Pancreas

- ▣ Pancreatic pseudocyst is a localised collection of pancreatic juice, necrotic debris and haemorrhages. It develops following either acute pancreatitis or trauma.
- ▣ The most common location of pancreatic cancer is the head of pancreas (70%). Major clinical features are obstructive jaundice, abdominal pain and anorexia.

✿ CLINICAL CASE 17

A 65 years old male complains of progressive abdominal distension, H/O loss of weight and appetite, progressive weakness and malaise, all for the last 6 months. He also had two episodes of haematemesis during this period. He gives history of having undergone coronary bypass surgery 15 years back when he received multiple blood transfusions. He denies use of alcohol since then, although prior to his surgery he used to occasionally drink. He also gives history of smoking about 20 cigarettes/day for about 20 years prior to bypass surgery but is now a non-smoker.

On examination, he has pallor, mild pedal oedema and jaundice. Abdomen is distended, the liver is palpable 4 cm below costal margin, tender and has a nodular feel. Spleen is palpable up to mid-umbilicus.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 910 (Appendix II)

✿ CLINICAL CASE 18

A 48 years old obese woman complains of severe ache in the right upper quadrant of the abdomen with radiation to interscapular area and yellowish discoloration of sclera for 2 days. She has also been having nausea and vomiting. She gives history of intermittent dull pain in the upper abdomen and bloating for the last 6 months, lasting for 1-2 days and gets relieved after taking some home remedies but she did not consult any physician for this. She has also been having intermittent malabsorption and flatulence, especially after meal for the last 6 months.

On examination, she has pallor +, icterus++, pedal edema+, pulse 90/min, blood pressure 130/90 mmHg. On deep palpation of the abdomen, there is pain in right hypochondrium. However, there is no fever, or any hepatosplenomegaly.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 911 (Appendix II)

CLINICAL CASE 19

A 65 years old male patient is brought to the hospital emergency with deep jaundice, moderate fever and pain in right hyochondrium for the last 2 weeks. He is also passing high coloured urine and clay coloured stools for the same duration. He also complains of intense itching, especially after taking bath. On further inquiry, he is found to have lost 10 kg weight during the last 2 months. He also gives history of smoking about 20 cigarettes/day for 40 years. There is history of alcohol intake on social occasions, 2-3 pegs about once a week, for the last 40 years.

On physical examination, there is a hard nodular mass in the midepigastrium. The liver is just palpable below costal margin, tender with smooth lower border.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

The Kidney and Lower Urinary Tract

KIDNEY

NORMAL STRUCTURE

ANATOMY The kidneys are bean-shaped paired organs, each weighing about 150 gm in the adult male and about 135 gm in the adult female. The hilum of the kidney is situated at the midpoint on the medial aspect where the artery, vein, lymphatics and ureter are located. The kidney is surrounded by a thin fibrous capsule which is adherent at the hilum.

Cut surface of the kidney shows 3 main structures: well-demarcated *peripheral cortex*, *inner medulla* and the innermost *renal pelvis* (Fig. 20.1):

◆ The **renal cortex** forms the outer rim of the kidney and is about 1 cm in thickness. It contains all the glomeruli and about 85% of the nephron tubules. Remaining 15% nephrons consisting of collecting tubules, collecting ducts, loops of Henle and vasa recta send their loops into the medulla, and are therefore called juxtamedullary nephrons. This latter part of the cortex forms faint striations called *medullary rays*, a misnomer since these structures are located in the cortex but are destined for medulla. Columns of renal cortical tissue that extend into the space between adjacent pyramids are called the *renal column (septa) of Bertin*; they contain the interlobar arteries.

◆ The **renal medulla** is composed of 8-18 cone-shaped renal pyramids. The base of a renal pyramid lies adjacent to the outer cortex and forms the cortico-medullary junction, while the apex of each called the *renal papilla* contains the opening of each renal pyramid for passage of urine collected from collecting ducts and goes down into minor calyces.

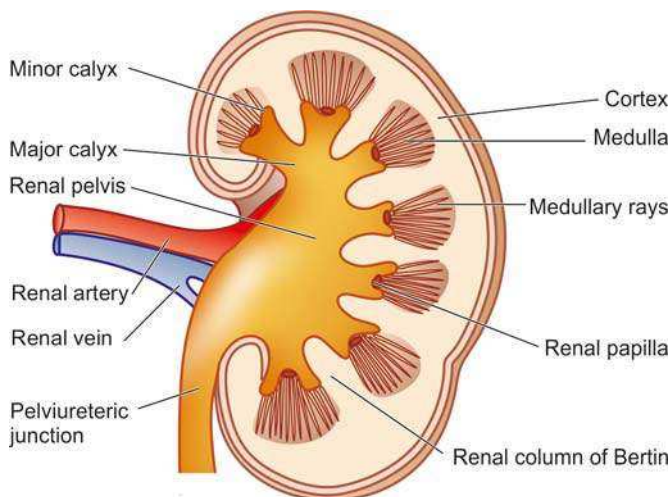

Figure 20.1 Cross-section of the kidney showing gross structures.

◆ The **renal pelvis** is the funnel-shaped collection area of the urine for drainage into the ureter. The minor calyces (8-18 in number in a normal kidney) collect urine from renal papillae and drain into major calyces (2-3 in a normal kidney).

HISTOLOGY The parenchyma of each kidney is composed of approximately one million microstructures called nephrons. A nephron, in turn, consists of 5 major parts, each having a functional role in the formation of urine: the glomerular capsule (glomerulus and Bowman's capsule), the proximal convoluted tubule (PCT), the loop of Henle, the distal convoluted tubule (DCT), and the collecting ducts. From point of view of diseases of the kidneys, 4 components of renal parenchyma require further elaboration: renal vasculature, glomeruli, tubules and interstitium.

1. Renal vasculature Each kidney is supplied with blood by a main *renal artery* which arises from the aorta at the level of the 2nd lumbar vertebra. It usually divides into *anterior and posterior divisions* at the hilum although occasionally these divisions may even arise directly from the aorta. The anterior and posterior divisions divide into *segmental branches* from which *interlobar arteries* arise which course between the lobes. Along their course, they give off the *arcuate arteries* which arch between the cortex and medulla. The arcuate arteries, in turn, give off *interlobular arteries* which lie in the cortex perpendicular to the capsular surface in the part overlying the pyramids and, therefore, are also called *straight arteries* (Fig. 20.2). It is from the interlobular arteries that the *afferent arterioles* take their origin, each one supplying a single glomerulus. From the glomerulus emerge the *efferent arterioles*. Up to this stage, the arteries and arterioles are end-vessels. The efferent arterioles leaving the glomerulus supply *peritubular*

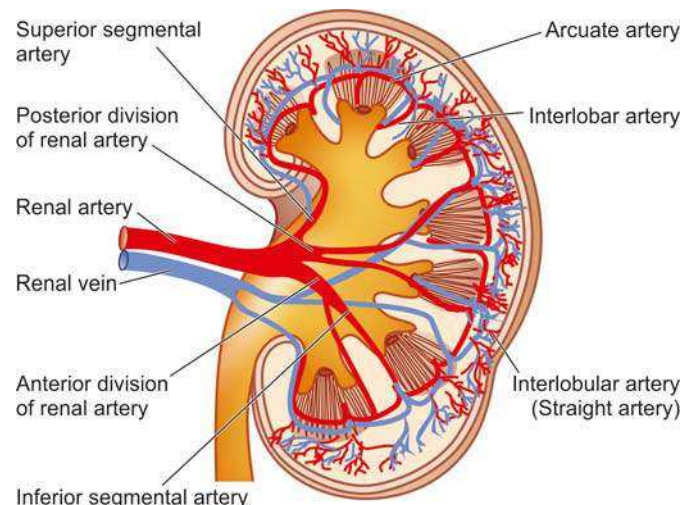

Figure 20.2 Cross-section of the kidney showing arterial blood supply.

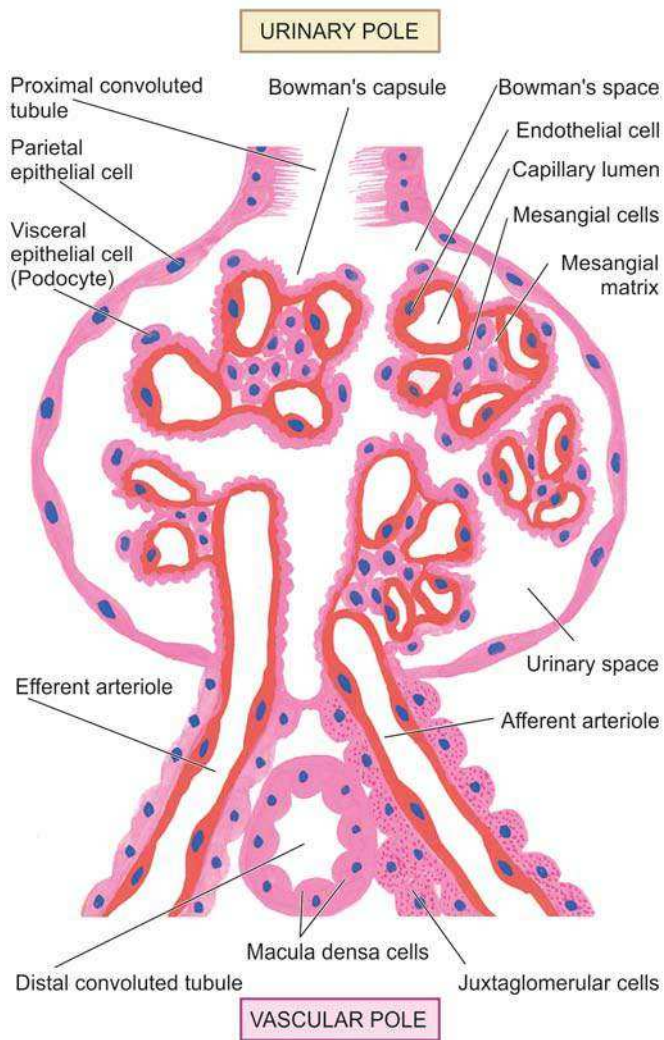

Figure 20.3 A schematic illustration of the structure of a nephron (in longitudinal section) and associated blood supply.

capillary plexus which anastomoses with the capillary plexus of another nephron.

The juxtamedullary glomeruli, however, give off a series of parallel vessels called *vasa recta* which descend to the inner medulla supplying the loop of Henle and collecting ducts and anastomose at all levels throughout the medulla with the ascending *vasa recta*. These drain into *arcuate veins* and then into the veins that accompany the corresponding arteries and finally through a single renal vein into the inferior vena cava (Fig. 20.3). Lymphatic drainage likewise occurs through lymphatics associated with the intrarenal vasculature leaving the kidney at the hilum and draining to lateral aortic lymph nodes.

The following important inferences can be drawn from the peculiarities of the renal vasculature:

- i) The renal cortex receives about 90% of the total renal blood supply and that the pressure in the glomerular capillaries is high. Therefore, renal cortex is more prone to the effects of hypertension.
- ii) The renal medulla, on the other hand, is poorly perfused and any interference in blood supply to it results in medullary necrosis.

iii) The divisions and subdivisions of the renal artery up to arterioles are end-arteries and have no anastomoses. Thus, occlusion of any of the branches results in infarction of the renal parenchyma supplied by it.

iv) Since the tubular capillary beds are derived from the efferent arterioles leaving the glomeruli, diseases affecting the blood flow through glomerular tuft have significant effects on the tubules as well.

2. Glomerulus The glomerulus consists of invagination of the blind end of the proximal tubule and contains a *capillary tuft* fed by the afferent arteriole and drained by efferent arteriole. These capillaries are lined by discontinuous endothelial cells. The capillary tuft is covered by visceral epithelial cells (podocytes) which are continuous with those of the parietal epithelium at the *vascular pole*. The transition to proximal tubular cells occurs at the *urinary pole* of the glomerulus. The visceral and parietal epithelial cells are separated by the urinary space or *Bowman's space*, into which glomerular filtrate passes (Fig. 20.4).

Subdivisions of capillaries derived from the afferent arterioles result in the formation of *lobules* (up to 8 in number) within a glomerulus. Each lobule of a glomerular tuft consists of a centrilobular supporting stalk composed of mesangium containing *mesangial cells* (≤ 3 per lobule) and *mesangial matrix*. The mesangium is continuous at the hilum with the *lacis cells* of the juxtaglomerular apparatus. Besides their role as supportive cells, mesangial cells are involved in the production of mesangial matrix and glomerular basement membrane; they function in endocytosis of leaked macromolecules and also possibly in the control of glomerular blood flow through contractile elements present in these cells.

The major *function* of glomerulus is complex filtration from the capillaries to the urinary space. Glomerular filtrate is quite similar in composition to plasma but lacks proteins and cells. Normally, glomerular filtration rate (GFR) is about 125 ml/minute. The barrier to glomerular filtration consists of the following 3 components (Fig. 20.5):

- i) Fenestrated endothelial cells lining the capillary loops.
- ii) Glomerular basement membrane (GBM) on which the endothelial cells rest. It further consists of 3 layers—the central lamina densa, bounded by lamina rara interna on endothelial side of the capillary and lamina rara externa on visceral epithelial side of the capillary.
- iii) Filtration slit pores between the foot processes of the visceral epithelial cells (podocytes) external to GBM.

The barrier to filtration of macromolecules of the size and molecular weight of albumin and larger depends upon the following:

- a) A normal lamina densa.
- b) Maintenance of negative charge on both laminae.
- c) A healthy covering of glomerular epithelial cells.

Juxtaglomerular apparatus The juxtaglomerular apparatus (JGA) is situated at the vascular pole of the glomerulus and is made up of 3 parts (Fig. 20.4):

- i) The *juxtaglomerular cells* are modified granular smooth muscle cells in the media of the afferent arteriole and contain the hormone, renin.
- ii) The *macula densa* is comprised by specialised region of the distal tubule when it returns to the vascular pole of its parent glomerulus. The tubular cells here are taller and narrower than elsewhere with the nuclei lying close together.

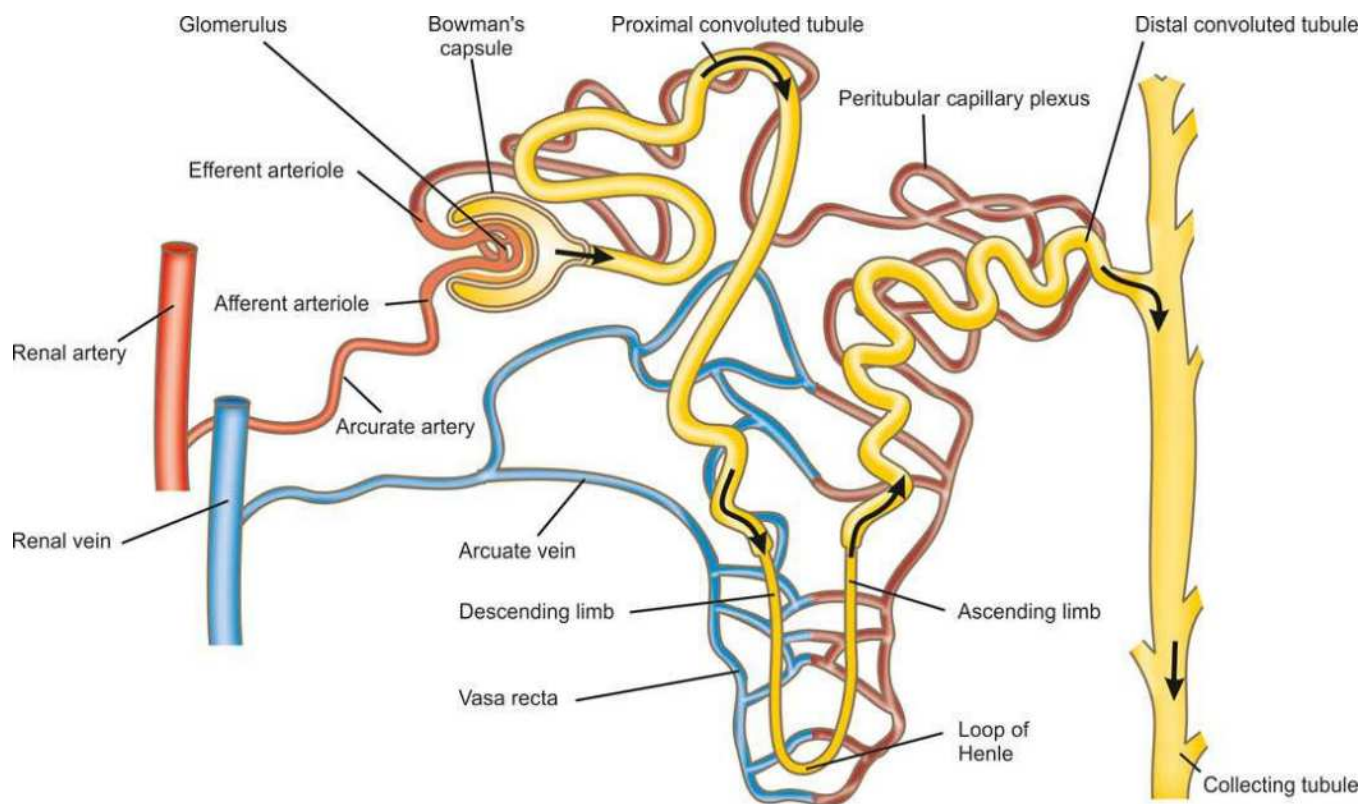

Figure 20.4 Structure of a nephron.

iii) The *lacis cells* or *non-granular cells* occupy the space between the macula densa and the arterioles and merge with the glomerular mesangium.

The JGA is intimately concerned with sodium metabolism and is the principal source of renin production. The mechanism of the release of renin and its role in hypertension are discussed on page 676.

3. Tubules The tubules of the kidney account for the greatest amount of the renal parenchyma. The structure of renal tubular epithelium varies in different parts of the nephron and is correlated with the functional capacity of that part of the tubule (see Fig. 20.4).

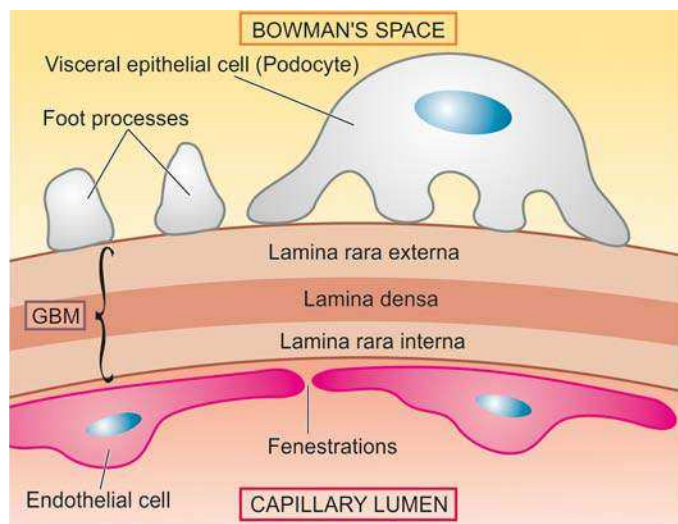

Figure 20.5 Ultrastructure of glomerular filtration barrier.

i) *Proximal convoluted tubule (PCT)* This is the first part arising from the glomerulus and is highly specialised part functionally. It is lined by cuboidal cells with a brush border composed of microvilli and contains numerous mitochondria, Golgi apparatus and endoplasmic reticulum. The major functions of PCT are: *active reabsorption* of filtered sodium, potassium, glucose, amino acids, proteins, vitamins, bicarbonate, phosphate, calcium and uric acid, and *passive reabsorption* of 80% of filtered water.

ii) *Loop of Henle* The PCT drains into the straight part of loop of Henle that consists of thin descending, and thin and thick ascending limbs, both of which have different structure and function. The descending limb is continuation of PCT, while ascending limb continues further into distal convoluted tubule (DCT). The descending segment of loop is lined by simple epithelium while the ascending limb is lined by columnar cells. The major function of loop of Henle is *active reabsorption* of sodium, potassium and chloride, and *passive diffusion* of water resulting in concentrated filtrate of urine.

iii) *Distal convoluted tubule (DCT)* The DCT represents a transition from thick ascending limb from the point where the ascending limb meets the vascular pole of the glomerulus of its origin, to the early collecting ducts. The lining cells in DCT are cuboidal. The epithelial cells at the point of beginning of DCT are taller, narrower and more closely packed to form the macula densa of JGA as already described. The DCT further contributes to urinary concentration and acidification, while the macula densa of JGA is the source of renin and has a role in sodium metabolism.

iv) *Collecting ducts* The system of collecting ducts is the final pathway by which urine reaches the tip of renal papilla. The cells lining the collecting ducts are cuboidal but lack the brush

border. Collecting ducts reabsorb water under control of ADH, and secrete H^+ and K^+ ions.

4. Interstitium In health, the renal cortical interstitium is scanty and consists of a small number of fibroblast-like cells. But the medullary interstitium is more plentiful and contains stellate interstitial cells which are considered to produce an anti-hypertensive agent and are involved in the metabolism of prostaglandins.

GIST BOX 20.1 Normal Structure of Kidney

- ▣ Each normal kidney weighs about 150 gm in the adult male and about 135 gm in the adult female.
- ▣ Cut surface of the kidney shows peripheral cortex, inner medulla and the innermost renal pelvis.
- ▣ Histologically, renal parenchyma is composed of 4 main components: renal vasculature, glomeruli, tubules and interstitium.
- ▣ Glomeruli have lobules having central stalk containing mesangial cells and matrix. Lobules have tuft of capillaries lined by endothelial cells and supported by visceral epithelial cells (podocytes).
- ▣ Bowman's space is lined by parietal epithelial cells.
- ▣ Glomerular basement membrane has lamina densa in the centre and bounded on either side by lamina rara.

RENAL FUNCTION TESTS

In general, the kidney performs the following vital functions in the body:

1. *Excretion of waste products* resulting from protein metabolism.
2. *Regulation of acid-base balance* by excretion of H^+ ions (acidification) and bicarbonate ions.
3. *Regulation of salt-water balance* by hormones secreted both intra- and extra-renally.
4. *Formation of renin and erythropoietin* and thereby playing a role in the regulation of blood pressure and erythropoiesis respectively.

In order to assess renal function, a number of tests have been devised which give information regarding the following parameters:

- a) Renal blood flow
- b) Glomerular filtration
- c) Renal tubular function
- d) Urinary outflow unhindered by any obstruction.

Renal function tests are broadly divided into 4 groups (Table 20.1):

1. Urine analysis.
2. Concentration and dilution tests.
3. Blood chemistry.
4. Renal clearance tests.

In addition, renal biopsy is performed to confirm the diagnosis of renal disease. Renal biopsy is ideally fixed in alcoholic Bouin's solution and examined by routine morphology combined with special stains and for further studies as under:

1. *Periodic acid-Schiff* stain for highlighting glomerular basement membrane.
2. *Silver impregnation* to outline the glomerular and tubular basement membrane.

Table 20.1 Renal function tests.

1. URINE ANALYSIS
 - i) Physical examination (output, colour, specific gravity, pH, osmolality)
 - ii) Chemical constituents (protein, glucose, red cells, haemoglobin)
 - iii) Bacteriologic examination
 - iv) Microscopy
2. CONCENTRATION AND DILUTION TESTS
 - i) Concentration test (fluid deprivation test)
 - ii) Dilution test (excess fluid intake test)
3. BLOOD CHEMISTRY
 - i) Urea
 - ii) Blood urea nitrogen (BUN)
 - iii) Creatinine
 - iv) β_2 -microglobulin
4. RENAL CLEARANCE TEST
 - i) Inulin or mannitol clearance test
 - ii) Creatinine clearance
 - iii) Urea clearance
 - iv) Para-aminohippuric acid (PAH) clearance

3. *Immunofluorescence* to localise the antigens, complements and immunoglobulins.

4. *Electron microscopy* to see the ultrastructure of glomerular changes.

1. URINE ANALYSIS The simplest diagnostic tests for renal function is the physical, chemical, bacteriologic and microscopic examination of the urine.

i) The *physical examination* includes 24-hour urinary output, colour, specific gravity and osmolality. Normally urine is clear, pale or straw-coloured due to pigment urochrome and 700-2500 ml (average 1200 ml) of urine is passed in 24 hours, mostly during day time. Specific gravity is used to measure the concentrating and diluting power of the kidneys.

ii) The *chemical tests* are carried out to detect the presence of protein, glucose, red cells and haemoglobin to assess the permeability of glomerular membrane. A number of convenient dipstick tests are available for testing these chemical substances and pH. These consist of paper strips impregnated with appropriate reagents and indicator dyes.

iii) The *bacteriologic examination* of the urine is done by proper and aseptic collection of midstream specimen of urine.

iv) *Urine microscopy* is undertaken on a fresh unstained sample. Various components observed on microscopic examination of the urine in renal disease are red cells, pus cells, epithelial cells, crystals and urinary casts. The casts are moulded into cylindrical shapes by passage along tubules in which they are formed. They are the result of precipitation of proteins in the tubule that includes not only albumin but also the tubular secretion of the *Tamm Horsfall protein*. The latter is a high molecular weight glycoprotein normally secreted by ascending loop of Henle and DCT and probably has body defense function normally. Its secretion is increased in glomerular and tubular diseases. Casts may be *hyaline type* consisting of only proteins indicating a non-inflammatory etiology of glomerular filtration of proteins, *leucocyte casts* inflammatory in origin, or *red cell casts* from haematuria.

2. CONCENTRATION AND DILUTION TESTS Concentration and dilution tests are designed to evaluate functional capacity of the renal tubules. The ability of the nephron to concentrate or dilute urine is dependent upon both functional activity of the tubular cells in the renal medulla and the presence of antidiuretic hormone (ADH). Failure to achieve adequate urinary concentration can be due to either defects within the renal medulla (*nephrogenic diabetes insipidus*), or due to the lack of ADH (*central diabetes insipidus*).

Traditionally, urinary concentration is determined by specific gravity of the urine (normal range 1.003 to 1.030, average 1.018) which in cases of tubular disease remains constant at approximately 1.010 regardless of changing levels of plasma hydration. However, determination of urinary specific gravity provides only a rough estimate of osmolarity of the urine. The tubular disease can be diagnosed in its early stage by *water deprivation* (concentration) or *water excess* (dilution) tests.

i) In **concentration test**, an artificial fluid deprivation is induced in the patient for more than 20 hours. If the nephron is normal, water is selectively reabsorbed resulting in excretion of urine of high solute concentration (specific gravity of 1.025 or more). However, if the tubular cells are nonfunctional, the solute concentration of the urine will remain constant regardless of stress of water deprivation.

ii) In **dilution test**, an excess of fluid is given to the patient. Normally, renal compensation should result in excretion of urine with high water content and lower solute concentration (specific gravity of 1.003 or less). If the renal tubules are diseased, the concentration of solutes in the urine will remain constant irrespective of the excess water intake.

3. BLOOD CHEMISTRY Impairment of renal function results in elevation of end-products of protein metabolism. This includes increased accumulation of certain substances in the blood, chiefly urea (normal range 20-40 mg/dl), blood urea nitrogen (BUN) (normal range 10-20 mg/dl) and creatinine (normal range 0.6-1.2 mg/dl). An increase of these end-products in the blood is called *azotaemia*.

High levels of creatinine are associated with high levels of β_2 -microglobulin in the serum as well as urine, a low-molecular weight protein filtered excessively in the urine due to glomerular disease or due to increased production by the liver.

4. RENAL CLEARANCE TESTS A clearance test is employed to assess the rate of glomerular filtration and the renal blood flow. The rate of this filtration can be measured by determining the excretion rate of a substance which is filtered through the glomerulus but subsequently is neither reabsorbed nor secreted by the tubules. The glomerular filtration rate (normal 120 ml/minute in an average adult) is usually equal to clearance of that substance and is calculated from the following equation:

$$C = \frac{UV}{P} \text{ where}$$

C is the clearance of the substance in ml/ minute;

U is the concentration of the substance in the urine;

V is the volume of urine passed per minute; and

P is the concentration of the substance in the plasma.

The substances which are used for clearance tests include inulin, mannitol, creatinine and urea.

i) In **inulin or mannitol clearance tests**, an intravenous infusion of the substance inulin or mannitol is given to maintain constant plasma concentration and accurately timed urine samples are collected. Inulin, a mixture of fructose polymers, is considered the ideal substance for the clearance test since it is filtered from the glomerulus and is excreted unchanged in the urine.

ii) In **creatinine clearance test**, there is no need of intravenous infusion of creatinine since creatinine is normally released into plasma by muscle metabolism and a very small fraction of this substance is secreted by the tubules. The clearance of creatinine is determined by collecting urine over 24-hour period and a blood sample is withdrawn during the day. In spite of disadvantages like poor reproducibility and secretion of creatinine by the tubules, the 'endogenous' creatinine clearance test is easy and routinely employed method of estimating GFR.

iii) In **urea clearance test**, the sensitivity is much less than the creatinine or inulin clearance because plasma concentration of urea is affected by a number of factors (e.g. dietary protein, fluid intake, infection, trauma, surgery, and corticosteroids) and is partly reabsorbed by the tubules. Like in creatinine clearance, there is no need for intravenous infusion of urea.

iv) **Para-aminohippuric acid (PAH) clearance test** is employed to measure renal blood flow (unlike the preceding tests which measure GFR). PAH when infused intravenously is both filtered at the glomerulus as well as secreted by the tubules and its clearance is measured by determining its concentration in arterial blood and urine. Normally, renal blood flow is about 1200 ml per minute in an average adult.

GIST BOX 20.2

Renal Function Tests

- ☐ The simplest diagnostic tests for renal function is the physical, chemical, bacteriologic and microscopic examination of the urine.
- ☐ Concentration and dilution tests are designed to evaluate functional capacity of the renal tubules.
- ☐ Impaired renal functions results in elevation of end-products of protein metabolism, namely blood urea, blood urea nitrogen BUN and creatinine.
- ☐ A clearance test is employed to assess the rate of glomerular filtration and the renal blood flow. These include clearance tests for inulin, mannitol, creatinine, urea and para-aminohippuric acid.
- ☐ Renal biopsy is performed to establish the specific diagnosis of renal disease.

PATHOPHYSIOLOGY OF RENAL DISEASE: RENAL FAILURE

Traditionally, diseases of the kidneys initially evolve from the predominant involvement of one of the morphologic component (glomeruli, tubules, interstitium or blood vessels), but eventually all components are affected leading to *end-stage kidneys*. Accordingly, major groups of renal diseases are as under:

1. *Glomerular diseases*: These are most often immunologically-mediated and may be acute or chronic.
2. *Tubular diseases*: These are more likely to be caused by toxic or infectious agents and are often acute.

3. **Interstitial diseases:** These are likewise commonly due to toxic or infectious agents and quite often involve interstitium as well as tubules (tubulo-interstitial diseases).

4. **Vascular diseases:** These include changes in the nephron as a consequence of increased intra-glomerular pressure such as in hypertension or impaired blood flow.

Regardless of cause, renal disease usually results in the evolution of one of the two major pathological syndromes: *acute renal failure* and *chronic renal failure (or chronic kidney disease, CKD)*. The term '*azotaemia*' is used for biochemical abnormality characterised by elevation of the blood urea nitrogen (BUN) and creatinine levels, while '*uraemia*' is defined as association of these biochemical abnormalities with clinical signs and symptoms. The pathophysiological aspects of acute and chronic renal failure are briefly discussed below.

ACUTE RENAL FAILURE (ARF)

Acute renal failure (ARF) is a syndrome characterised by rapid onset of renal dysfunction, chiefly oliguria or anuria, and sudden increase in metabolic waste-products (urea and creatinine) in the blood with consequent development of uraemia.

ETIOPATHOGENESIS The causes of ARF may be classified as pre-renal, intra-renal and post-renal in nature.

1. Pre-renal causes Pre-renal diseases are those which cause sudden decrease in blood flow to the nephron. Renal ischaemia ultimately results in functional disorders or depression of GFR, or both. These causes include inadequate cardiac output and hypovolaemia or vascular disease causing reduced perfusion of the kidneys.

2. Intra-renal causes Intra-renal disease is characterised by disease of renal tissue itself. These include vascular disease of the arteries and arterioles within the kidney, diseases of glomeruli, acute tubular necrosis due to ischaemia, or the effect of a nephrotoxin, acute tubulointerstitial nephritis and pyelonephritis.

3. Post-renal causes Post-renal disease is characteristically caused by obstruction to the flow of urine anywhere along the renal tract distal to the opening of the collecting ducts. This may be caused by a mass within the lumen or from wall of the tract, or from external compression anywhere along the lower urinary tract—ureter, bladder neck or urethra.

It is important to note that ARF originating in pre- and post-renal disease such as by renal ischaemia or renal infection, eventually leads to intra-renal disease. Thus, full-blown ARF reflects some degree of nephron damage.

CLINICAL FEATURES The clinical features will depend to a large extent on the underlying cause of ARF and on the stage of the disease at which the patient presents. However, one of the following three major patterns usually emerge:

1. Syndrome of acute nephritis This is most frequently associated with acute post-streptococcal glomerulonephritis and rapidly progressive glomerulonephritis. Renal dysfunction results from extensive proliferation of epithelial cells in the glomeruli with consequent mild increase in glomerular permeability and decrease in GFR. The characteristic features

are: mild proteinuria, haematuria, oedema and mild hypertension. Fluid retention in acute nephritis syndrome appears to be due to both diminished GFR and increased salt and water reabsorption in distal nephron.

2. Syndrome accompanying tubular pathology When the ARF is caused by destruction of the tubular cells of the nephron as occurs in acute tubular necrosis (page 666), the disease typically progresses through 3 characteristic stages from oliguria to diuresis to recovery.

i) **Oliguric phase:** The initial oliguric phase lasting on an average from 7 to 10 days is characterised by urinary output of less than 400 ml per day. The decline in formation of the urine leads to accumulation of waste products of protein metabolism in the blood and resultant azotaemia, metabolic acidosis, hyperkalaemia, hypernatraemia and hypervolaemia due to secondary effects of circulatory overload and pulmonary oedema. The specific gravity of the urine is low but the concentration of sodium in urine tends to be elevated.

ii) **Diuretic phase:** With the onset of healing of tubules, there is improvement in urinary output. This is believed to occur due to drawing of water and sodium by preceding high levels of creatinine and urea as they move through the nephron so as to be excreted. Since tubular cells have not regained normal functional capacity, the urine is of low or fixed specific gravity.

iii) **Phase of recovery:** Full recovery with healing of tubular epithelial cells occurs in about half the cases, while others terminate in death. The process of healing may take up to one year with restoration of normal tubular function.

3. Pre-renal syndrome The ARF occurring secondary to disorders in which neither the glomerulus nor the tubules are damaged, results in pre-renal syndrome. Typically, this pattern is seen in marginal ischaemia caused by renal arterial obstruction, hypovolaemia, hypotension or cardiac insufficiency. Due to depressed renal blood flow, there is decrease in GFR causing oliguria, azotaemia (elevation of BUN and creatinine) and possible fluid retention and oedema. Since the tubular cells are functioning normally, the nephron retains its ability to concentrate the glomerular filtrate according to the adaptive needs.

CHRONIC RENAL FAILURE (CRF)

Chronic renal failure is a syndrome characterised by progressive and irreversible deterioration of renal function due to slow destruction of renal parenchyma, eventually terminating in death when sufficient number of nephrons have been damaged. Acidosis is the major problem in CRF with development of biochemical azotaemia and clinical uraemia syndrome.

ETIOPATHOGENESIS All chronic nephropathies can lead to CRF. The diseases leading to CRF can generally be classified into two major groups: *those causing glomerular pathology*, and *those causing tubulointerstitial pathology*. Though this classification is useful to facilitate study, the disease rarely remains confined to either glomeruli or tubulointerstitial tissue alone. In the final stage of CRF, all parts of the nephron are involved.

1. Diseases causing glomerular pathology A number of glomerular diseases associated with CRF have their patho-

genesis in immune mechanisms (page 649). Glomerular destruction results in changes in filtration process and leads to development of the nephrotic syndrome characterised by proteinuria, hypoalbuminaemia and oedema. The important examples of chronic glomerular diseases causing CRF are covered under two headings: primary and systemic.

i) *Primary glomerular pathology*: The major cause of CRF is chronic glomerulonephritis, usually initiated by various types of *glomerulonephritis* such as membranous glomerulonephritis, membranoproliferative glomerulonephritis, lipoid nephrosis (minimal change disease) and anti-glomerular basement membrane nephritis.

ii) *Systemic glomerular pathology*: Certain conditions originate outside the renal system but induce changes in the nephrons secondarily. Major examples of this type are systemic lupus erythematosus, serum sickness nephritis and diabetic nephropathy.

2. Diseases causing tubulointerstitial pathology Damage to tubulointerstitial tissues results in alterations in reabsorption and secretion of important constituents leading to excretion of large volumes of dilute urine. Tubulointerstitial diseases can be categorised according to initiating etiology into 4 groups: vascular, infectious, toxic and obstructive.

i) *Vascular causes*: Long-standing primary or essential hypertension produces characteristic changes in renal arteries and arterioles referred to as nephrosclerosis (page 677). Nephrosclerosis causes progressive renal vascular occlusion terminating in ischaemia and necrosis of renal tissue.

ii) *Infectious causes*: A good example of chronic renal infection causing CRF is chronic pyelonephritis. The chronicity of process results in progressive damage to increasing number of nephrons leading to CRF.

iii) *Toxic causes*: Some toxic substances induce slow tubular injury, eventually culminating in CRF. The most common example is intake of high doses of analgesics such as phenacetin, aspirin and acetaminophen (chronic analgesic nephritis). Other substances that can cause CRF after prolonged exposure are lead, cadmium and uranium.

iv) *Obstructive causes*: Chronic obstruction in the urinary tract leads to progressive damage to the nephron due to fluid back-pressure. The examples of this type of chronic injury are stones, blood clots, tumours, strictures and enlarged prostate.

Regardless of the initiating cause, CRF evolves progressively through 4 stages:

◆ **Decreased renal reserve** At this stage, damage to renal parenchyma is marginal and the kidneys remain functional. The GFR is about 50% of normal, BUN and creatinine values are normal and the patients are usually asymptomatic except at times of stress.

◆ **Renal insufficiency** At this stage, about 75% of functional renal parenchyma has been destroyed. The GFR is about 25% of normal accompanied by elevation in BUN and serum creatinine. Polyuria and nocturia occur due to tubulointerstitial damage. Sudden stress may precipitate uraemic syndrome.

◆ **Renal failure** At this stage, about 90% of functional renal tissue has been destroyed. The GFR is approximately 10% of normal. Tubular cells are essentially nonfunctional. As a result, the regulation of sodium and water is lost resulting in oedema,

metabolic acidosis, hypocalcaemia, and signs and symptoms of uraemia.

◆ **End-stage kidney (chronic kidney disease)** The GFR at this stage is less than 5% of normal and results in complex clinical picture of uraemic syndrome with progressive primary (renal) and secondary systemic (extra-renal) symptoms.

CLINICAL FEATURES Clinical manifestations of full-blown CRF culminating in uraemic syndrome are described under 2 main headings: primary (renal) uraemic manifestations and secondary (systemic or extra-renal) uraemic manifestations (**Fig. 20.6**):

A. Primary uraemic (renal) manifestations Primary symptoms of uraemia develop when there is slow and progressive deterioration of renal function. The resulting imbalances cause the following manifestations:

1. Metabolic acidosis As a result of renal dysfunction, acid-base balance is progressively lost. Excess of hydrogen ions occurs, while bicarbonate level declines in the blood, resulting in metabolic acidosis. The clinical symptoms of metabolic acidosis include: compensatory Kussmaul breathing, hyperkalaemia and hypercalcaemia.

2. Hyperkalaemia A decreased GFR results in excessive accumulation of potassium in the blood since potassium is normally excreted mainly in the urine. Hyperkalaemia is further worsened by metabolic acidosis. The clinical features of hyperkalaemia are: cardiac arrhythmias, weakness, nausea, intestinal colic, diarrhoea, muscular irritability and flaccid paralysis.

3. Sodium and water imbalance As GFR declines, sodium and water cannot pass sufficiently into Bowman's capsule leading to their retention. Release of renin from juxtaglomerular

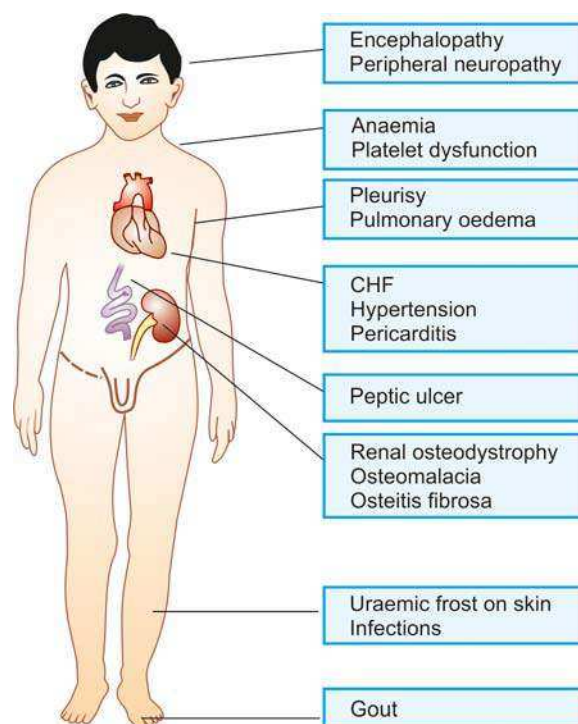

Figure 20.6 Clinical manifestations in chronic kidney disease.

apparatus further aggravates sodium and water retention. The main symptoms referable to sodium and water retention are: hypervolaemia and circulatory overload with congestive heart failure.

4. Hyperuricaemia Decreased GFR results in excessive accumulation of uric acid in the blood. Uric acid crystals may be deposited in joints and soft tissues resulting in gout.

5. Azotaemia The waste-products of protein metabolism fail to be excreted resulting in elevation in the blood levels of urea, creatinine, phenols and guanidines causing biochemical abnormality, azotaemia. The secondary manifestations of uraemia are related to toxic effects of these metabolic waste-products.

B. Secondary uraemic (extra-renal) manifestations A number of extra-renal systemic manifestations develop secondarily following fluid-electrolyte and acid-base imbalances. These include the following:

1. Anaemia Decreased production of erythropoietin by diseased kidney results in decline in erythropoiesis and anaemia. Besides, gastrointestinal bleeding may further aggravate anaemia.

2. Integumentary system Deposit of urinary pigment such as urochrome in the skin causes sallow-yellow colour. The urea content in the sweat as well as in the plasma rises. On evaporation of the perspiration, urea remains on the facial skin as powdery 'uraemic frost'.

3. Cardiovascular system Fluid retention secondarily causes cardiovascular symptoms such as increased workload on the heart due to the hypervolaemia and eventually congestive heart failure.

4. Respiratory system Hypervolaemia and heart failure cause pulmonary congestion and pulmonary oedema due to back pressure. Radiologically, uraemic pneumonitis shows characteristic central, butterfly-pattern of oedema and congestion in the chest radiograph.

5. Digestive system Azotaemia directly induces mucosal ulcerations in the lining of the stomach and intestines. Subsequent bleeding can aggravate the existing anaemia. Gastrointestinal irritation may cause nausea, vomiting and diarrhoea.

6. Skeletal system The skeletal manifestations of renal failure are referred to as *renal osteodystrophy* (page 827). Two major types of skeletal disorders may occur:

i) *Osteomalacia* occurs from deficiency of a form of vitamin D which is normally activated by the kidney (page 245). Since vitamin D is essential for absorption of calcium, its deficiency results in inadequate deposits of calcium in bone tissue.

ii) *Osteitis fibrosa* occurs due to elevated levels of parathormone. How parathormone excess develops in CRF is complex. As the GFR is decreased, increasing levels of phosphates accumulate in the extracellular fluid which, in turn, cause decline in calcium levels. Decreased calcium level triggers the secretion of parathormone which mobilises calcium from bone and increases renal tubular reabsorption of calcium thereby conserving it. However, if the process of resorption of calcium phosphate from bone continues for sufficient time, hypercalcaemia may be induced with deposits of excess calcium salts in joints and soft tissues and weakening of bones (renal osteodystrophy).

- ☐ Renal diseases, irrespective of cause, usually result in acute renal failure (ARF) and chronic renal failure (CRF).
- ☐ ARF may result from prerenal, intrarenal and postrenal causes. Clinically, ARF depending upon the stage, may result in syndrome of acute nephritis, or syndrome of tubular pathology.
- ☐ CRF is characterised by progressive and irreversible deterioration of renal function due to slow destruction of renal parenchyma, eventually terminating in death.
- ☐ CRF may be caused by diseases of glomeruli or tubulointerstitium.
- ☐ Clinically, CRF has uraemic manifestations. These may be primary or secondary and involve multiple organs and systems.

CONGENITAL MALFORMATIONS

Approximately 10% of all persons are born with potentially significant malformations of the urinary system. These range in severity from minor anomalies which may not produce clinical manifestations to major anomalies which are incompatible with extrauterine life. About half of all patients with malformations of the kidneys have coexistent anomalies either elsewhere in the urinary tract or in other organs.

Malformations of the kidneys are classified into 3 broad groups:

I. Abnormalities in amount of renal tissue These include: anomalies with deficient renal parenchyma (e.g. unilateral or bilateral renal hypoplasia) or with excess renal tissue (e.g. renomegaly, supernumerary kidneys).

II. Anomalies of position, form and orientation These are: renal ectopia (pelvic kidney), renal fusion (horseshoe kidney) and persistent foetal lobation.

III. Anomalies of differentiation This group consists of the more important and common morphologic forms covered under the heading of '*cystic diseases of the kidney*' described in detail below.

CYSTIC DISEASES OF KIDNEY

Cystic lesions of the kidney may be *congenital or acquired, non-neoplastic or neoplastic*. Majority of these lesions are congenital non-neoplastic. Cystic lesions in the kidney may occur at any age, extending from foetal life (detected on ultrasonography) to old age. Their clinical presentation may include: abdominal mass, infection, respiratory distress (due to accompanied pulmonary hypoplasia), haemorrhage, and neoplastic transformation.

Potter divided developmental renal cystic lesions into three types—I, II and III. A simple classification including all cystic lesions of the kidney is given in **Table 20.2** and illustrated in **Fig. 20.7**. Non-neoplastic cysts are discussed below while neoplastic cystic lesions of the kidney are described later (page 681).

I. Multicystic Renal Dysplasia

The term 'multicystic renal dysplasia' or Potter type II is used for disorganised metanephrogenic differentiation with persistence of structures in the kidney which are not represented in

Table 20.2 Classification of cystic lesions of the kidney.

- A. NON-NEOPLASTIC CYSTIC LESIONS
- I. Renal multicystic dysplasia (Potter type II)
 - II. Polycystic kidney disease (PKD)
 1. Adult (autosomal dominant) polycystic kidney disease (ADPKD) (Potter type III)
 2. Infantile (autosomal recessive) polycystic kidney disease (ARPKD) (Potter type I)
 - III. Medullary cystic disease
 1. Medullary sponge kidney (MSK)
 2. Nephronophthisis-medullary cystic disease complex
 - IV. Simple renal cysts
 - V. *Acquired renal cysts* (i. dialysis-associated cystic disease, ii. hydatid cyst, iii. tuberculosis, iv. renal cell carcinoma, v. traumatic intrarenal haematoma)
 - VI. *Para-renal cysts* (i. Pyelocalyceal, ii. hilar lymphangiectatic, iii. retroperitoneal, iv. perinephric pseudocysts from trauma)
- B. NEOPLASTIC CYSTIC LESIONS
- I. Cystic nephroma (page 681)
 - II. Cystic partially-differentiated nephroblastoma (CPDN)
 - III. Multifocal cystic change in Wilms' tumour (page 684)

normal nephrogenesis. Renal dysplasia is the most common form of cystic renal disease in the newborn and infants. The condition may occur sporadically or maybe familial and part of a syndrome of other anomalies. It is commonly associated with obstructive abnormalities of the ureter and lower urinary tract such as obstruction of pelviureteric junction (PUJ), ureteral atresia and urethral obstruction.

MORPHOLOGIC FEATURES Renal dysplasia may be unilateral or bilateral. The dysplastic process may involve the entire renal mass or a part of it.

Grossly, the dysplastic kidney is almost always cystic. The kidney or its affected part is replaced by disorderly mass of multiple cysts resembling a bunch of grapes. Normal renal parenchyma is almost totally obscured by the mass while calyces and pelvis may not be recognised. The ureter is invariably abnormal, being either absent or atretic.

Histologically, the characteristic feature is the presence of undifferentiated mesenchyme that contains smooth muscle, cartilage and immature collecting ducts. The cysts in the mass represent dilated tubules lined by flattened epithelium which are surrounded by concentric layers of connective tissue (Fig. 20.8). Glomeruli and tubules are scanty, primitive or absent.

CLINICAL FEATURES Unilateral renal dysplasia is frequently discovered in newborn or infants as a flank mass. Often, renal dysplasia is associated with other congenital malformations and syndromes such as ventricular septal defect, tracheo-esophageal fistula, lumbosacral meningomyelocele and Down's syndrome.

The prognosis of unilateral renal dysplasia following removal of the abnormal kidney is excellent while bilateral renal dysplasia results in death in infancy unless renal transplant is done.

II. Polycystic Kidney Disease

Polycystic disease of the kidney (PKD) is a disorder in which major portion of the renal parenchyma is converted into cysts of varying size. The disease occurs in two forms:

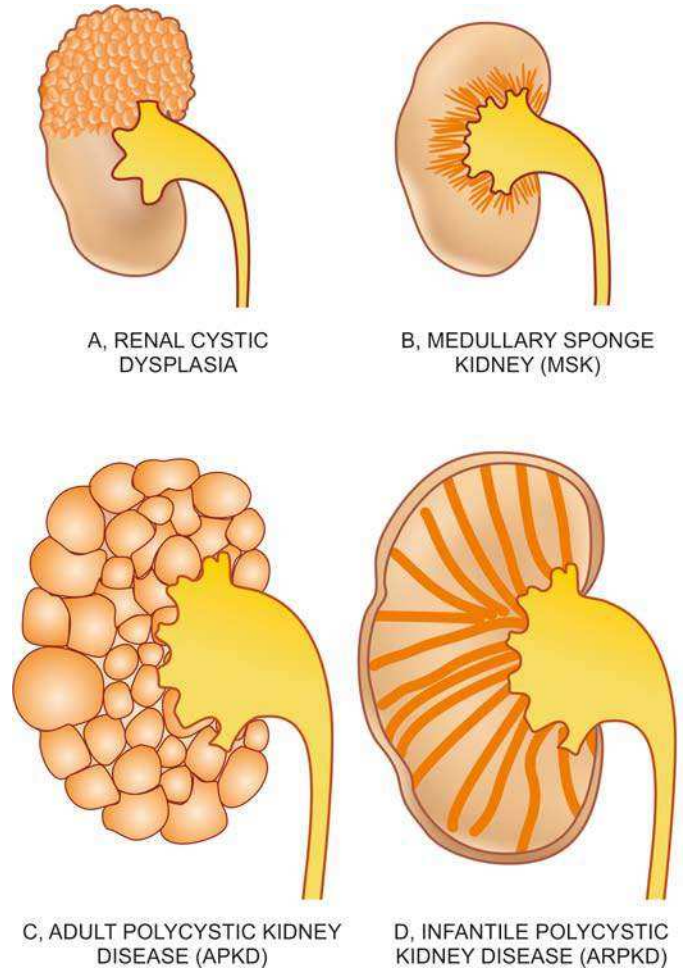

Figure 20.7 Cystic diseases of kidney.

A. An *adult type* inherited as an *autosomal dominant* disease; and

B. An *infantile type* inherited as an *autosomal recessive* disorder.

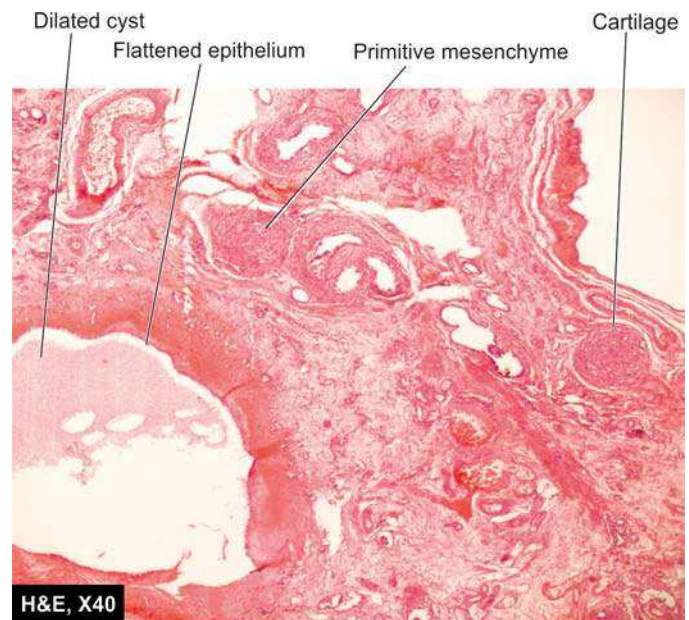

Figure 20.8 Renal cystic dysplasia. There are cysts lined by flattened epithelium while the intervening parenchyma consists of primitive connective tissue and cartilage.

A. ADULT POLYCYSTIC KIDNEY DISEASE

Adult (autosomal dominant) polycystic kidney disease (ADPKD) is relatively common (incidence 1:400 to 1:1000) and is the cause of end-stage renal failure in approximately 4% of haemodialysis patients. The pattern of inheritance is *autosomal dominant* with mutation in *PKD* gene: mutation in *PKD-1* gene located on chromosome 16 in over 85% cases (ADPKD-1) while remainder 15% cases have mutation in *PKD-2* gene located on chromosome 4 (ADPKD-2). Family history of similar renal disease may be present. The true adult polycystic renal disease is always bilateral and diffuse. Though the kidneys are abnormal at birth, renal function is retained, and symptoms appear in adult life, mostly between the age of 30 and 50 years.

MORPHOLOGIC FEATURES *Grossly*, kidneys in ADPKD are always bilaterally enlarged, usually symmetrically, heavy (weighing up to 4 kg) and give it a lobulated appearance on external surface due to underlying cysts. The cut surface shows cysts throughout the renal parenchyma varying in size from tiny cysts to 4-5 cm in diameter (Fig. 20.9,A). The contents of the cysts vary from clear straw-yellow fluid to reddish-brown material. The renal pelvis and calyces are present but are greatly distorted by the cysts and may contain concretions (Fig. 20.10). The cysts, however, do not communicate with the pelvis of the kidney—a feature that helps to distinguish polycystic kidney from hydronephrosis of the kidney on sectioned surface (page 674).

Histologically, the cysts arise from all parts of nephron. It is possible to find some cysts containing recognisable glomerular tufts reflecting their origin from Bowman's capsule, while others have epithelial lining like that of distal or proximal tubules or collecting ducts. The intervening tissue between the cysts shows some normal renal parenchyma. With advancement of age of the patient, acquired lesions such as pyelonephritis, nephrosclerosis, fibrosis and chronic inflammation are seen with increasingly frequency.

CLINICAL FEATURES The condition may become clinically apparent at any age but most commonly manifests in 3rd to 5th decades of life. The most frequent and earliest presenting

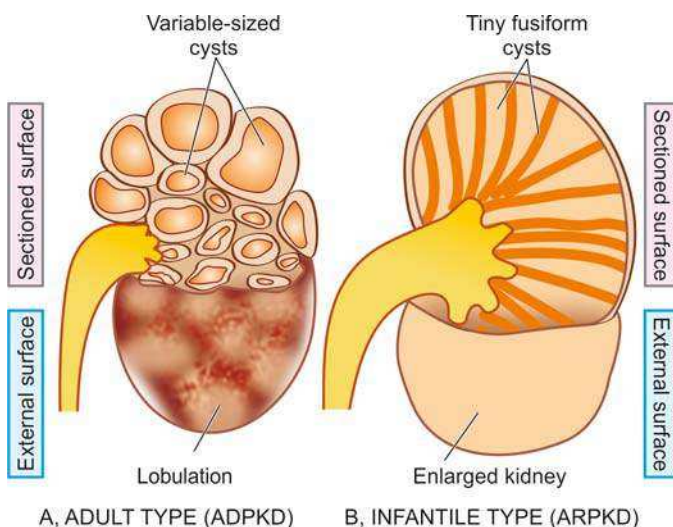

Figure 20.9 Polycystic kidney disease. Diagrammatic representation of comparison of gross appearance of the two main forms.

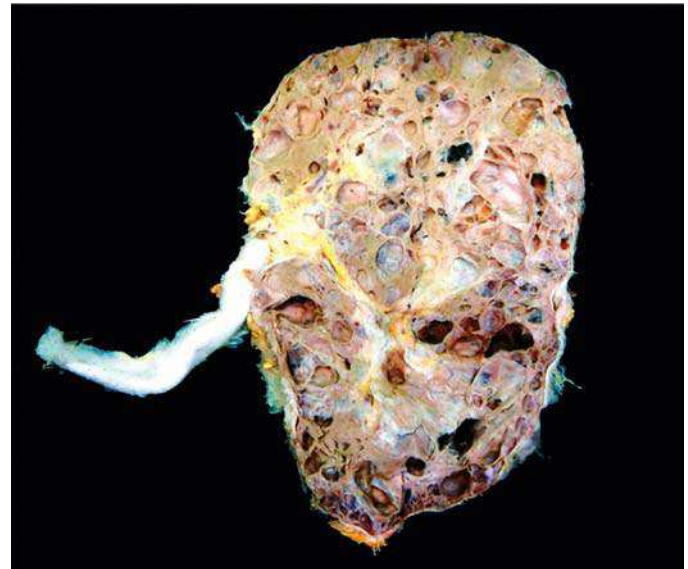

Figure 20.10 Adult (autosomal dominant) polycystic kidney disease (ADPKD). The kidney is enlarged and heavy. Sectioned surface shows loss of demarcation between cortex and medulla and replacement of the entire renal parenchyma by cysts varying in diameter from a few millimeters to 4-5 cm. These cysts are not communicating with the pelvi-calyceal system. The renal pelvis and calyces are distorted due to cystic change.

feature is a dull-ache in the lumbar regions. In others, the presenting complaints are haematuria or passage of blood clots in urine, renal colic, hypertension, urinary tract infection and progressive CRF with polyuria and proteinuria.

ADPKD is considered a systemic disease. About a third of patients with ADPKD have cysts of the liver (page 617). Other associated congenital anomalies seen less frequently are cysts in the pancreas, spleen, lungs and other organs. Approximately 15% of patients have one or more intracranial berry aneurysms of the circle of Willis. Any acquired renal disease is more prone to occur in polycystic kidneys.

B. INFANTILE POLYCYSTIC KIDNEY DISEASE

The infantile (autosomal recessive) form of polycystic kidney disease (ARPKD) is distinct from the adult form and is less common (incidence 1:20,000 births). It is transmitted as an *autosomal recessive* trait and the family history of similar disease is usually not present. The condition occurs due to a mutation in chromosome 6—*6p21*, *PKHD1* (polycystic kidney and hepatic disease 1). It is invariably bilateral. The age at presentation may be perinatal, neonatal, infantile or juvenile, but frequently serious manifestations are present at birth and result in death from renal failure in early childhood.

MORPHOLOGIC FEATURES *Grossly*, the kidneys are bilaterally enlarged with smooth external surface and retained normal reniform shape. Cut surface reveals small, fusiform or cylindrical cysts radiating from the medulla and extend radially to the outer cortex. This gives the sectioned surface of the kidney *sponge-like appearance* (Fig. 20.9,B). No normal renal parenchyma is grossly recognised. Pelvis, calyces and ureters are normal.

Histologically, the total number of nephrons is normal. Since the cysts are formed from dilatation of collecting

tubules, all the collecting tubules show cylindrical or saccular dilatations and are lined by cuboidal to low columnar epithelium. Many of the glomeruli are also cystically dilated.

CLINICAL FEATURES The clinical manifestations depend on age of the child. In severe form, the gross bilateral cystic renal enlargement may interfere with delivery. In infancy, renal failure may manifest early. Almost all cases of infantile polycystic kidney disease have associated multiple epithelium-lined cysts in the liver or proliferation of portal bile ductules. In older children, associated hepatic changes develop into what is termed *congenital hepatic fibrosis* which may lead to portal hypertension and splenomegaly.

The contrasting features of the two main forms of the polycystic kidney disease are presented in **Table 20.3**.

III. Medullary Cystic Disease

Cystic disease of the renal medulla has two main types:

- A. *Medullary sponge kidney*, a relatively common and innocuous condition; and
- B. *Nephronophthiasis-medullary cystic disease complex*, a common cause of chronic renal failure in juvenile age group.

A. MEDULLARY SPONGE KIDNEY

Medullary sponge kidney consists of multiple cystic dilatations of the papillary ducts in the medulla. It has an autosomal dominant transmission. The condition occurs in adults and may be recognised as an incidental radiographic finding in asymptomatic cases, or the patients may complain of colicky flank pain, dysuria, haematuria and passage of sandy material in the urine. Renal function remains largely normal or may be mildly impaired in long-standing disease with secondary complications of infection and calculus formation.

MORPHOLOGIC FEATURES *Grossly*, the kidneys may be enlarged, normal or shrunken in size depending upon the extent of secondary pyelonephritis. On cut surface, the characteristic feature is the presence of several, small (less

than 0.5 cm diameter), cystically dilated papillary ducts, which may contain spherical calculi.

Microscopically, the cysts are lined by tall columnar, cuboidal, transitional or squamous epithelium. Renal cortex may show secondary pyelonephritis but cortical cysts are never a component of medullary sponge kidney.

B. NEPHRONOPHTHIASIS-MEDULLARY CYSTIC DISEASE COMPLEX

This form of medullary cystic disease, also called *juvenile nephronophthiasis* or *uraemic sponge kidney*, is a progressive renal disease. It is classified into infantile, juvenile and adolescent type depending upon the age at presentation, juvenile form being the most common. It is the most common form of genetic cause of end-stage renal disease in children and adolescents. The condition has an autosomal recessive inheritance. Familial occurrence is common. The clinical manifestations are due to impaired urinary concentration consequent upon the medullary lesions and consist of polyuria, polydipsia and enuresis. Other features include renal osteodystrophy, growth retardation, anaemia and progressive renal failure leading to uraemia.

MORPHOLOGIC FEATURES *Grossly*, the kidneys are moderately reduced in size and granular and have narrow cortices. Cut surface reveals minute cysts, majority of which are present at the cortico-medullary junction.

Microscopically, the cysts are lined by flattened or cuboidal epithelium. There is widespread nonspecific chronic inflammatory infiltrate and interstitial fibrosis. Many glomeruli are hyalinised but tubular atrophy is more pronounced due to marked thickening of tubular basement membrane.

IV. Simple Renal Cysts

Simple renal cysts or cortical cysts are a very common postmortem finding. They are seen in about half of all persons above the age of 50 years. Since these cysts are rare in infants and children, they appear to be acquired rather than congenital

Table 20.3 Contrasting features of autosomal dominant (adult) and autosomal recessive (infantile) polycystic kidney disease (ADPKD versus ARPKD).

| FEATURE | ADPKD | ARPKD |
|--------------------------------|--|--|
| 1. <i>Inheritance</i> | Autosomal dominant | Autosomal recessive |
| 2. <i>Cytogenetic defect</i> | Chromosome 16 (85%): ADPKD-1 Chromosome 4 (15%): ADPKD-2 | Chromosome 6 |
| 3. <i>Mutations</i> | PKD 1 gene (85%) PKD 2 gene (15%) | 6p21 <i>PKHD1</i> |
| 4. <i>Incidence</i> | 1:400 to 1:1000 | 1:20,000 |
| 5. <i>Age at presentation</i> | Adults (3rd to 5th decades) | Infancy, perinatal |
| 6. <i>G/A</i> | Symmetric bilateral enlargement Macrocyts | Micro- and macrocyts radiating from medulla to outer cortex Enlarged, sometimes asymmetric, sponge-like |
| 7. <i>M/E</i> | Cysts derived from all parts of nephron (glomeruli, tubules) | Cysts from dilated collecting ducts |
| 8. <i>Other manifestations</i> | Intracranial aneurysms, cysts of other organs | None |

lesions. Simple cysts of the kidneys are rarely responsible for symptoms. However, symptoms may result from rupture, haemorrhage or infection. The association between simple cysts and hypertension is common.

MORPHOLOGIC FEATURES *Grossly*, simple renal cysts are usually solitary but may be multiple. They are commonly located in the cortex. Their size varies from a few millimeters to 10 cm in diameter. The wall of cyst is characteristically yellowish-white and translucent. The cyst usually contains clear straw-coloured fluid which may become rust-coloured due to haemorrhage.

Microscopically, the lining of the cyst is by flattened epithelium. The cyst wall contains variable amount of collagenised fibrous tissue which may occasionally have deposits of haemosiderin or calcium salts.

GIST BOX 20.4

Cystic Diseases of Kidney

- ▣ Multicystic renal dysplasia is a common condition in newborn and is disorganised metanephrogenic differentiation with persistence of structures in the kidney.
- ▣ Polycystic disease of the kidney is a disorder in which major portion of the renal parenchyma is converted into cysts of varying size. It has 2 types: adult and infantile
- ▣ Adult (autosomal dominant) polycystic kidney disease (ADPKD) is relatively common while the infantile (autosomal recessive) form (ARPKD) is less common.
- ▣ Cystic disease of the renal medulla has two main types: medullary sponge kidney causing small cystic dilatations of papillary ducts of medulla and nephronophthisis-medullary cystic disease complex.
- ▣ Simple renal cysts or cortical cysts are a very common postmortem finding.

GLOMERULAR DISEASES

DEFINITION AND CLASSIFICATION

Glomerular diseases encompass a large and clinically significant group of renal diseases. Glomerulonephritis (GN) or Bright's disease is the term used for diseases that primarily involve the renal glomeruli. It is convenient to classify glomerular diseases into 2 broad groups:

- I. *Primary glomerulonephritis* in which the glomeruli are the predominant site of involvement.
- II. *Secondary glomerular diseases* include certain systemic and hereditary diseases which secondarily affect the glomeruli.

Though this division is widely followed, it is somewhat arbitrary since many primary forms of glomerulonephritis have systemic effects, and many systemic diseases may initially present with glomerular involvement. Many classifications of different types of glomerulonephritis have been described, but most widely accepted classification is based on clinical presentation and pathologic changes in the glomeruli given in **Table 20.4**.

CLINICAL MANIFESTATIONS

The clinical presentation of glomerular disease is quite variable but in general four features—proteinuria, haematuria, hypertension and disturbed excretory function, are present

Table 20.4 Clinicopathologic classification of glomerular diseases.

| | |
|------|--|
| I. | PRIMARY GLOMERULONEPHRITIS |
| 1. | Acute GN |
| | i) Post-streptococcal |
| | ii) Non-streptococcal |
| 2. | Rapidly progressive GN |
| 3. | Minimal change disease |
| 4. | Membranous GN |
| 5. | Membrano-proliferative GN |
| 6. | Focal and diffuse proliferative GN |
| 7. | Focal segmental glomerulosclerosis (FSGS) |
| 8. | IgA nephropathy |
| 9. | Chronic glomerulonephritis |
| II. | SECONDARY SYSTEMIC GLOMERULAR DISEASES |
| 1. | Lupus nephritis (SLE) |
| 2. | Diabetic nephropathy |
| 3. | Amyloidosis (page 66) |
| 4. | Polyarteritis nodosa (page 383) |
| 5. | Wegener's granulomatosis (page 383) |
| 6. | Goodpasture's syndrome (page 655) |
| 7. | Henoch-Schönlein purpura (page 309) |
| 8. | Systemic infectious diseases (<i>bacterial</i> e.g. bacterial endocarditis, syphilis, leprosy; <i>viral</i> e.g. HBV, HCV, HIV; <i>parasitic</i> e.g. falciparum malaria, filariasis) |
| 9. | Idiopathic mixed cryoglobulinaemia |
| III. | HEREDITARY NEPHRITIS |
| 1. | Alport's syndrome |
| 2. | Fabry's disease |
| 3. | Nail-patella syndrome |

in varying combinations depending upon the underlying condition. A firm diagnosis, however, can be established by examination of renal biopsy under light, electron and immunofluorescence microscopy.

A number of clinical syndromes are recognised in glomerular diseases. Following six major glomerular syndromes are commonly found in different glomerular diseases:

- ◆ nephritic and nephrotic syndromes;
 - ◆ acute and chronic renal failure;
 - ◆ asymptomatic proteinuria and haematuria.
- These are briefly described below.

I. ACUTE NEPHRITIC SYNDROME This is the acute onset of microscopic haematuria, mild proteinuria, hypertension, oedema and oliguria following an infective illness about 10 to 20 days earlier.

1. **Haematuria** is generally slight giving the urine smoky appearance and erythrocytes are detectable by microscopy or by chemical testing for haemoglobin. Appearance of red cell casts is another classical feature of acute nephritic syndrome.
2. **Proteinuria** is mild (less than 3 gm per 24 hrs) and is usually non-selective (*nephritic range proteinuria*).
3. **Hypertension** is variable depending upon the severity of the glomerular disease but is generally mild.
4. **Oedema** in nephritic syndrome is usually mild and results from sodium and water retention (page 84).
5. **Oliguria** is variable and reflects the severity of glomerular involvement.

The underlying causes of acute nephritic syndrome may be primary glomerulonephritic diseases (classically acute

Table 20.5 Causes of acute nephritic syndrome.

- I. PRIMARY GLOMERULONEPHRITIS
 1. Acute GN
 - i) Post-streptococcal
 - ii) Non-streptococcal
 2. Rapidly progressive GN
 3. Membranoproliferative GN
 4. Focal and diffuse proliferative GN
 5. IgA nephropathy

 2. Polyarteritis nodosa
 3. Wegener's granulomatosis
 4. Henoch-Schonlein purpura
 5. Cryoglobulinaemia

glomerulonephritis and rapidly progressive glomerulonephritis) or certain systemic diseases (Table 20.5).

II. NEPHROTIC SYNDROME Nephrotic syndrome is a constellation of features in different diseases having varying pathogenesis; it is characterised by findings of massive proteinuria, hypoalbuminaemia, oedema, hyperlipidaemia, lipiduria, and hypercoagulability.

1. Heavy proteinuria (protein loss of more than 3 gm per 24 hrs) is the chief characteristic of nephrotic syndrome (*nephrotic range proteinuria*). In children, protein loss is correspondingly less. A small amount of protein (20 to 150 mg/day) normally passes through the glomerular filtration barrier and is reabsorbed by the tubules. But in case of increased glomerular permeability to plasma proteins, excess of protein is filtered out exceeding the capacity of tubules for reabsorption and, therefore, appears in the urine. Another feature of protein loss is its 'selectivity'. A *highly-selective proteinuria* consists mostly of loss of low molecular weight proteins, while a *poorly-selective proteinuria* is loss of high molecular weight proteins in the urine. In nephrotic syndrome, proteinuria mostly consists of loss of albumin (molecular weight 66,000) in the urine.

2. Hypoalbuminaemia is produced primarily consequent to urinary loss of albumin, and partly due to increased renal catabolism and inadequate hepatic synthesis of albumin. Often, the plasma albumin level is 1 to 3 gm/dl (normal 3.5 to 5.5 gm/dl) and there is reversed albumin-globulin ratio. The concentration of other proteins in the plasma such as immunoglobulins, clotting factors and antithrombin may fall rendering these patients more vulnerable to infections and thrombotic and thromboembolic complications.

3. Oedema in nephrotic syndrome appears due to fall in colloid osmotic pressure consequent upon hypoalbuminaemia. Sodium and water retention further contribute to oedema. Nephrotic oedema is usually peripheral but in children facial oedema may be more prominent (page 84).

4. Hyperlipidaemia is a frequent accompaniment of nephrotic syndrome. The exact mechanism of its genesis is not clear. It is hypothesised that the liver faced with the stress of massive protein synthesis in response to heavy urinary protein loss, also causes increased synthesis of lipoproteins. There are increased blood levels of total lipids, cholesterol, triglycerides, VLDL and LDL but decrease in HDL. Low blood level of HDL is partly due to its loss in the urine.

Table 20.6 Causes of nephrotic syndrome.

- I. PRIMARY GLOMERULONEPHRITIS
 1. Minimal change disease (*most common in children*)
 2. Membranous GN (*most common in adults*)
 3. Membranoproliferative GN
 4. Focal segmental glomerulosclerosis
 5. Focal and diffuse proliferative GN
 6. IgA nephropathy
- II. SYSTEMIC DISEASES
 1. Diabetes mellitus
 2. Amyloidosis
 3. SLE
- III. SYSTEMIC INFECTIONS
 1. Viral infections (HBV, HCV, HIV)
 2. Bacterial infections (bacterial endocarditis, syphilis, leprosy)
 3. Protozoa and parasites (*P. falciparum* malaria, filariasis)
- IV. HYPERSENSITIVITY REACTIONS
 1. Drugs (heavy metal compounds like gold and mercury, other drugs like penicillamine, trimethadione and tolbutamide, heroin addiction)
 2. Bee stings, snake bite, poison ivy
- V. MALIGNANCY
 1. Carcinomas
 2. Myeloma
 3. Hodgkin's disease
- VI. PREGNANCY
 - Toxaemia of pregnancy
- VII. CIRCULATORY DISTURBANCES
 1. Renal vein thrombosis
 2. Constrictive pericarditis
- VIII. HEREDITARY DISEASES
 1. Alport's disease
 2. Fabry's disease
 3. Nail-patella syndrome

5. Lipiduria occurs following hyperlipidaemia due to excessive leakiness of glomerular filtration barrier.

6. Hypercoagulability Patients with nephrotic syndrome may develop spontaneous arterial or venous thrombosis, renal vein thrombosis and pulmonary embolism due to various factors. These include: increased urinary loss of antithrombin III, hyperfibrinogenaemia from increased synthesis in the liver, decreased fibrinolysis, increased platelet aggregation and altered levels of protein C and S (page 102).

The causes of nephrotic syndrome are diverse and are listed in Table 20.6. The morphology of individual types is described later. But it must be mentioned here that:

◆ In *children*, primary glomerulonephritis is the cause in majority of cases of the nephrotic syndrome; most frequent being *lipoid nephrosis* (65%).

◆ In *adults*, on the other hand, systemic diseases (diabetes, amyloidosis and SLE) are more frequent causes of nephrotic syndrome. The most common primary glomerular disease in adults is *membranous glomerulonephritis* (40%).

Features of nephritic and nephrotic syndromes have been contrasted in Table 20.7.

Table 20.7 Contrasting features of acute nephritic and nephrotic syndromes.

| FEATURE | ACUTE NEPHRITIC SYNDROME | NEPHROTIC SYNDROME |
|-------------------------------|-------------------------------------|--|
| 1. <i>Proteinuria</i> | Mild (< 3 gm per 24 hrs) | Heavy (> 3 gm per 24 hrs) |
| 2. <i>Hypoalbuminaemia</i> | Uncommon | Present |
| 3. <i>Oedema</i> | Mild, in loose tissues | Marked, generalised peripheral |
| 4. <i>Mechanism of oedema</i> | Na ⁺ and water retention | ↓ plasma osmotic pressure, Na ⁺ and water retention |
| 5. <i>Haematuria</i> | Present, microscopic | Absent |
| 6. <i>Hypertension</i> | Present | Present in advanced disease |
| 7. <i>Hyperlipidaemia</i> | Absent | Present |
| 8. <i>Lipiduria</i> | Absent | Present |
| 9. <i>Oliguria</i> | Present | Present in advanced disease |
| 10. <i>Hypercoagulability</i> | Absent | Present |

III. ACUTE RENAL FAILURE As already described above, acute renal failure (ARF) is characterised by rapid decline in renal function. ARF has many causes including glomerular disease, principally rapidly progressive GN and acute diffuse proliferative GN.

IV. CHRONIC RENAL FAILURE Glomerular causes of chronic renal failure (CRF) have already been described. These cases have advanced renal impairment progressing over years and is detected by significant proteinuria, haematuria, hypertension and azotaemia. Such patients generally have small contracted kidneys due to chronic glomerulonephritis.

V. ASYMPTOMATIC PROTEINURIA Presence of proteinuria unexpectedly in a patient may be unrelated to renal disease (e.g. exercise-induced, extreme lordosis and orthostatic proteinuria), or may indicate an underlying mild glomerulonephritis. Association of asymptomatic haematuria, hypertension or impaired renal function with asymptomatic proteinuria should raise strong suspicion of underlying glomerulonephritis.

VI. ASYMPTOMATIC HAEMATURIA Asymptomatic microscopic haematuria is common in children and young adolescents and has many diverse causes such as diseases of the

glomerulus, renal interstitium, calyceal system, ureter, bladder, prostate, urethra, and underlying bleeding disorder, congenital abnormalities of the kidneys or neoplasia. Glomerular haematuria is indicated by the presence of red blood cells, red cell casts and haemoglobin in the urine. Glomerular haematuria is frequently associated with asymptomatic proteinuria.

**GIST BOX 20.5****Clinical Manifestations of Renal Diseases**

- ☐ In general, different glomerular diseases fall in to one or more of 6 clinical syndromes: nephritic and nephrotic syndromes; acute and chronic renal failure; asymptomatic proteinuria and haematuria.
- ☐ Acute nephritic syndrome is acute onset of microscopic haematuria, mild proteinuria, hypertension, oedema and oliguria following an infective illness about 10 to 20 days earlier.
- ☐ Nephrotic syndrome is characterised by findings of massive proteinuria, hypoalbuminaemia, oedema, hyperlipidaemia, lipiduria, and hypercoagulability.

PATHOGENESIS OF GLOMERULAR INJURY

Most forms of primary GN and many of the secondary glomerular diseases in human beings have immunologic pathogenesis. This view is largely based on immunofluorescence studies of GN in humans which have revealed glomerular deposits of immunoglobulins and complement in patterns that closely resemble those of experimental models. The consequences of injury at different sites within the glomerulus in various glomerular diseases can be assessed when compared with the normal physiologic role of the main cells involved i.e. *endothelial*, *mesangial*, *visceral epithelial*, and *parietal epithelial cells* as well as of the *GBM* as summed up in **Table 20.8**.

Immunologic mechanisms underlying glomerular injury are primarily *antibody-mediated* (immune-complex disease). There is evidence to suggest that *cell-mediated immune reactions* in the form of delayed type hypersensitivity can also cause glomerular injury in some conditions. In addition, a few secondary mechanisms and some non-immunologic mechanisms are involved in the pathogenesis of some forms of glomerular diseases in human beings (**Table 20.9**).

I. IMMUNOLOGIC MECHANISMS

Experimental studies and observations in humans have revealed that immunologic mechanisms, most importantly antigen-antibody complexes, underlie most forms of

Table 20.8 Relationship of physiologic role of glomerular components with consequences in glomerular injury.

| COMPONENT | PHYSIOLOGIC FUNCTION | CONSEQUENCE OF INJURY | RELATED GLOMERULAR DISEASE |
|-------------------------------------|---|--|---|
| 1. <i>Endothelial cells</i> | i) Maintain glomerular perfusion ii) Prevent leucocyte adhesion iii) Prevent platelet aggregation | Vasoconstriction Leucocyte infiltration Intravascular microthrombi | Acute renal failure Focal/diffuse proliferative GN Thrombotic microangiopathies |
| 2. <i>Mesangial cells</i> | Control glomerular filtration | Proliferation and increased matrix | Membranoproliferative GN |
| 3. <i>Visceral epithelial cells</i> | Prevent plasma protein filtration | Proteinuria | Minimal change disease, FSGS |
| 4. <i>GBM</i> | Prevents plasma protein filtration | Proteinuria | Membranous GN, ? MPGN |
| 5. <i>Parietal epithelial cells</i> | Maintain Bowman's space | Crescent formation | RPGN |

| 5. Drugs | NSAIDs-associated minimal change disease |
| 6. Inherited | Alport's syndrome, nail-patella syndrome |

glomerular injury. The general principles of these mechanisms in different forms of glomerular diseases are discussed below, while specific features pertaining to individual types of GN are described separately later.

A. Antibody-Mediated Glomerular Injury

1. IMMUNE COMPLEX DISEASE Majority of cases of glomerular disease result from deposits of immune complexes (antigen-antibody complexes). The immune complexes are represented by *irregular or granular glomerular deposits* of

immunoglobulins (IgG, IgM and IgA) and complement (mainly C3). Based on the experimental models and studies in human beings, the following 3 patterns of glomerular deposits of immune complexes in various glomerular diseases have been observed as illustrated in **Fig. 20.11**:

- Exclusive mesangial deposits* are characterised by very mild form of glomerular disease.
- Extensive subendothelial deposits* along the GBM are accompanied by severe hypercellular sclerosing glomerular lesions.

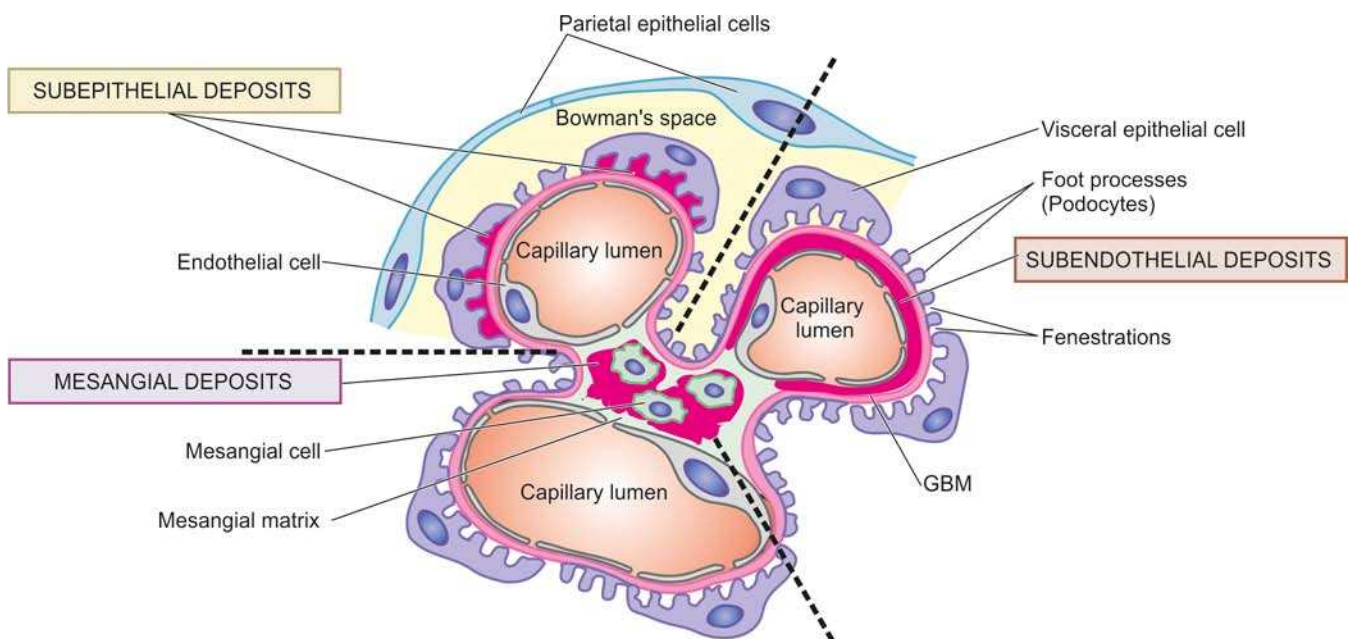

Figure 20.11 Diagrammatic representation of ultrastructure of a portion of glomerular lobule. It shows three patterns of irregular or granular glomerular deposits in immune-complex disease.

iii) *Subepithelial deposits* are seen between the outer surface of the GBM and the podocytes.

Deposits may be located at one or more of the above sites in any case of glomerular injury.

It was widely believed earlier that glomerular deposits result from circulating immune complexes. Now, it has been shown that glomerular deposits are formed by one of the following two mechanisms:

i) Local immune complex deposits Classic experimental model to understand human *in situ* immune complex GN is Heymann nephritis. In this, rats were injected with homologous kidney homogenates that resulted in a chronic glomerular disease manifested by heavy proteinuria. It was due to autoimmunity induced by antibodies to intrinsic glomerular antigens resulting in formation of *in situ* immune deposits on glomerular basement membrane. The intrinsic antigen in the experiment was found in epithelial brush borders of proximal convoluted tubules and has been named *megalín*.

Similar phenomenon is seen in human *membranous glomerulonephritis*. In humans, the corresponding autologous non-basement membrane antigen is identified as gp330 (glyco protein with a mass of 330 kD) or nonglomerular antigens planted on glomeruli (e.g. certain drugs, endotoxins, parasitic products etc). It is located on the podocytes and coated on pits of proximal tubular epithelial cells. Antibodies are formed against such planted antigens. Main antigen-antibody reaction takes place at soles of the foot processes of podocytes and the immune complexes get deposited at the lamina rara externa of the basement membrane. Correspondingly, in membranous glomerulonephritis, granular IgG deposits are found along the subepithelial side of basement membrane. Similarly, electron dense deposits are found on the epithelial side of basement membrane.

Currently, this mechanism is considered responsible for most cases of immune complex GN.

ii) Circulating immune complex deposits This mechanism used to be considered important for glomerular injury earlier but now it is believed that circulating immune complexes cause glomerular damage under certain circumstances only. These situations are: their presence in high concentrations for prolonged periods, or when they possess special properties that cause their binding to glomeruli, or when host mechanisms are defective and fail to eliminate immune complexes. The antigens evoking antibody response may be endogenous (e.g. in SLE) or may be exogenous (e.g. Hepatitis B virus, *Treponema pallidum*, *Plasmodium falciparum* and various tumour antigens). The antigen-antibody complexes are formed in the circulation and then trapped in the glomeruli where they produce glomerular injury after combining with complement.

Immune complex GN by either of the above mechanisms is observed in the following human diseases:

i) *Primary GN* e.g. acute diffuse proliferative GN, membranous GN, membranoproliferative GN, IgA nephropathy and some cases of rapidly progressive GN and focal GN.

ii) *Systemic diseases* e.g. glomerular disease in SLE, malaria, syphilis, hepatitis, Henoch-Schonlein purpura and idiopathic mixed cryoglobulinaemia.

2. ANTI-GBM DISEASE Less than 5% cases of human GN are associated with anti-GBM antibodies. The constituent of GBM acting as antigen appears to be a component of collagen IV of the basement membrane. The experimental model of

anti-GBM disease is *Masugi nephritis* (nephrotoxic serum nephritis) produced in rats by injection of heterologous antibodies against GBM prepared in rabbits by immunisation with rat kidney glomerular tissue.

Anti-GBM disease is classically characterised by *interrupted linear deposits* of anti-GBM antibodies (mostly IgG; rarely IgA and IgM) and complement (mainly C3) along the glomerular basement membrane. These deposits are detected by immunofluorescence microscopy or by electron microscopy.

Anti-GBM disease is characteristically exemplified by glomerular injury in Goodpasture's syndrome in some cases of rapidly progressive GN. About half to two-third of the patients with renal lesions in Goodpasture's syndrome have pulmonary haemorrhage mediated by cross-reacting autoantibodies against alveolar basement membrane (page 475).

3. ALTERNATE PATHWAY DISEASE As apparent from the above mechanisms, the complement system, in particular C3, contributes to glomerular injury in most forms of GN. Deposits of C3 are associated with the early components C1, C2 and C4 which are evidence of classic pathway activation of complement. But in alternate pathway activation, there is decreased serum C3 level, decreased serum levels of factor B and properdin, normal serum levels of C1, C2 and C4 but C3 and properdin are found deposited in the glomeruli without immunoglobulin deposits, reflecting activation of alternate pathway of complement. Such patients have circulating anti-complementary nephritic factor (C3NeF) which is an IgG antibody and acts as an autoantibody to the alternate C3 convertase, leading to persistent alternate pathway activation.

The deposits in alternate pathway disease are characteristically electron-dense under electron microscopy; glomerular lesions in such cases are referred to as *dense-deposit disease*.

Alternate pathway disease occurs in most cases of type II membranoproliferative GN, some patients of rapidly progressive GN, acute diffuse proliferative GN, IgA nephropathy and in SLE.

4. OTHER MECHANISMS OF ANTIBODY-MEDIATED INJURY A few autoantibodies have been implicated in some patients of focal segmental glomerulosclerosis and few other types of GN. These antibodies include the following:

i) Anti-neutrophil cytoplasmic antibodies (ANCA) About 40% cases of rapidly progressive GN are deficient in immunoglobulins in glomeruli (pauci-immune GN) and are positive for ANCA against neutrophil cytoplasmic antigens in their circulation. ANCA causes endothelial injury by generation of reactive oxygen radicals. ANCA-mediated vasculitis is also seen in Wegenger's granulomatosis and Churg-Strauss syndrome.

ii) Anti-endothelial cell antibodies (AECA) Autoantibodies against endothelial antigens have been detected in circulation in several inflammatory vasculitis and glomerulonephritis. These antibodies increase the adhesiveness of leucocytes to endothelial cells.

B. Cell-mediated Glomerular Injury (Delayed-type Hypersensitivity)

There is evidence to suggest that cell-mediated immune reactions may be involved in causing glomerular injury, particularly in cases with deficient immunoglobulins (e.g. in

pauci-immune type glomerulonephritis in RPGN). Cytokines and other mediators released by activated T cells stimulate cytotoxicity, recruitment of more leucocytes and fibrogenesis. CD4+ T lymphocytes recruit more macrophages while CD8+ cytotoxic T lymphocytes and natural killer cells cause further glomerular cell injury by antibody-dependent cell toxicity. Soluble factor derived from T lymphocytes is implicated in proteinuria in minimal change disease and focal GS.

However, cell-mediated injury is yet less clear than antibody-mediated glomerular injury.

C. Secondary Pathogenetic Mechanisms (Mediators of Immunologic Injury)

Secondary pathogenetic mechanisms are a number of mediators of immunologic glomerular injury operating in man and in experimental models. These include the following:

1. NEUTROPHILS Neutrophils are conspicuous in certain forms of glomerular disease such as in acute diffuse proliferative GN, and may also be present in membranoproliferative GN and lupus nephritis. Neutrophils can mediate glomerular injury by activation of complement as well as by release of proteases, arachidonic acid metabolites and oxygen-derived free radicals. These agents cause degradation of GBM and cell injury.

2. MONONUCLEAR PHAGOCYTES Many forms of human and experimental proliferative GN are associated with glomerular infiltration by monocytes and macrophages. Accumulation of mononuclear phagocytes is considered an important constituent of hypercellularity in these forms of GN aside from proliferation of mesangial and endothelial cells. Activated macrophages release a variety of biologically active substances which take part in glomerular injury.

3. COMPLEMENT SYSTEM The pathogenetic role of classical and alternate pathway of activation of complement has already been highlighted above. Besides the components of complement which mediate glomerular injury via neutrophils already mentioned, C5bC6789 (MAC, acronym for membrane attack complex, also called terminal complex) is capable of inducing damage to GBM directly.

4. PLATELETS Platelet aggregation and release of mediators play a role in the evolution of some forms of GN. Increased intrarenal platelet consumption has been found to occur in some forms of glomerular disease.

5. MESANGIAL CELLS There is evidence to suggest that mesangial cells present in the glomeruli may be stimulated to produce mediators of inflammation and take part in glomerular injury.

6. COAGULATION SYSTEM The presence of fibrin in early crescents in certain forms of human and experimental GN suggests the role of coagulation system in glomerular damage. Fibrinogen may leak into Bowman's space and act as stimulus for cell proliferation. Crescents usually transform into scar tissue under the influence of fibronectin which is regularly present in crescents in human glomerular disease.

II. NON-IMMUNOLOGIC MECHANISMS

Though most forms of GN are mediated by immunologic mechanisms, a few examples of glomerular injury by non-immunologic mechanisms are found:

1. *Metabolic glomerular injury* e.g. in diabetic nephropathy (due to hyperglycaemia), Fabry's disease (due to sulfatidosis).
2. *Haemodynamic glomerular injury* e.g. systemic hypertension, intraglomerular hypertension in FSGS.
3. *Deposition diseases* e.g. amyloidosis.
4. *Infectious diseases* e.g. HBV, HCV, HIV, *E. coli*-derived nephrotoxin.
5. *Drugs* e.g. minimal change disease due to NSAIDs.
6. *Inherited glomerular diseases* e.g. Alport's syndrome, nail-patella syndrome.

The evolution of *end-stage renal failure* in glomerular injury is explained on the basis of adaptive glomerular hypertrophy of unaffected glomeruli that results in increased glomerular blood flow and increased glomerular capillary pressure inducing intraglomerular hypertension. These events lead to increased deposition of mesangial matrix and proliferation of mesangial cells, endothelial and epithelial cell injury, and eventually to progressive glomerulosclerosis and end-stage renal failure.

GIST BOX 20.6 Pathogenesis of Glomerular Diseases

- Most forms of glomerular diseases in human beings have immunologic pathogenesis—antibody-mediated or cell-mediated.
- Antibody-mediated glomerular injury is often immune-complex disease, either local (*in situ*) or circulating deposits. Anti-GBM disease and alternate pathway activation of complement are the other antibody mechanisms. A few autoantibodies (ANCA, AECA) are also implicated in certain glomerular diseases with vasculitis.
- Cell-mediated immune reactions by delayed type hypersensitivity can also cause glomerular injury.
- Secondary mechanisms involve role of neutrophils, monocytes, complement, platelets, mesangial cells and activation of coagulation system.
- Non-immunologic mechanisms have role in certain forms of metabolic, infiltrative and inherited glomerular diseases.

SPECIFIC TYPES OF GLOMERULAR DISEASES

Classification of different forms of glomerular diseases into primary and secondary is already presented in Table 20.4. Features of individual types are described below and a summary of major forms of primary glomerulonephritis is given in Table 20.11 at the end of this discussion.

I. PRIMARY GLOMERULONEPHRITIS

Acute Glomerulonephritis (Synonyms: Acute Diffuse Proliferative GN, Diffuse Endocapillary GN)

Acute GN is known to follow acute infection and characteristically presents as acute nephritic syndrome. Based on etiologic agent, acute GN is subdivided into 2 main groups: acute post-streptococcal GN and acute non-streptococcal GN, the former being more common.

ACUTE POST-STREPTOCOCCAL GN

Acute post-streptococcal GN, though uncommon and sporadic in the Western countries, is a common form of GN in developing countries, mostly affecting children between

2 to 14 years of age but 10% cases are seen in adults above 40 years of age. The onset of disease is generally sudden after 1-2 weeks of streptococcal infection, most frequently of the throat (e.g. streptococcal pharyngitis) and sometimes of the skin (e.g. streptococcal impetigo).

ETIOPATHOGENESIS The relationship between streptococcal infection and this form of GN is now well established. Particularly nephritogenic are types 12,4,1 and Red Lake of group A β -haemolytic streptococci (compare the etiologic agent with that of RHD, page 419). The glomerular lesions appear to result from deposition of immune complexes in the glomeruli. The evidences cited in support are as under:

- i) There is *epidemiological* evidence of preceding streptococcal sore throat or skin infection about 1-2 weeks prior to the attack.
- ii) The *latent period* between streptococcal infection and onset of clinical manifestations of the disease is compatible with the period required for building up of antibodies.
- iii) Streptococcal infection may be identified by *culture* or may be inferred from elevated titres of *antibodies* against streptococcal antigens. These include the following:
 - a) anti-streptolysin O (ASO);
 - b) anti-deoxyribonuclease B (anti-DNase B);
 - c) anti-streptokinase (ASKase);
 - d) anti-nicotinyl adenine dinucleotidase (anti-NADase);
 and
 - e) anti-hyaluronidase (AHase).
- iv) There is usually *hypocomplementaemia* indicating involvement of complement in the glomerular deposits.
- v) It has also been possible to identify antigenic component of streptococci which is cytoplasmic antigen, *endostreptosin*.

MORPHOLOGIC FEATURES *Grossly*, the kidneys are symmetrically enlarged, weighing one and a half to twice the normal weight. The cortical as well as sectioned surface show petechial haemorrhages giving the characteristic appearance of flea-bitten kidney (Fig. 20.12).

Light microscopic findings are as under (Fig. 20.13):

i) Glomeruli The glomeruli are affected diffusely. They are enlarged and hypercellular. The diffuse hypercellularity

Figure 20.12 Flea-bitten kidney. The kidney is enlarged in size and weight. The cortex shows tiny petechial haemorrhages visible through the capsule (arrow).

of the tuft is due to proliferation of mesangial, endothelial and occasionally epithelial cells (*acute proliferative lesions*) as well as by infiltration of leucocytes, chiefly polymorphs and sometimes monocytes (*acute exudative lesion*). There may be small deposits of fibrin within the capillary lumina and in the mesangium.

ii) Tubules Tubular changes are not very striking. There may be swelling and hyaline droplets in tubular cells, and tubular lumina may contain red cell casts.

iii) Interstitium There may be some degree of interstitial oedema and leucocytic infiltration.

iv) Vessels Changes in arteries and arterioles are seldom present in acute GN.

Electron microscopic findings, besides confirming the light microscopic findings, demonstrate the characteristic

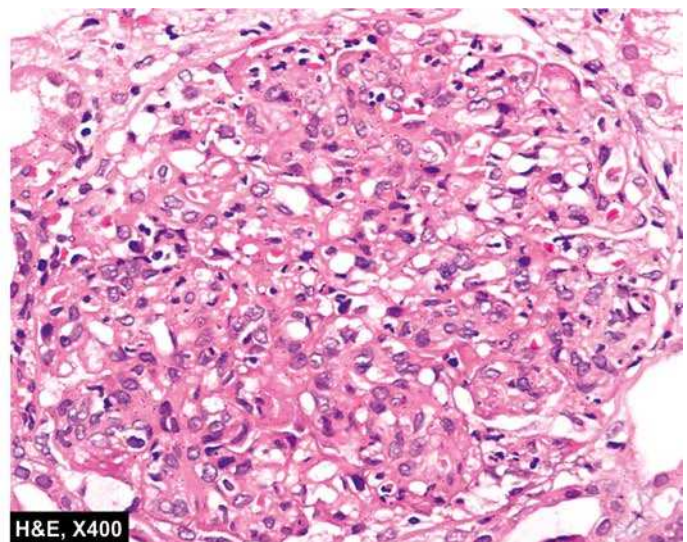

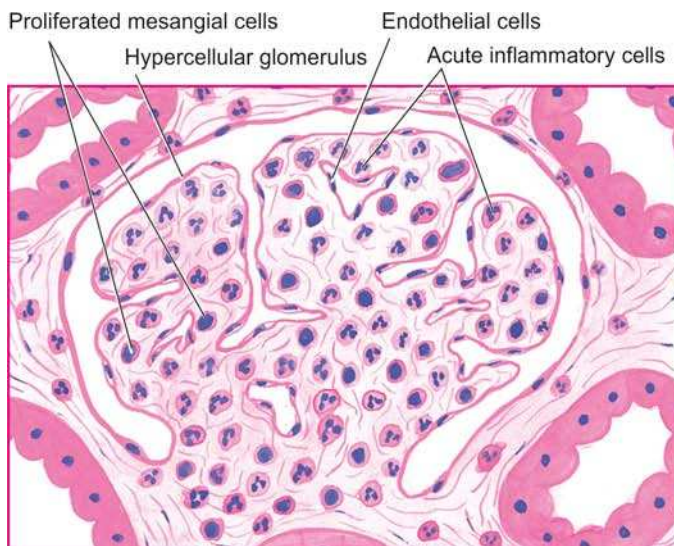

Figure 20.13 Acute post-streptococcal GN, light microscopic appearance. There is increased cellularity due to proliferation of mesangial cells, endothelial cells and some epithelial cells and infiltration of the tuft by neutrophils and monocytes.

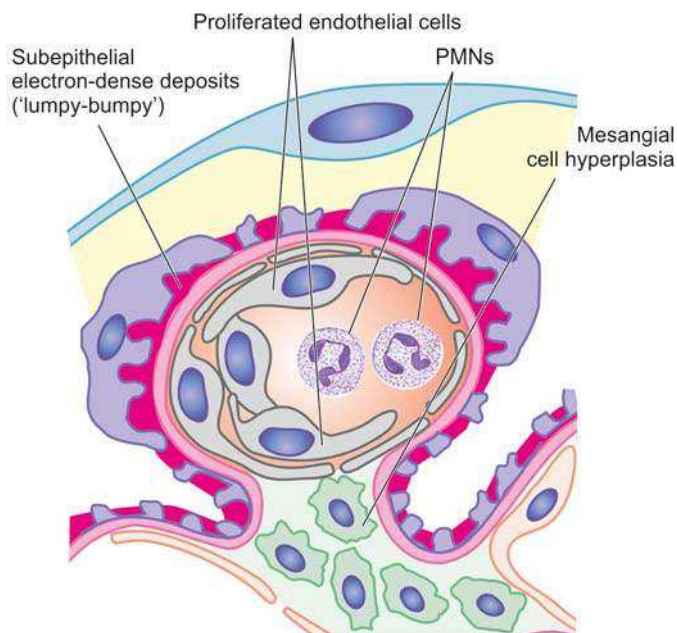

Figure 20.14 Acute glomerulonephritis, diagrammatic representation of ultrastructure of a portion of glomerular lobule showing characteristic electron-dense irregular deposits or 'humps' on the epithelial side of the GBM.

electron-dense irregular deposits ('humps') on the epithelial side of the GBM. These deposits represent the immune complexes (Fig. 20.14).

Immunofluorescence microscopy reveals that the irregular deposits along the GBM consist principally of IgG and complement C3.

CLINICAL FEATURES Typically, the patient is a young child, presenting with acute nephritic syndrome (page 647), having sudden and abrupt onset following an episode of sore throat or skin infection 1-2 weeks prior to the development of symptoms. The features include microscopic or intermittent haematuria, red cell casts, mild non-selective proteinuria (less than 3 gm per 24 hrs), hypertension, periorbital oedema and variably oliguria. Less often, the presentation may be as nephrotic syndrome. In adults, the features are atypical and include sudden hypertension, oedema and azotaemia. Development of hypertension in either case is a poor prognostic sign.

Prognosis varies with the age of the patient. Children almost always (95%) recover completely with reversal of proliferative glomerular changes. Complications arise more often in adults and occasionally in children. These include development of rapidly progressive GN, chronic GN, uraemia and chronic renal failure.

ACUTE NON-STREPTOCOCCAL GN

About one-third cases of acute GN are caused by organisms other than haemolytic streptococci. These include other bacteria (e.g. staphylococci, pneumococci, meningococci, *Salmonella* and *Pseudomonas*), viruses (e.g. hepatitis B virus, mumps, infectious mononucleosis and varicella), parasitic infections (e.g. malaria, toxoplasmosis and schistosomiasis) and syphilis. The appearance of renal biopsy by light microscopy, EM and immunofluorescence microscopy is similar to that seen in acute post-streptococcal GN. The prognosis of non-streptococcal GN is not as good as that of streptococcal GN.

Rapidly Progressive Glomerulonephritis (Synonyms: RPGN, Crescentic GN, Extracapillary GN)

RPGN presents with an acute reduction in renal function resulting in acute renal failure in a few weeks or months. It is characterised by formation of 'crescents' (*crescentic GN*) outside the glomerular capillaries (*extracapillary GN*). 'Crescents' are formed from the proliferation of parietal epithelial cells lining Bowman's capsule with contribution from visceral epithelial cells and the invading mononuclear cells. The stimulus for crescent formation appears to be the presence of fibrin in the capsular space. RPGN occurs most frequently in adults, with a slight male preponderance. Prognosis of RPGN in general is dismal.

ETIOPATHOGENESIS A number of primary glomerular and systemic diseases are characterised by formation of crescents. Based on the etiologic agents and pathogenetic mechanism, patients with RPGN are divided into 3 groups (Table 20.10):

1. RPGN in systemic diseases (anti-GBM type)
2. Post-infectious RPGN (immune-complex type)
3. Pauci-immune RPGN.

Following three serologic markers are used for categorising RPGN:

- i) serum C3 level,
- ii) anti-GBM antibody; and
- iii) anti-neutrophil cytoplasmic antibody (ANCA).

Table 20.10 Distinguishing features of three main categories of rapidly progressive glomerulonephritis.

| FEATURE | TYPE I RPGN (ANTI-GBM DISEASE) | TYPE II RPGN (IMMUNE COMPLEX DISEASE) | TYPE III RPGN (PAUCI-IMMUNE GN) |
|------------------------------|--|--|---|
| 1. <i>Clinical syndrome</i> | Nephritic | Nephritic | Nephritic |
| 2. <i>Pathogenetic type</i> | Anti-GBM | Immune-complex | Pauci-immune |
| 3. <i>Immunofluorescence</i> | Linear Ig and C3 | Granular Ig and C3 | Sparse or absent Ig and C3 |
| 4. <i>Serologic markers</i> | | | |
| i) <i>Serum C3 level</i> | Normal | Low-to-normal | Normal |
| ii) <i>Anti-GBM antibody</i> | Positive | Negative | Negative |
| iii) <i>ANCA</i> | Negative | Negative | Positive |
| 5. <i>Underlying cause</i> | Idiopathic Goodpasture's syndrome, SLE, vasculitis, Wegener's granulomatosis, Henoch-Schonlein purpura | Idiopathic Post-infectious (post-streptococcal GN) | Idiopathic Polyarteritis nodosa, Wegener's granulomatosis |

Type I RPGN: Anti-GBM disease A number of systemic diseases such as Goodpasture's syndrome, SLE, vasculitis, Wegener's granulomatosis, Henoch-Schonlein purpura and idiopathic mixed cryoglobulinaemia are associated with crescentic GN. Goodpasture's syndrome is the characteristic example of anti-GBM disease and is described below:

Goodpasture's syndrome Goodpasture's syndrome is characterised by acute renal failure due to RPGN and pulmonary haemorrhages (page 475). The condition is more common in males in 3rd decade of life. The disease results from damage to the glomeruli by anti-GBM antibodies which cross-react with alveolar basement membrane and hence, produce renal as well as pulmonary lesions. The evidences in support are the characteristic linear deposits of anti-GBM antibodies consisting of IgG and complement along the GBM, detection of circulating anti-GBM antibodies and induction of glomerular lesions with injection of anti-GBM antibodies experimentally in monkeys. Pulmonary lesions can be experimentally induced if the lungs are previously injured by viral or bacterial infection or exposed to hydrocarbons. The Goodpasture's antigen appears to be a component of collagen type IV.

Type II RPGN: Immune complex disease A small proportion of cases of post-streptococcal GN, particularly in adults and sometimes of non-streptococcal origin, develop RPGN. The evidences in support of post-infectious RPGN having immune complex pathogenesis are granular deposits of immune complexes of IgG and C3 along the glomerular capillary walls, lowering of blood complement level and demonstration of circulating complexes.

Type III RPGN: Pauci-immune GN These include cases of Wegener's granulomatosis and microscopic polyarteritis nodosa. The pathogenesis of pauci-immune GN is yet not fully defined. However, majority of these patients are ANCA-positive, implying a defect in humoral immunity. Serum complement levels are normal and anti-GBM antibody is negative. There is little or no glomerular immune deposit (i.e. pauci-immune).

MORPHOLOGIC FEATURES *Grossly*, the kidneys are usually enlarged and pale with smooth outer surface (*large*

white kidney). Cut surface shows pale cortex and congested medulla.

Light microscopic findings vary according to the cause but, in general, following features are present (**Fig. 20.15**):

i) Glomeruli Irrespective of the underlying etiology, all forms of RPGN show pathognomonic '*crescents*' on the inside of Bowman's capsules. These are collections of pale-staining polygonal cells which commonly tend to be elongated. Eventually, crescents obliterate the Bowman's space and compress the glomerular tuft. Fibrin deposition is invariably present alongside crescents. Besides the crescents, glomerular tufts may show increased cellularity as a result of proliferation of endothelial and mesangial cells and leucocytic infiltration. Fibrin thrombi are frequently present in the glomerular tufts.

ii) Tubules Tubular epithelial cells may show hyaline droplets. Tubular lumina may contain casts, red blood cells and fibrin.

iii) Interstitium The interstitium is oedematous and may show early fibrosis. Inflammatory cells, usually lymphocytes and plasma cells, are commonly distributed in the interstitial tissue.

iv) Vessels Arteries and arterioles may show no change, but cases associated with hypertension usually show severe vascular changes.

Electron microscopic findings vary according to the type of RPGN. Post-infectious RPGN cases show electron-dense subepithelial granular deposits similar to those seen in acute GN, while cases of RPGN in Goodpasture's syndrome show characteristic linear deposits along the GBM (**Fig. 20.16**).

Immunofluorescence microscopy shows following patterns in various types of RPGN:

- i) linear pattern of RPGN in Goodpasture's syndrome (type I RPGN), containing IgG accompanied by C3 along the capillaries.
- ii) Granular pattern of post-infectious RPGN (type II RPGN) consisting of IgG and C3 along the capillary wall.
- iii) Scanty or no deposits of immunoglobulin and C3 in pauci-immune GN (type III RPGN).

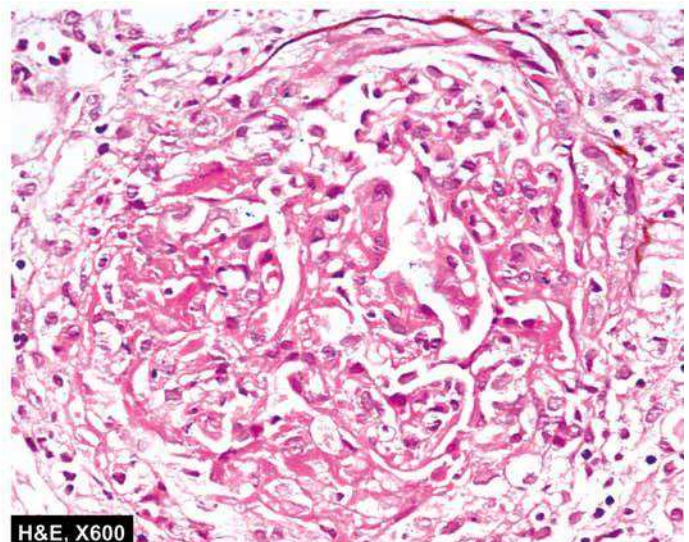

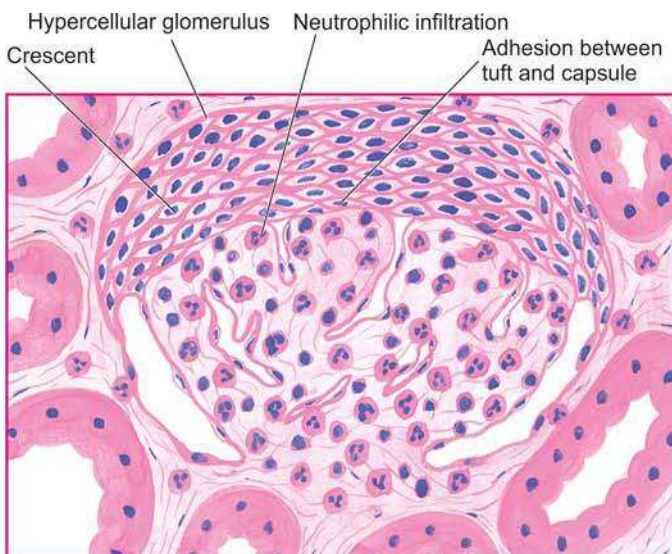

Figure 20.15 RPGN (post-infectious type), light microscopic appearance. There are crescents in Bowman's space forming adhesions between the glomerular tuft and Bowman's capsule. The tuft shows hypercellularity and leucocytic infiltration.

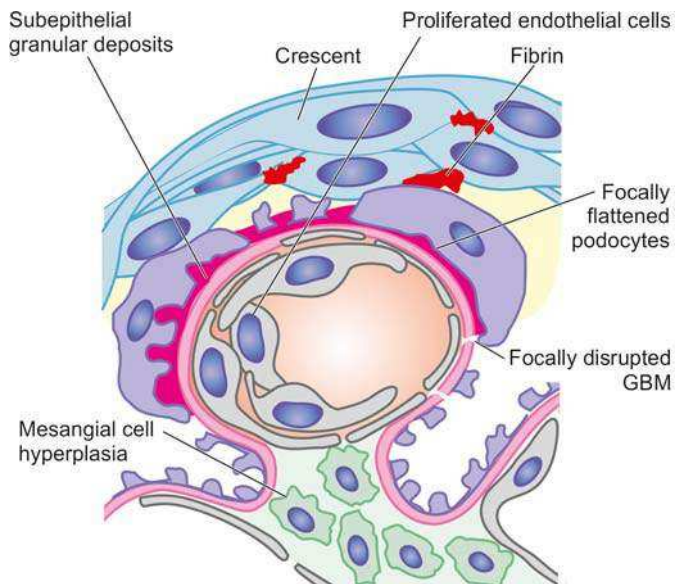

Figure 20.16 RPN, diagrammatic representation of ultrastructure of a portion of glomerular lobule showing epithelial crescent formation and subepithelial granular deposits.

CLINICAL FEATURES Generally, the features of post-infectious RPN are similar to those of acute GN, presenting as acute renal failure. The patients of Goodpasture's syndrome may present as acute renal failure and/or associated intrapulmonary haemorrhage producing recurrent haemoptysis. Prognosis of all forms of RPN is poor. However, post-infectious cases have somewhat better outcome and may show recovery.

Minimal Change Disease
(Synonyms: MCD, Lipoid Nephrosis, Foot Process Disease, Nil Deposit Disease)

Minimal change disease (MCD) is a condition in which the nephrotic syndrome is accompanied by no apparent change in glomeruli by light microscopy. Its other synonyms, lipoid nephrosis and foot process disease, are descriptive terms for fatty changes in the tubules and electron microscopic appearance of flattened podocytes respectively. Minimal change disease accounts for 80% cases of nephrotic syndrome in children under 16 years of age with preponderance in boys (ratio of boys to girls 2:1). In fact, historically, lipoid nephrosis was the first condition associated with nephrotic syndrome.

ETIOPATHOGENESIS The etiology of MCD remain elusive. However, following two groups have been identified:

- i) Idiopathic (majority of cases).
- ii) Cases associated with systemic diseases (Hodgkin's disease, HIV infection) and drug therapy (e.g. NSAIDs, rifampicin, interferon- α).

The following features point to possible immunologic pathogenesis for MCD:

- i) Absence of deposits by immunofluorescence microscopy.
- ii) Normal circulating levels of complement but presence of circulating immune complexes in many cases.
- iii) Universal satisfactory response to steroid therapy.
- iv) Evidence of increased suppressor T cell activity with elaboration of cytokines (interleukin-8, tumour necrosis factor) which probably cause foot process flattening and altered charge on the GBM.

v) Detection of a mutation in nephrin gene in cases of congenital MCD has focused attention on genetic basis.

Nephrotic syndrome in MCD in children is characterised by *selective proteinuria* containing mainly albumin, and minimal amounts of high molecular weight proteins such as α_2 -macroglobulin. The basis for selective proteinuria appears to be as under:

- i) Reduction of normal negative charge on GBM due to loss of heparan sulfate proteoglycan from the GBM.
- ii) Change in the shape of epithelial cells producing foot process flattening due to reduction of sialoglycoprotein cell coat.

Adults having MCD, however, have *non-selective proteinuria*, suggesting more extensive membrane permeability defect.

MORPHOLOGIC FEATURES *Grossly*, the kidneys are of normal size and shape.

By light microscopy, the findings are as under (Fig. 20.17,A):

- i) **Glomeruli** The most characteristic feature is no apparent abnormality in the glomeruli except for slight increase in the mesangial matrix at the most (minimal change disease or nil lesion).
- ii) **Tubules** There is presence of fine lipid vacuolation and hyaline droplets in the cells of proximal convoluted tubules and, hence, the older name of the condition as 'lipoid nephrosis'.
- iii) **Interstitium** There may be oedema of the interstitium.
- iv) **Vessels** Blood vessels do not show any significant change.

By electron microscopy, the most characteristic feature of the disease is identified which is diffuse flattening of foot processes of the visceral epithelial cells (podocytes) and, hence, the name foot process disease or podocytopathy (Fig. 20.17,B). Unlike other forms of GN, no deposits are seen and the GBM is normal.

By immunofluorescence microscopy, no deposits of complement or immunoglobulins are recognised (nil deposit disease).

CLINICAL FEATURES The classical presentation of MCD is of fully-developed nephrotic syndrome with massive and *highly selective proteinuria*; hypertension is unusual. Most frequently, the patients are children under 16 years (peak incidence at 6-8 years of age).

The onset may be preceded by an upper respiratory infection, atopic allergy or immunisation.

The disease characteristically responds to steroid therapy. In spite of remissions and relapses, long-term prognosis is very good and most children become free of albuminuria after several years.

Membranous Glomerulonephritis
(Synonym: Epimembranous Nephropathy)

Membranous GN is characterised by widespread thickening of the glomerular capillary wall and is the most common cause of nephrotic syndrome in adults. In majority of cases (85%), membranous GN is truly *idiopathic*, while in about 15% of

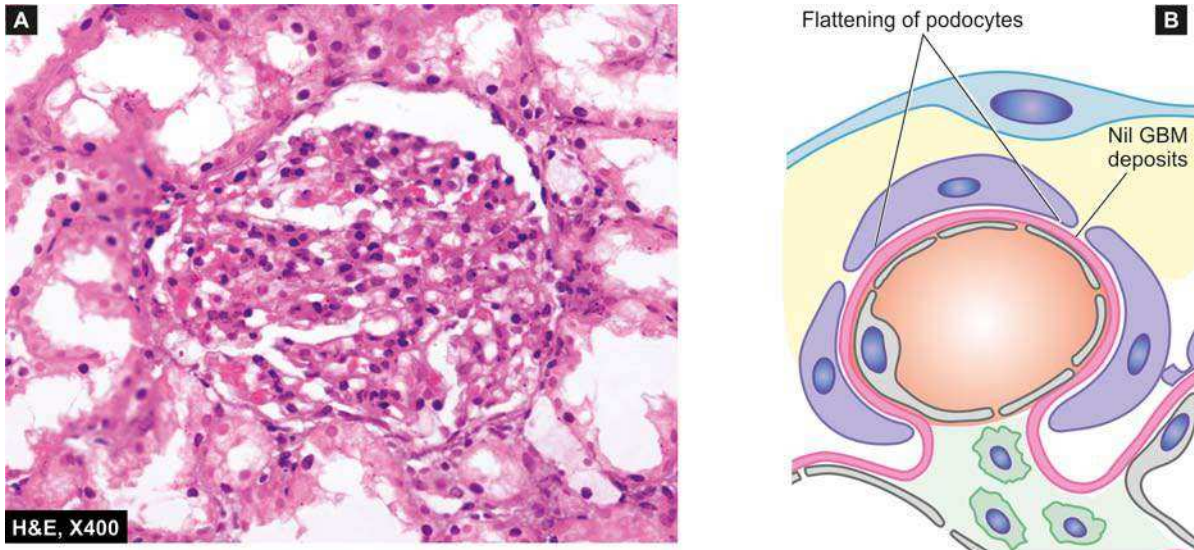

Figure 20.17 Minimal change disease. A, Light microscopy shows a normal glomerulus while tubules show cytoplasmic vacuolation and proteinaceous material. B, Diagrammatic representation of ultrastructure of a portion of glomerular lobule showing diffuse fusion or flattening of foot processes of visceral epithelial cells (podocytes). The GBM is normal and there are no deposits.

cases it is *secondary* to an underlying condition (e.g. SLE, malignancies, infections such as chronic hepatitis B and C, syphilis, malaria and drugs).

ETIOPATHOGENESIS *Idiopathic membranous GN* is an immune complex disease. The deposits of immune complex are formed locally because circulating immune complexes are detected in less than a quarter of cases. Since leucocytic infiltration is not a feature of membranous GN, damage to the GBM is mediated directly by complement. While nephritogenic antigen against which autoantibodies are formed in *idiopathic membranous GN* is not known yet, the antigen in cases of *secondary membranous GN* is either an endogenous (e.g. DNA in SLE) or exogenous one (e.g. hepatitis B virus, tumour antigen, treponema antigen, drug therapy with penicillamine). Currently, pathogenesis of membrane alteration in membranous GN is believed to be by MAC (membrane attack complex i.e. C35b-C9) terminal complex on podocytes.

MORPHOLOGIC FEATURES *Grossly*, the kidneys are enlarged, pale and smooth.

Light microscopy shows the following findings (**Fig. 20.18**):

i) Glomeruli The characteristic finding is diffuse thickening of the glomerular capillary walls with all the glomeruli being affected more or less uniformly. As the disease progresses, the deposits are incorporated into enormously thickened basement membrane, producing 'duplication' of GBM which is actually formation of a new basement membrane. These basement membrane changes are best appreciated by silver impregnation stains (black colour) or by periodic acid-Schiff stain (pink colour). There is no cellular proliferation in the glomerular tufts.

ii) Tubules The renal tubules remain normal except in the early stage when lipid vacuolation of the proximal convoluted tubules may be seen.

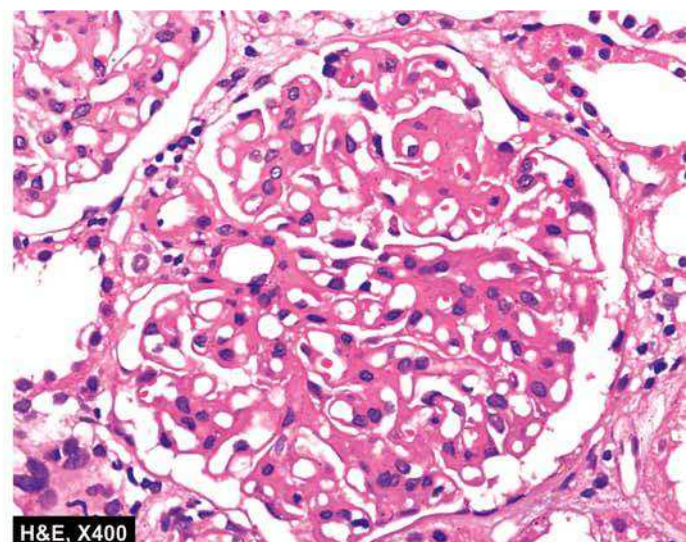

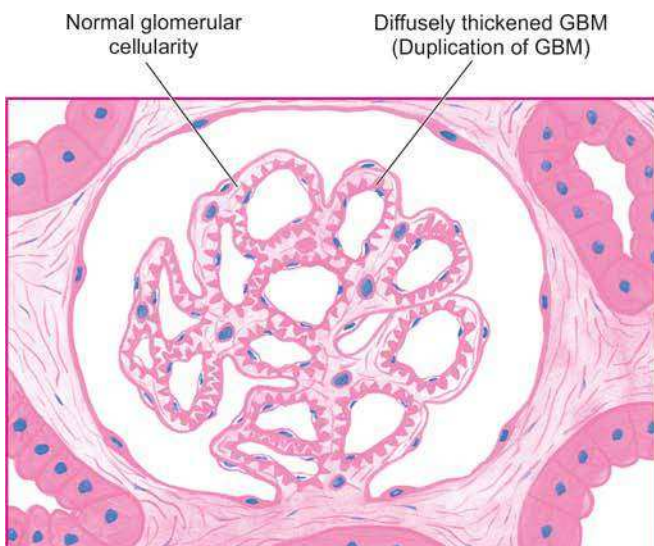

Figure 20.18 Membranous GN, light microscopic appearance. Glomeruli are normocellular but the capillary walls are diffusely thickened due to duplication of the GBM.

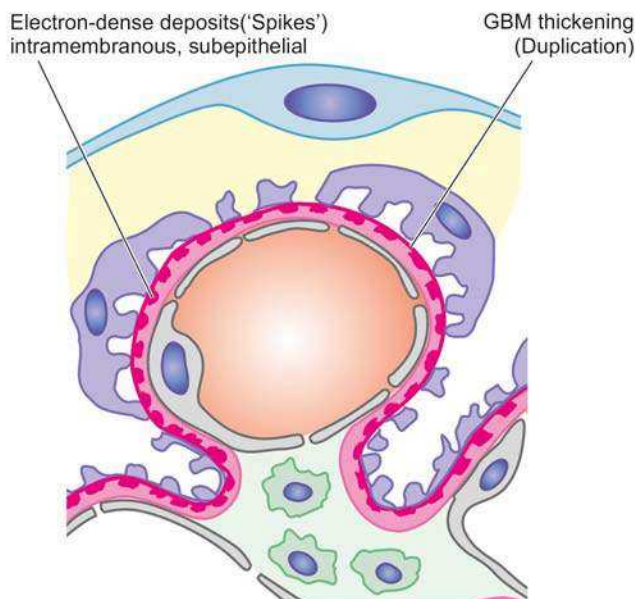

Figure 20.19 Membranous GN, diagrammatic representation of ultrastructure of a portion of glomerular lobule showing subepithelial deposits of electron-dense material so that the basement membrane material protrudes between these deposits.

iii) Interstitium The interstitium may show fine fibrosis and scanty chronic inflammatory cells.

iv) Vessels In the early stage, vascular changes are not prominent, while later hypertensive changes of arterioles may occur.

Electron microscopy shows characteristic electron-dense deposits in subepithelial location. The basement membrane material protrudes between deposits as 'spikes' (**Fig. 20.19**).

Immunofluorescence microscopy reveals granular deposits of immune complexes consisting of IgG associated with complement C3. In secondary cases of membranous GN the relevant antigen such as hepatitis B or tumour antigen may be seen.

CLINICAL FEATURES The presentation in majority of cases is insidious onset of nephrotic syndrome in an adult. The proteinuria is usually of *non-selective* type. In addition, microscopic haematuria and hypertension may be present at the onset or may develop during the course of the disease. The changes in membranous GN are irreversible in majority of patients. Progression to impaired renal function and end-stage renal disease with progressive azotaemia occurs in approximately 50% cases within a span of 2 to 20 years. Renal vein thrombosis has been found to develop in patients with membranous GN due to hypercoagulability. The role and beneficial effects of steroid therapy with or without the addition of immunosuppressive drugs is debatable.

Membranoproliferative Glomerulonephritis (Synonyms: MPGN, Mesangiocapillary GN)

Membranoproliferative GN is another important cause of nephrotic syndrome in children and young adults. As the name implies, it is characterised by two histologic features—increased in cellularity of the mesangium associated with increased

lobulation of the tuft, and irregular thickening of the capillary wall.

ETIOPATHOGENESIS Etiology of MPGN is unknown though in some cases there is evidence of preceding streptococcal infection. Based on ultrastructural, immunofluorescence and pathogenetic mechanisms, three types of MPGN are recognised:

◆ **Type I or classic form** is an example of immune complex disease and comprises more than 70% cases. It is characterised by immune deposits in the subendothelial position. Immune-complex MPGN is seen in association with systemic immune-complex diseases (e.g. SLE, mixed cryoglobulinaemia, Sjögren's syndrome), chronic infections (e.g. bacterial endocarditis, HIV, hepatitis B and C) and malignancies (e.g. lymphomas and leukaemias).

◆ **Type II or dense deposit disease** is the example of alternate pathway disease (page 651) and constitutes about 30% cases. The capillary wall thickening is due to the deposition of electron-dense material in the lamina densa of the GBM. Type II MPGN is an autoimmune disease in which patients have IgG autoantibody termed C3 nephritic factor. Type II cases have an association with partial lipodystrophy, an unusual condition of unknown pathogenesis characterised by symmetrical loss of subcutaneous fat from the upper half of the body.

◆ **Type III** is rare and shows features of type I MPGN and membranous nephropathy in association with systemic diseases or drugs.

MORPHOLOGIC FEATURES *Grossly*, and by light microscopy, all the three types of MPGN are similar.

Grossly, the kidneys are usually pale in appearance and firm in consistency.

By light microscopy, the features are as under (**Fig. 20.20**):

i) Glomeruli Glomeruli show highly characteristic changes. They are enlarged with accentuated lobular pattern. The enlargement is due to variable degree of mesangial cellular proliferation and increase in mesangial matrix. The GBM is considerably thickened; with silver stains it shows two basement membranes with a clear zone between them. This is commonly referred to as 'double contour', 'splitting', or 'tram track' appearance.

ii) Tubules Tubular cells may show vacuolation and hyaline droplets.

iii) Interstitium There may be scattered chronic inflammatory cells and some finely granular foam cells in the interstitium.

iv) Vessels Hypertensive vascular changes are prominent in cases in which hypertension develops.

By electron microscopy and immunofluorescence microscopy, the changes are different in the three types of MPGN (**Fig. 20.21**):

Type I: It shows *electron-dense deposits* in subendothelial location conforming to immune-complex character of the disease. These deposits reveal positive fluorescence for C3 and slightly fainter staining for IgG.

Type II: The hallmark of type II MPGN is the presence of *dense amorphous deposits* within the lamina densa of the GBM and in the mesangium. Immunofluorescence studies reveal the universal presence of C3 and properdin in the deposits but the immunoglobulins are usually absent.

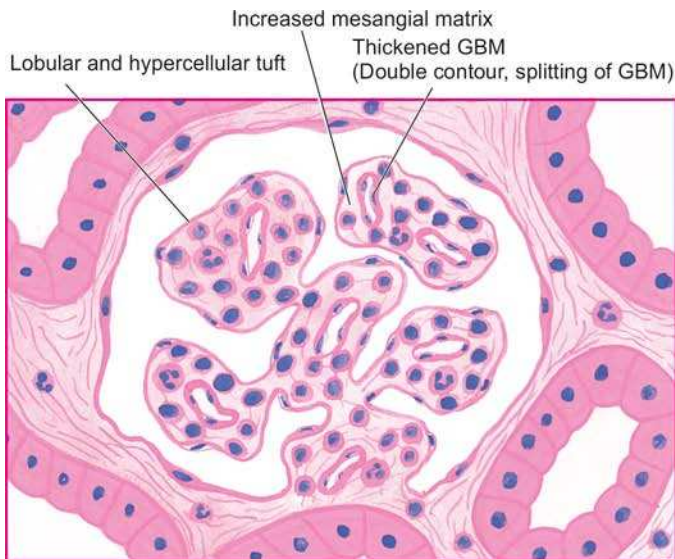

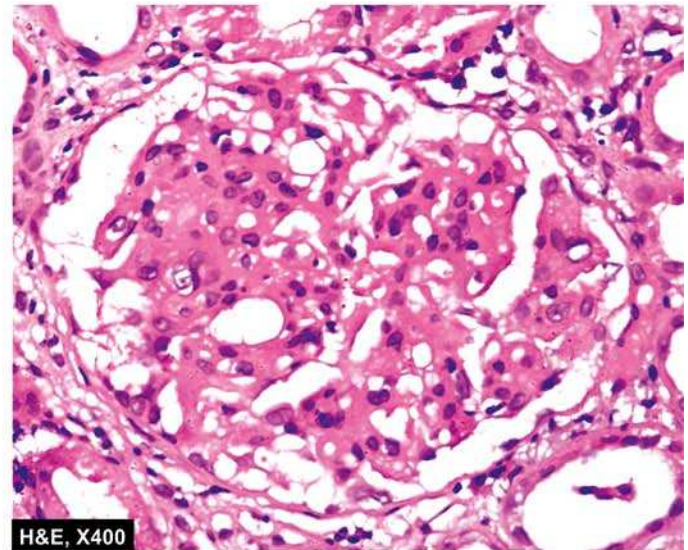

Figure 20.20 Membranoproliferative GN, light microscopic appearance. The glomerular tufts show lobulation and mesangial hypercellularity. There is increase in the mesangial matrix between the capillaries. There is widespread thickening of the GBM.

Type III: This rare form has *electron-dense deposits* within the GBM as well as in subendothelial and subepithelial regions of the GBM. Immunofluorescence studies show the presence of C3, IgG and IgM.

CLINICAL FEATURES Clinically, there are many similarities between the main forms of MPGN. The most common age at diagnosis is between 15 and 20 years. Approximately 50% of the patients present with nephrotic syndrome; about 30% have asymptomatic proteinuria; and 20% have nephritic syndrome at presentation. The proteinuria is non-selective. Haematuria and hypertension are frequently present. Hypocomplementaemia is a common feature. With time, majority of patients progress

to renal failure, while some continue to have proteinuria, haematuria and hypertension with stable renal function.

Prognosis of type I is relatively better and majority of patients survive without clinically significant impairment of GFR, while type II cases run a variable clinical course.

Focal Proliferative Glomerulonephritis (Synonym: *Mesangial Proliferative GN*)

Focal proliferative GN is characterised by pathologic changes in fewer than 50% glomeruli (*focal*), often confined to one or two lobules of the affected glomeruli while other glomeruli are normal. Focal GN is, thus, a pathologic diagnosis.

ETIOPATHOGENESIS It may occur under following diverse clinical settings:

- i) As an early manifestation of a number of *systemic diseases* such as SLE (class III), Henoch-Schonlein purpura, sub-acute bacterial endocarditis, Wegener's granulomatosis, and polyarteritis nodosa, Goodpasture's syndrome.
- ii) As a component of a known *renal disease* such as in IgA nephropathy.
- iii) As a primary *idiopathic* glomerular disease unrelated to systemic or other renal disease.

The diverse settings under which focal GN is encountered make it unlikely that there are common etiologic agents or pathogenetic mechanisms. However, the observation of mesangial deposits of immunoglobulins and complement suggest immune complex disease and participation of the mesangium.

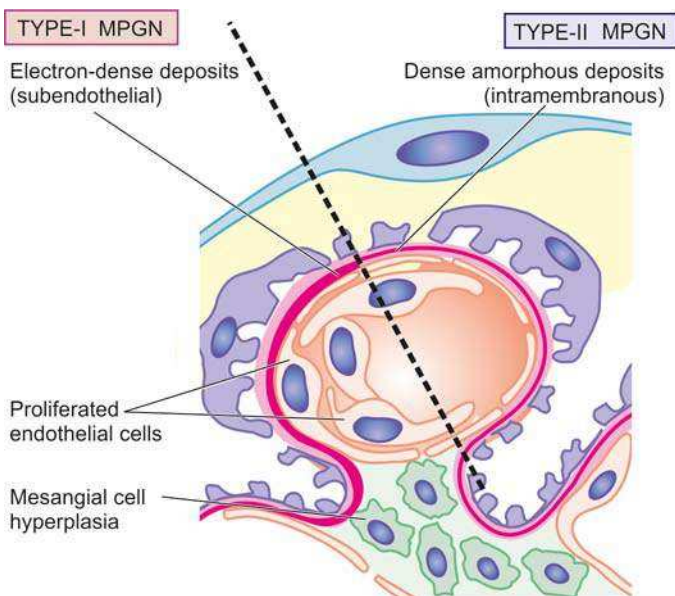

Figure 20.21 MPGN, diagrammatic representation of ultrastructure of a portion of glomerular lobule showing features of type I (left half) and type II (right half) MPGN. Type I (classic form) shows the characteristic subendothelial electron-dense deposits, while type II (dense deposit disease) is characterised by intramembranous dense deposits.

MORPHOLOGIC FEATURES By *light microscopy*, the single most important feature in focal GN is the abnormality seen in certain number of glomeruli and generally confined to one or two lobules of the affected glomeruli i.e. *focal and segmental glomerular involvement* (Fig. 20.22,A). The pathologic change most frequently consists of focal and segmental cellular proliferation of mesangial cells and endothelial cells but sometimes necrotising changes can be seen. The condition must be distinguished from focal segmental glomerulosclerosis.

By immunofluorescence microscopy, widespread mesangial deposits of immunoglobulins (mainly IgA with or without IgG), complement (C3) and fibrin are demonstrated in most cases of focal GN.

CLINICAL FEATURES The clinical features vary according to the condition causing it. Haematuria is one of the most common clinical manifestation. Proteinuria is frequently mild to moderate but hypertension is uncommon.

Diffuse Proliferative Glomerulonephritis (Synonym: DPGN)

DPGN is similar to focal proliferative GN in terms of etiology and pathogenesis.

MORPHOLOGIC FEATURES These are similar to focal proliferative GN but in its advanced form. It differs from focal GN in following ways:

1. The number of glomeruli involved is more than 50% i.e. diffuse proliferation.
2. The cells partaking in DPGN are more diffuse type and not mesangial cells alone; it also includes proliferation of epithelial, endothelial and inflammatory cells.
3. DPGN represents class IV lupus nephritis.

Focal Segmental Glomerulosclerosis (Synonyms: Focal Sclerosis, Focal Hyalinosis)

Focal segmental glomerulosclerosis (FSGS) is a condition in which there is sclerosis and hyalinosis of some glomeruli and portions of their tuft (less than 50% in a tissue section), while the other glomeruli are normal by light microscopy i.e. involvement is focal and segmental. The incidence of FSGS has increased over the last decades and is currently responsible for about one-third cases of nephrotic syndrome in the adults.

ETIOPATHOGENESIS FSGS was previously believed to be a variant of MCD with accentuation of epithelial damage in the form of hyalinosis and sclerosis. Currently, the condition is divided into 3 groups:

i) Idiopathic type This group comprises majority of cases. It is found in children and young adults with presentation of nephrotic syndrome. It differs from minimal change disease in having non-selective proteinuria, in being steroid-resistant, and may progress to chronic renal failure. Immunofluorescence microscopy reveals deposits of IgM and C3 in the sclerotic segment.

ii) With superimposed primary glomerular disease There may be cases of FSGS with superimposed MCD or IgA nephropathy. Those associated with MCD show good response to steroid therapy and progression to chronic renal failure may occur after a long time.

iii) Secondary type This group consists of focal segmental sclerotic lesions as a secondary manifestation of certain diseases such as HIV, diabetes mellitus, reflux nephropathy, heroin abuse and analgesic nephropathy.

The hallmark of pathogenesis of FSGS is injury to visceral epithelial cells that results in disruption of visceral epithelial cells and resultant nephron loss.

MORPHOLOGIC FEATURES By light microscopy, depending upon the severity of the disease, variable number of glomeruli are affected focally and segmentally, while others are normal. The affected glomeruli show solidification or sclerosis of one or more lobules of the tuft. *Hyalinosis* refers to collection of eosinophilic, homogeneous, PAS-positive, hyaline material present on the inner aspect of a sclerotic peripheral capillary loop. Mesangial hypercellularity is present in appreciable number of cases. In addition, to glomerular changes, there is interstitial fibrosis and infiltration by mononuclear leucocytes, and tubular epithelial cell atrophy and degeneration (Fig. 20.22, B, C).

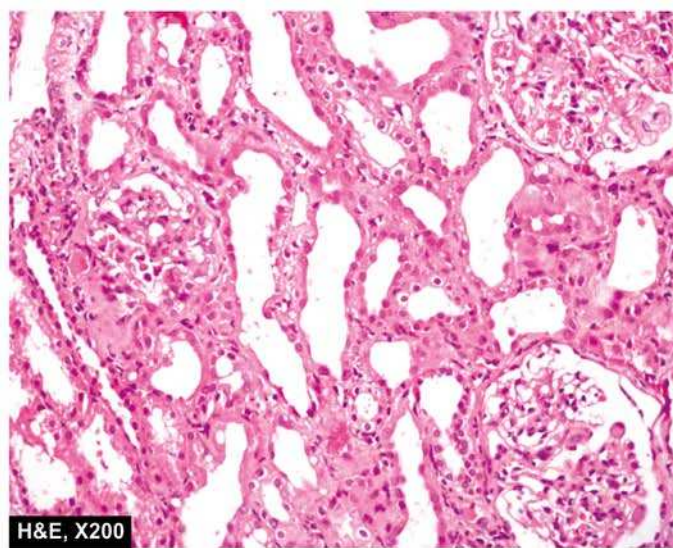

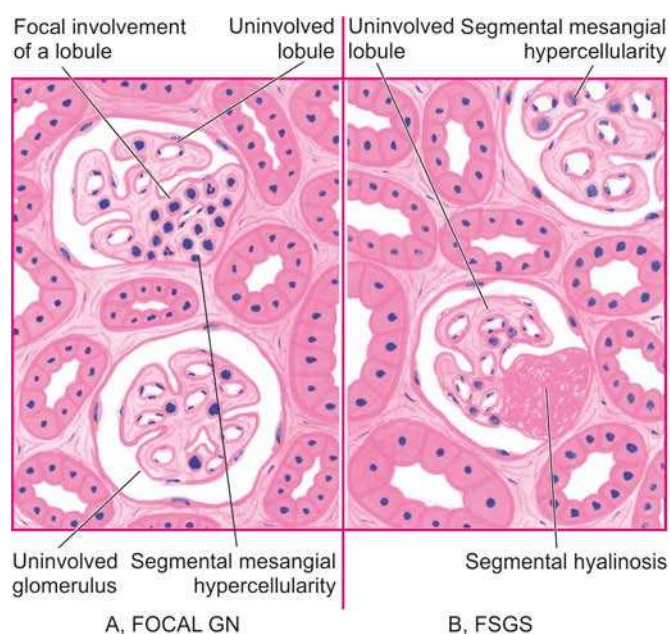

Figure 20.22 A, Focal GN. The characteristic feature is the cellular proliferation in some glomeruli and in one or two lobules of the affected glomeruli i.e. focal and segmental proliferative change. B, C, Focal segmental glomerulosclerosis. The features are focal and segmental involvement of the glomeruli by sclerosis and hyalinosis and mesangial hypercellularity.

Besides the lesions of focal and segmental scarring, a variant of FSGS, *collapsing glomerulopathy*, has been described in HIV patients. It is segmental or global glomerular collapse of the tuft along with the presence of hyperplasia and hypertrophy of podocytes producing a pseudo-crescent and a rapid decline in renal function.

By electron microscopy, diffuse loss of foot processes as seen in minimal change disease is evident but, in addition, there are electron-dense deposits in the region of hyalinosis and sclerosis which are believed to be immune complexes.

By Immunofluorescence microscopy, the deposits in the lesions are shown to contain IgM and C3.

CLINICAL FEATURES The condition may affect all ages including children and has male preponderance. The most common presentation is in the form of nephrotic syndrome with heavy proteinuria. Haematuria and hypertension tend to occur more frequently than in minimal change disease. Evidence of renal failure may be present at the onset.

IgA Nephropathy (Synonyms: Berger's Disease, IgA GN)

IgA nephropathy is emerging as the most common form of glomerulopathy worldwide and its incidence has been rising. It is characterised by aggregates of IgA, deposited principally in the mesangium. The condition was first described by Berger, a French physician in 1968 (Not to be confused with Buerger's disease or thromboangiitis obliterans described by an American pathologist in 1908 and discussed on page 384).

ETIOPATHOGENESIS The etiology of IgA nephropathy remains unclear:

- i) It is idiopathic in most cases.
- ii) Seen as part of Henoch-Schonlein purpura.
- iii) Association with chronic inflammation in various body systems (e.g. chronic liver disease, inflammatory bowel disease, interstitial pneumonitis, leprosy, dermatitis herpetiformis, uveitis, ankylosing spondylitis, Sjögren's syndrome, monoclonal IgA gammopathy).

Pathogenesis of IgA nephropathy is explained on the basis of following mechanisms:

- i) In view of exclusive mesangial deposits of IgA and elevated serum levels of IgA and IgA-immune complexes, IgA nephropathy has been considered to arise from *entrapment* of these complexes in the mesangium.
- ii) There is absence of early components of the complement but presence of C3 and properdin in the mesangial deposits, which point towards activation of *alternate complement pathway*.
- iii) Since there is close association between mucosal infections (e.g. of the respiratory, gastrointestinal or urinary tract), it is suggested that IgA deposited in the mesangium could be due to increased *mucosal secretion of IgA*.
- iv) HLA-B35 association has been reported in some cases. Another possibility is *genetically-determined* abnormality of the immune system producing an increase in circulating IgA.

MORPHOLOGIC FEATURES **By light microscopy**, the pattern of involvement varies. These include: focal

proliferative GN, focal segmental glomerulosclerosis, membranoproliferative GN, and rarely RPGN.

By electron microscopy, finely granular electron-dense deposits are seen in the mesangium.

By immunofluorescence microscopy, the diagnosis is firmly established by demonstration of mesangial deposits of IgA, with or without IgG, and usually with C3 and properdin.

CLINICAL FEATURES The disease is common in children and young adults. The clinical picture is usually characterised by recurrent bouts of haematuria that are often precipitated by mucosal infections. Mild proteinuria is usually present and occasionally nephrotic syndrome may develop.

Chronic Glomerulonephritis (Synonym: End-Stage Kidney, Chronic Kidney Disease)

Chronic GN is the final stage of a variety of glomerular diseases which result in irreversible impairment of renal function. The conditions which may progress to chronic GN, in descending order of frequency, are as under:

- i) Rapidly progressive GN (90%)
- ii) Membranous GN (50%)
- iii) Membranoproliferative GN (50%)
- iv) Focal segmental glomerulosclerosis (50%)
- v) IgA nephropathy (40%)
- vi) Acute post-streptococcal GN (1%).

However, about 20% cases of chronic GN are *idiopathic* without evidence of preceding GN of any type.

MORPHOLOGIC FEATURES **Grossly**, the kidneys are usually small and contracted weighing as low as 50 gm each. The capsule is adherent to the cortex. The cortical surface is generally diffusely granular (**Fig. 20.23**). On cut section, the cortex is narrow and atrophic, while the medulla is unremarkable.

Microscopically, the changes vary greatly depending upon the underlying glomerular disease. In general, the following changes are seen (**Fig. 20.24**).

i) Glomeruli Glomeruli are reduced in number and most of those present show completely hyalinised tufts, giving the appearance of acellular, eosinophilic masses which are PAS-positive. Evidence of underlying glomerular disease may be present.

ii) Tubules Many tubules completely disappear and there may be atrophy of tubules close to scarred glomeruli. Tubular cells show hyaline-droplets, degeneration and tubular lumina frequently contain eosinophilic, homogeneous casts.

iii) Interstitium There is fine and delicate fibrosis of the interstitial tissue and varying number of chronic inflammatory cells are often seen.

iv) Vessels Advanced cases which are frequently associated with hypertension show conspicuous arterial and arteriolar sclerosis.

Patients of chronic kidney disease on dialysis show a variety of dialysis associated changes that include acquired cystic disease (page 644), occurrence of adenomas and adenocarcinomas of the kidney, calcification of tufts and deposition of calcium oxalate crystals in tubules.

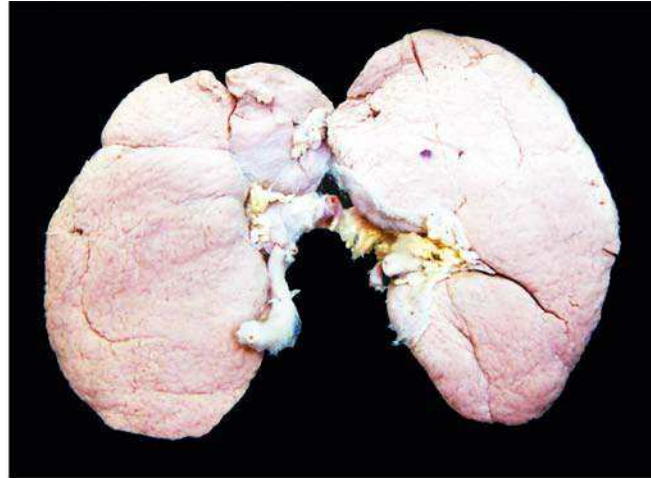

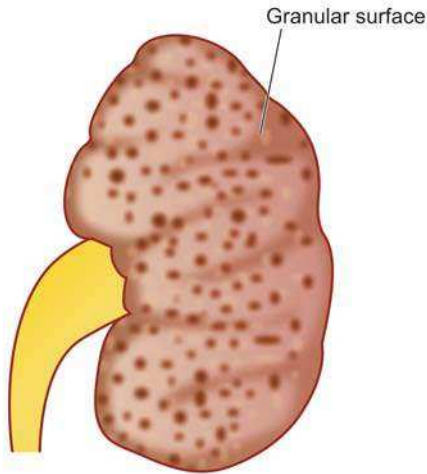

Figure 20.23 End-stage kidney, gross appearance of short contract kidney in chronic glomerulonephritis. The kidney is small and contracted. The capsule is adherent to the cortex and has diffusely granular cortical surface.

CLINICAL FEATURES The patients are usually adults. The terminal stage of chronic GN is characterised by hypertension, uraemia and progressive deterioration of renal function. Besides the primary changes due to chronic renal failure, there are a variety of systemic manifestations of uraemia (page 641). These patients eventually die if they do not receive a renal transplant.

The salient features of various types of primary glomerulonephritis are summarised in [Table 20.11](#).

II. SECONDARY GLOMERULAR DISEASES

Glomerular involvement may occur secondary to certain systemic diseases or a few hereditary diseases. In some of these, renal involvement may be the initial presentation, while in others clinical evidence of renal disease appears long after other manifestations have appeared. A list of these conditions has already been given in [Table 20.4](#). The important examples are described below.

Lupus Nephritis

Renal manifestations of systemic lupus erythematosus (SLE) are termed lupus nephritis. Other clinical manifestations, etiology and pathogenesis of this multi-system autoimmune disease are described in Chapter 3 (page 62). The incidence of renal involvement in SLE ranges from 40 to 75%. The two cardinal clinical manifestations of lupus nephritis are proteinuria and haematuria. In addition, hypertension and casts of different types such as red cell casts, fatty casts and leucocyte casts in the urinary sediment are found.

Pathogenesis of lesions in lupus nephritis is linked to genes related to major histocompatibility complex and B-cell signaling pathways such as TNF superfamily members.

MORPHOLOGIC FEATURES According to the WHO, six patterns of mutually-merging renal lesions are seen in lupus nephritis (*also refer to Table 3.9, page 63*):

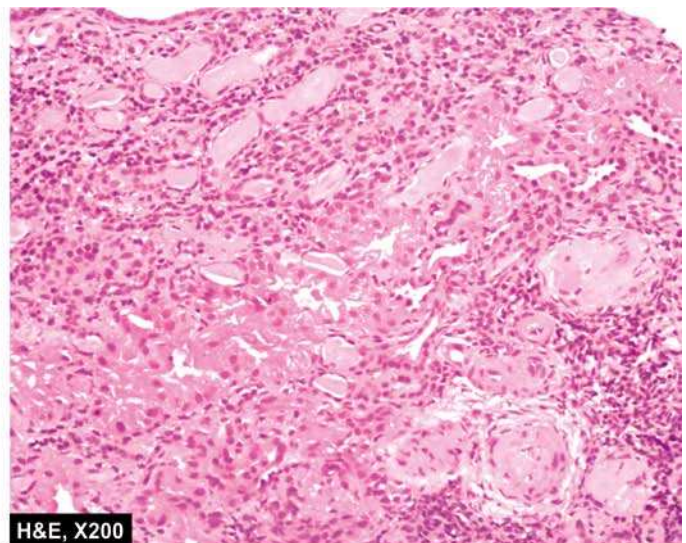

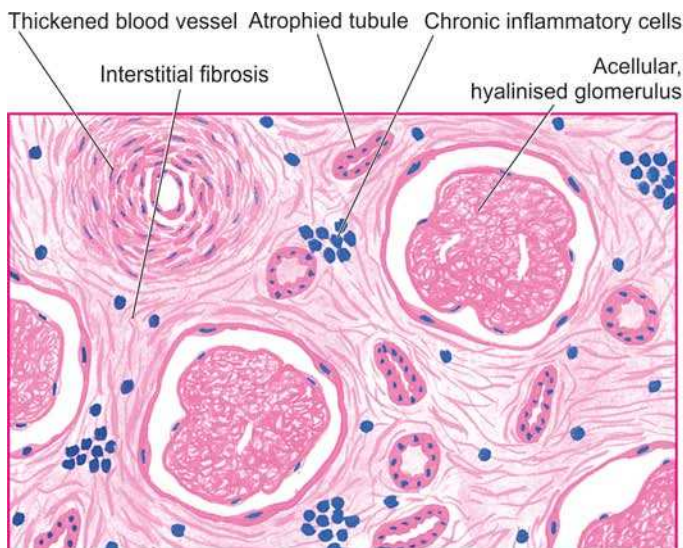

Figure 20.24 End-stage kidney in chronic GN, light microscopy. Glomerular tufts are acellular and completely hyalinised. Blood vessels in the interstitium are hyalinised and thickened while the interstitium shows fine fibrosis and a few chronic inflammatory cells.

Table 20.11 Comparative features of major forms of primary glomerulonephritis.

| TYPE | CLINICAL FEATURES | PATHOGENESIS | PATHOLOGY | | |
|--|---|---|---|---|--|
| | | | LM | EM | IFM |
| 1. <i>Acute GN</i> | Acute nephrotic syndrome | Immune complex disease (local or circulating) | Diffuse proliferation, leucocytic infiltration | Subepithelial deposits ('humps') | Irregular IgG, C3 |
| 2. <i>RPGN</i> | Acute renal failure | i) Type I: anti-GBM type ii) Type II: immune complex type iii) Type III: pauci-immune RPGN | Proliferation, crescents | i) Linear deposits along GBM ii) Subepithelial deposits iii) No deposits | i) Linear IgG, C3 ii) Granular IgG, C3 iii) Negative |
| 3. <i>Minimal change disease</i> | Nephrotic syndrome (highly selective proteinuria) | Reduction of normal negative charge on GBM ?Cell-mediated mechanism | Normal glomeruli, lipid vacuolation in tubules | Loss of foot processes, no deposits | Negative |
| 4. <i>Membranous GN</i> | Nephrotic syndrome | Immune complex disease (local) | Diffuse thickening of capillary wall | Subepithelial deposits ('spikes') | Granular IgG, C3 |
| 5. <i>Membrano-proliferative GN</i> | Nephrotic syndrome | Type I: immune complex disease Type II: dense deposit disease (alternate pathway activation) Type III: rare, with systemic diseases and drugs | Lobular proliferation of mesangial cells, increased mesangial matrix, double contour of GBM | Type I: Subendothelial deposits Type II: Dense intramembranous deposits Type III: Subendothelial and subepithelial deposits | Type I: IgG, C3 Type II: C3 properdin Type III: C3, IgG, IgM |
| 6. <i>Focal GN</i> | Variable, haematuria common | Variable, possibly immune complex disease | Focal and segmental proliferation | Mesangial deposits | IgA ± IgG, C3 and fibrin |
| 7. <i>Focal segmental glomerulosclerosis</i> | Nephrotic syndrome | i) Idiopathic ii) With superimposed primary glomerular disease iii) Secondary type | Focal and segmental sclerosis and hyalinosis | Loss of foot processes, electron dense deposits in regions of sclerosis and hyalinosis | IgM, C3 |
| 8. <i>IgA nephropathy</i> | Recurrent haematuria, mild proteinuria | Unknown, possibly alternate pathway disease | Variable, commonly focal proliferative GN | Mesangial electron-dense deposits | IgA ± IgG, C3, properdin |
| 9. <i>Chronic GN</i> | Chronic renal failure | Variable | Hyalinised glomeruli | Variable | Variable |

(GN = glomerulonephritis; LM = light microscopy; EM = electron microscopy; IFM = immunofluorescence microscopy)

Class I: Minimal lesions On light microscopy, these cases do not show any abnormality. But examination by electron microscopy and immunofluorescence microscopy shows deposits within the mesangium which consist of IgG and C3.

Class II: Mesangial lupus nephritis These cases have mild clinical manifestations. By light microscopy, there is increase in the number of mesangial cells and amount of mesangial matrix. Ultrastructural and immunofluorescence studies reveal granular mesangial deposits of IgG and C3; sometimes IgA and IgM are also present in the deposits.

Class III: Focal segmental lupus nephritis This is characterised by focal and segmental proliferation of endothelial and mesangial cells, together with infiltration by macrophages and sometimes neutrophils. Haematoxylin bodies of Gross may be present. Subendothelial and subepithelial deposits of IgG, often with IgM or IgA and C3, are seen.

Class IV: Diffuse proliferative lupus nephritis In this type, all the morphologic manifestations of lupus are present in most advanced form. This is the most severe and the most common form of lupus nephritis. There is diffuse proliferation of endothelial, mesangial, and sometimes epithelial cells, involving most or all glomeruli. Electron microscopy shows large electron-dense deposits in the mesangium and in the subendothelial region which on immunofluorescence are positive for IgG; sometimes also for IgA or IgM, and C3.

Class V: Membranous lupus nephritis These lesions resemble those of idiopathic membranous GN. These consist of diffuse thickening of glomerular capillary wall on light microscopy and show subendothelial deposits of immune complexes containing IgG, IgM and C3 on ultrastructural studies. Mesangial hypercellularity is present in some cases.

Class VI: Sclerosing lupus nephritis This is chronic kidney disease of SLE, similar to chronic GN. Most glomeruli are sclerosed and hyalinised and there may be remnants of preceding lesions.

Although in a given case, the lesions in lupus nephritis fit into one of the classes described above, it is not unusual to find overlapping and progressive transformation of lupus lesions during the course of disease.

Diabetic Nephropathy

Renal involvement is an important complication of diabetes mellitus. Chronic kidney disease with renal failure accounts for deaths in more than 10% of all diabetics. Renal complications are more severe, develop early and more frequently in type 1 (earlier called insulin-dependent) diabetes mellitus (30-40% cases) than in type 2 (earlier termed non-insulin-dependent) diabetics (about 20% cases). A variety of clinical syndromes are associated with diabetic nephropathy that includes asymptomatic proteinuria, nephrotic syndrome, progressive renal failure and hypertension. Cardiovascular disease is 40 times more common in patients of chronic kidney disease in diabetes mellitus than in non-diabetics and more diabetics die from cardiovascular complications than from uraemia.

MORPHOLOGIC FEATURES Diabetic nephropathy encompasses 4 types of renal lesions in diabetes mellitus: diabetic glomerulosclerosis, vascular lesions, diabetic pyelonephritis and tubular lesions (Armani-Ebstein lesions).

1. DIABETIC GLOMERULOSCLEROSIS Glomerular lesions in diabetes mellitus are particularly common and account for majority of abnormal findings referable to the kidney.

Pathogenesis of these lesions in diabetes mellitus is explained by following sequential changes: hyper-

glycaemia → glomerular hypertension → renal hyperperfusion → deposition of proteins in the mesangium → glomerulosclerosis → renal failure. In addition, cellular infiltration in renal lesions in diabetic glomerular lesions is due to growth factors, particularly transforming growth factor- β . Strict control of blood glucose level and control of systemic hypertension in these patients retards progression to diabetic nephropathy.

Glomerulosclerosis in diabetes may take one of the 2 forms: diffuse or nodular lesions:

i) Diffuse glomerulosclerosis Diffuse glomerular lesions are the most common. There is involvement of all parts of glomeruli. The pathologic changes consist of thickening of the GBM and diffuse increase in mesangial matrix with mild proliferation of mesangial cells. Various exudative lesions such as capsular hyaline drops and fibrin caps may also be present (**Fig. 20.25,A**) *Capsular drop* is an eosinophilic hyaline thickening of the parietal layer of Bowman's capsule and bulges into the glomerular space. *Fibrin cap* is homogeneous, brightly eosinophilic material appearing on the wall of a peripheral capillary of a lobule.

ii) Nodular glomerulosclerosis Nodular lesions of diabetic glomerulosclerosis are also called as *Kimmelstiel-Wilson (KW) lesions* or *intercapillary glomerulosclerosis*. These lesions are specific for type 1 diabetes (juvenile-onset diabetes) or islet cell antibody-positive diabetes mellitus. The pathologic changes consist of one or more nodules in a few or many glomeruli. *Nodule* is an ovoid or spherical, laminated, hyaline, acellular mass located within a lobule of the glomerulus. The nodules are surrounded peripherally by glomerular capillary loops which may have normal or thickened GBM (**Fig. 20.25,B**). The nodules are PAS-positive and contain lipid and fibrin. As the nodular lesions enlarge, they compress the glomerular capillaries and obliterate the glomerular tuft (**Fig. 20.26**). As a result of glomerular and arteriolar

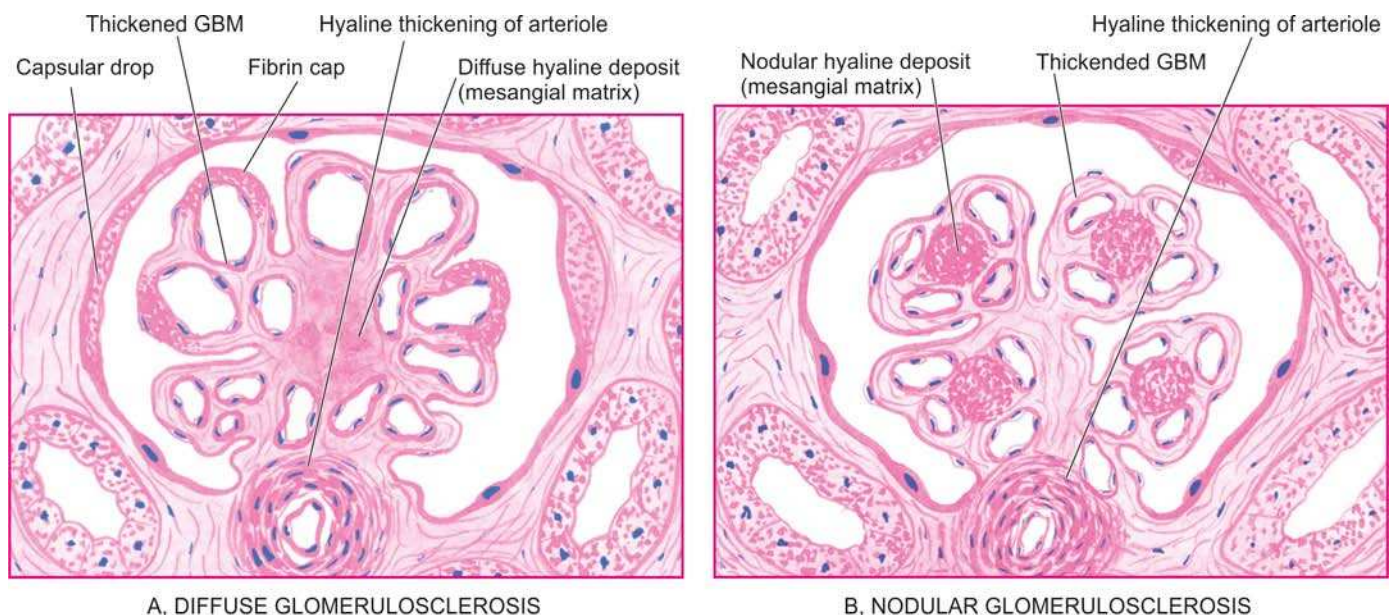

Figure 20.25 Diabetic glomerulosclerosis. *A, Diffuse lesions.* The characteristic features are diffuse involvement of the glomeruli showing thickening of the GBM and diffuse increase in the mesangial matrix with mild proliferation of mesangial cells and exudative lesions (fibrin caps and capsular drops). *B, Nodular lesion (Kimmelstiel-Wilson Lesion).* There are one or more hyaline nodules within the lobules of glomeruli, surrounded peripherally by glomerular capillaries with thickened walls.

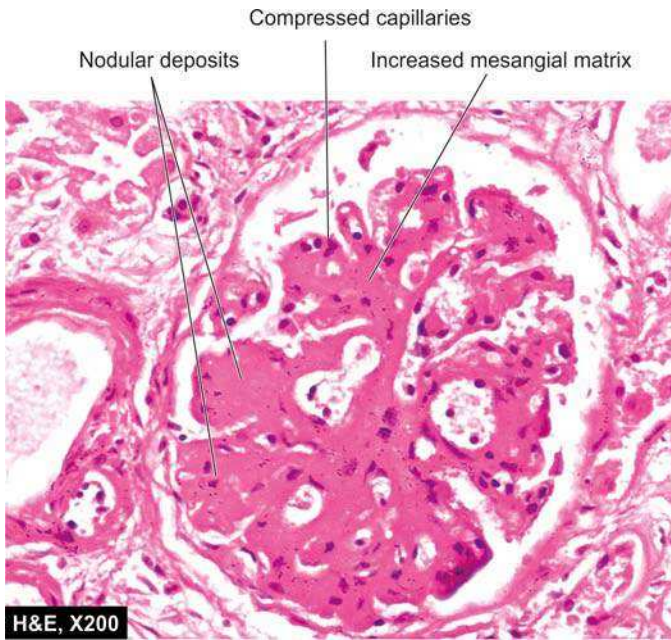

Figure 20.26 Diabetic nephropathy—nodular (Kimmelstiel-Wilson or KW) lesions.

involvement, renal ischaemia occurs leading to tubular atrophy and interstitial fibrosis and results in grossly small, contracted kidney.

2. VASCULAR LESIONS *Atheroma* of renal arteries is very common and severe in diabetes mellitus. *Hyaline arteriosclerosis* (page 371) affecting the afferent and efferent arterioles of the glomeruli is also often severe in diabetes. These vascular lesions are responsible for renal ischaemia that results in tubular atrophy and interstitial fibrosis.

3. DIABETIC PYELONEPHRITIS Poorly-controlled diabetics are particularly susceptible to bacterial infections. Papillary necrosis (necrotising papillitis) (page 669) is an important complication of diabetes that may result in acute pyelonephritis. Chronic pyelonephritis is 10 to 20 times more common in diabetics than in others.

4. TUBULAR LESIONS (ARMANNI-EBSTEIN LESIONS) In untreated diabetics who have extremely high blood sugar level, the epithelial cells of the proximal convoluted tubules develop extensive glycogen deposits appearing as vacuoles. These are called Armani-Ebstein lesions. The tubules return to normal on control of hyperglycaemic state.

Hereditary Nephritis

A group of hereditary diseases principally involving the glomeruli are termed hereditary nephritis. These include Alport's syndrome, Fabry's disease and nail-patella syndrome.

1. Alport's syndrome Out of various hereditary nephritis, Alport's syndrome is relatively more common and has been extensively studied. This is an X-linked dominant disorder having mutation in α -5 chain of type IV collagen located on X-chromosome. It affects males more severely than females. The syndrome consists of sensori-neural deafness and ophthalmic complications (lens dislocation, posterior cataracts and corneal dystrophy) associated with hereditary nephritis. The condition is slowly progressive, terminating in chronic kidney disease in the 2nd to 3rd decades of life. The common presenting

features are persistent or recurrent haematuria accompanied by erythrocyte casts, proteinuria and hypertension.

By **light microscopy**, the glomeruli have predominant involvement and show segmental proliferation of mesangial cells with increased mesangial matrix and occasional segmental sclerosis. Another prominent feature is the presence of *lipid-laden foam cells* in the interstitium. As the disease progresses, there is increasing sclerosis of glomeruli, tubular atrophy and interstitial fibrosis.

Electron microscopy reveals characteristic basement membrane splitting or lamination in the affected parts of glomeruli.

Immunofluorescence studies fail to show deposits of immunoglobulins or complement components.

2. Fabry's disease, another hereditary nephritis is characterised by accumulation of neutral glycosphingolipids in lysosomes of glomerular, tubular, vascular and interstitial cells.

3. Nail-patella syndrome or osteonychodysplasia is a rare hereditary disease having abnormality in α -1 chain of collagen V on chromosome 9 associated with multiple osseous defects of elbows, knees and nail dysplasia. About half the cases develop nephropathy.

GIST BOX 20.7 Specific Glomerular Diseases

- ☐ Glomerular diseases are divided into primary glomerulonephritis (GN) and secondary forms.
- ☐ Acute GN is known to follow acute infection (post-streptococcal) and characteristically presents as acute nephritic syndrome in children.
- ☐ RPGN is an acute reduction in renal function resulting in acute renal failure rapidly and is characterised by formation of 'crescents'.
- ☐ Minimal change disease is nephrotic syndrome in children accompanied by no apparent change in glomeruli by light microscopy.
- ☐ Membranous GN is characterised by widespread thickening of the glomerular capillary wall and is the most common cause of nephrotic syndrome in adults.
- ☐ Membranoproliferative GN is characterised by increase in mesangial cellularity associated with increased lobulation of the tuft, and irregular thickening of the capillary wall.
- ☐ Focal and diffuse proliferative GN is a pathologic diagnosis depending upon whether <50% or > 50% glomeruli show proliferative changes.
- ☐ Focal segmental glomerulosclerosis is sclerosis and hyalinosis of some glomeruli and portions of their tuft.
- ☐ IgA nephropathy or Berger's disease is another common form of GN in which there are mesangial deposits of IgA.
- ☐ Chronic GN is the final stage of a variety of glomerular diseases which result in irreversible impairment of renal function.
- ☐ Renal manifestations of systemic lupus erythematosus are termed lupus nephritis and consists of 6 progressive classes (class I to VI).
- ☐ Diabetic nephropathy encompasses diabetic glomerulosclerosis, vascular lesions, diabetic pyelonephritis and tubular lesions.
- ☐ Hereditary nephritis includes Alport's syndrome, Fabry's disease and nail-patella syndrome.

TUBULAR AND TUBULOINTERSTITIAL DISEASES

It is difficult to separate the involvement of the tubules and the interstitium since most forms of tubular diseases also involve the interstitium, while the tubules and interstitium may be involved secondarily as a part of the diseases of other renal parenchymal components. For the purpose of present discussion, this group parenchymal of diseases is discussed under 2 headings:

I. Primary tubular diseases that include tubular injury by ischaemic or toxic agents i.e. acute tubular necrosis.

II. Tubulointerstitial diseases that include inflammatory involvement of the tubules and the interstitium i.e. pyelonephritis (acute and chronic).

ACUTE TUBULAR NECROSIS

Acute tubular necrosis (ATN) is the term used for acute renal failure (ARF) resulting from destruction of tubular epithelial cells. ATN is the most common and most important cause of ARF characterised by sudden cessation of renal function. Various other causes of ARF (pre-renal, intra-renal and post-renal) as well as the clinical syndrome accompanying ATN (oliguric phase, diuretic phase and phase of recovery) are described already on page 641. Based on etiology and morphology, two forms of ATN are distinguished—*ischaemic* and *toxic*; however both forms have a somewhat common pathogenesis.

PATHOGENESIS OF ATN The pathogenesis of both types of ATN resulting in ARF is explained on the basis of the following sequential mechanism and is illustrated in **Fig. 20.27**:

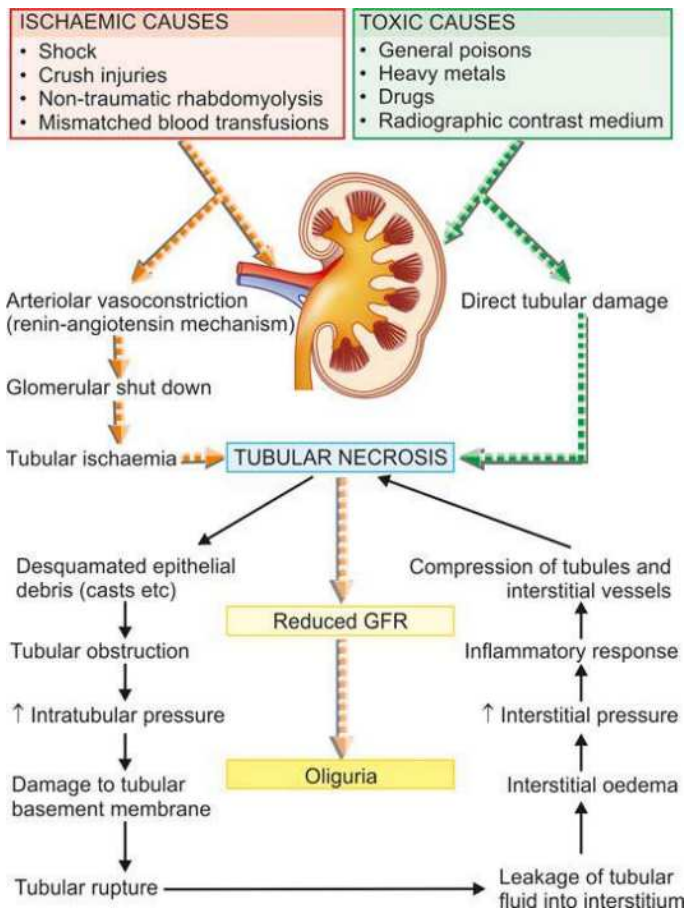

Figure 20.27 Pathogenesis of ATN.

i) Renal tubules are highly *susceptible* to injury by ischaemia and toxic agents.

ii) *Tubular damage* in ischaemic ATN is initiated by arteriolar vasoconstriction induced by renin-angiotensin system, while in toxic ATN by direct damage to tubules by the agent.

iii) Debris of the desquamated epithelium due to necrosis causes *tubular obstruction* and may block urinary outflow with consequent reduction of GFR and also produce casts in the urine.

iv) These events cause *increased intratubular pressure* resulting in damage to tubular basement membrane.

v) Due to increased intratubular pressure, there is *tubular rupture*.

vi) Damage to tubules is accompanied with leakage of fluid into the interstitium causing *interstitial oedema*.

vii) Leakage of tubular fluid into the interstitium increases *interstitial pressure*.

viii) Leaked fluid incites host *inflammatory response*.

ix) Increased interstitial pressure causes *compression of tubules and blood vessels* and setting up a vicious cycle of accentuated ischaemia and necrosis.

x) Ultimately, it leads to reduced GFR and consequently *oliguria*.

Ischaemic ATN

Ischaemic ATN, also called tubulorrhctic ATN, lower (distal) nephron nephrosis, anoxic nephrosis, or shock kidney, occurs due to hypoperfusion of the kidneys resulting in focal damage to the distal parts of the convoluted tubules.

ETIOLOGY Ischaemic ATN is more common than toxic ATN and accounts for more than 80% cases of tubular injury. Ischaemia may result from a variety of causes as follows:

1. Shock (post-traumatic, surgical, burns, dehydration, obstetrical and septic type).
2. Crush injuries.
3. Non-traumatic rhabdomyolysis induced by alcohol, coma, muscle disease or extreme muscular exertion (myoglobinuric nephrosis).
4. Mismatched blood transfusions, black-water fever (haemoglobinuric nephrosis).

MORPHOLOGIC FEATURES *Grossly*, the kidneys are enlarged and swollen. On cut section, the cortex is often widened and pale, while the medulla is dark.

Histologically, predominant changes are seen in the tubules, while glomeruli remain unaffected. The interstitium shows oedema and mild chronic inflammatory cell infiltrate. Tubular changes are as follows (**Fig. 20.28**):

1. Dilatation of the proximal and distal convoluted tubules.
2. Focal tubular necrosis at different points along the nephron.
3. Flattened epithelium lining the tubules suggesting epithelial regeneration.
4. Eosinophilic hyaline casts or pigmented haemoglobin and myoglobin casts in the tubular lumina.
5. Disruption of tubular basement membrane adjacent to the cast may occur (tubulorrhexis).

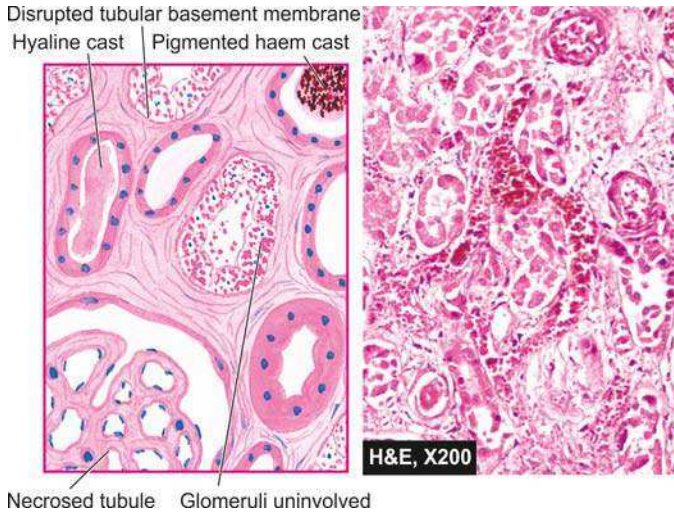

Figure 20.28 Ischaemic ATN. There is focal necrosis along the nephron involving proximal convoluted tubule (PCT) as well as distal convoluted tubule (DCT). The affected tubules are dilated, their lumina contain casts (hyaline or pigmented haem) and the affected regions are lined by regenerating thin and flat epithelium.

Prognosis of ischaemic ATN depends upon the underlying etiology. In general, cases that follow severe trauma, surgical procedures, extensive burns and sepsis have much worse outlook than the others.

Toxic ATN

Toxic ATN, also called nephrotoxic ATN or toxic nephrosis or upper (proximal) nephron nephrosis, occurs as a result of direct damage to tubules, more marked in proximal portions, by ingestion, injection or inhalation of a number of toxic agents.

ETIOLOGY The toxic agents causing toxic ATN are as under:

1. General poisons such as mercuric chloride, carbon tetrachloride, ethylene glycol, mushroom poisoning and insecticides.
2. Heavy metals (mercury, lead, arsenic, phosphorus and gold).
3. Drugs such as sulfonamides, certain antibiotics (gentamycin, cephalosporin), anaesthetic agents (methoxyflurane, halothane), barbiturates, salicylates.
4. Radiographic contrast material.

MORPHOLOGIC FEATURES Poisoning with mercuric chloride provides the classic example that produces widespread and readily discernible tubular necrosis (*acute mercury nephropathy*).

Grossly, the kidneys are enlarged and swollen. On cut section, the cortex is pale and swollen, while the medulla is slightly darker than normal.

Histologically, the appearance varies according to the cause of toxic ATN but, in general, it involves the segment of tubule diffusely (unlike ischaemic ATN where the involvement of nephron is focal). In mercuric chloride poisoning, the features are as follows (**Fig. 22.29**):

1. Epithelial cells of mainly proximal convoluted tubules are necrotic and desquamated into the tubular lumina.

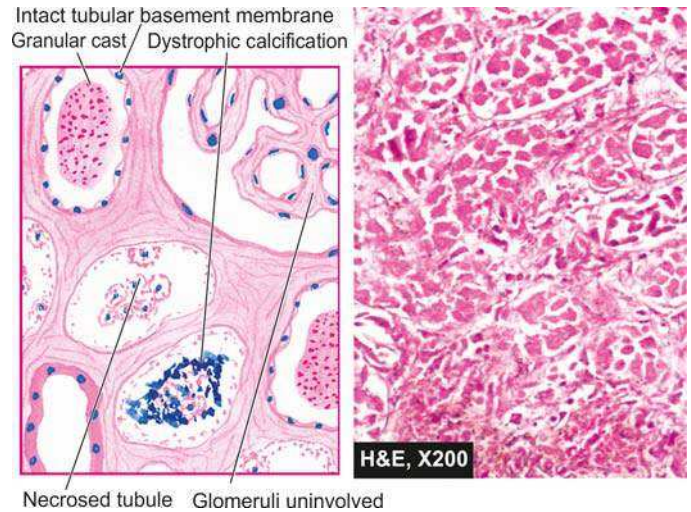

Figure 20.29 Toxic ATN. There is extensive necrosis of epithelial cells involving predominantly proximal convoluted tubule (PCT) diffusely. The necrosed cells are desquamated into the tubular lumina and may undergo dystrophic calcification. The tubular lumina contain casts (granular) and the regenerating flat epithelium lines the necrosed tubule.

2. The desquamated cells may undergo dystrophic calcification.
3. Tubular basement membrane is generally intact.
4. The regenerating epithelium, which is flat and thin with few mitoses, may be seen lining the tubular basement membrane.

Prognosis of toxic ATN is good if there is no serious damage to other organs such as heart and liver.

The contrasting features of the two forms of ATN are presented in **Table 20.12**.

TUBULOINTERSTITIAL DISEASES

The term tubulointerstitial nephritis is used for inflammatory process that predominantly involves the renal interstitial tissue and is usually accompanied by some degree of tubular damage. A number of primary glomerular, tubular, vascular and obstructive diseases are secondarily associated with interstitial reaction. However, the term *interstitial nephritis* is reserved for those cases where there is no primary involvement of glomeruli, tubules or blood vessels. The older nomenclature, interstitial nephritis, is currently used synonymously with *tubulointerstitial nephritis* or *tubulointerstitial nephropathy*.

A number of bacterial and non-bacterial, acute and chronic conditions may produce tubulointerstitial nephritis and are listed in **Table 20.13**. The important and common examples among these are discussed below.

Acute Pyelonephritis

Acute pyelonephritis is an acute suppurative inflammation of the kidney caused by pyogenic bacteria.

ETIOPATHOGENESIS Most cases of acute pyelonephritis follow infection of the lower urinary tract. The most common

Table 20.12 Contrasting features of ischaemic and toxic ATN.

| FEATURE | ISCHAEMIC ATN | TOXIC ATN |
|----------------------------|---|--|
| 1. <i>Synonyms</i> | Tubulorrhectic ATN, lower (distal) nephron nephrosis, anoxic nephrosis, shock kidney | Nephrotoxic ATN, upper (proximal) nephron nephrosis, toxic ATN |
| 2. <i>Frequency</i> | More common (80% cases) | Less common |
| 3. <i>Major etiologies</i> | Shock, crush injuries, mismatched blood transfusion | Poisons, heavy metals, certain drugs |
| 4. <i>G/A</i> | Kidneys enlarged, swollen, cut section cortex pale, medulla dark | Similar to ischaemic ATN |
| 5. <i>M/E</i> | i) Distal tubular damage more prominent ii) Focal tubular necrosis iii) Regenerating epithelium iv) Casts: Hyaline, pigment, myoglobin v) Basement membrane disrupted | i) Proximal tubular damage more prominent ii) More diffuse tubular injury iii) Regenerating epithelium iv) Tubular lumina may contained dystrophic calcification v) Basement membrane generally intact |
| 6. <i>Prognosis</i> | Worse | Good |

pathogenic organism in urinary tract infection (UTI) is *Escherichia coli* (in 90% of cases), followed in decreasing frequency, by *Enterobacter*, *Klebsiella*, *Pseudomonas* and *Proteus*. The bacteria gain entry into the urinary tract, and then into the kidney by one of the two routes: ascending infection and haematogenous infection (Fig. 20.30):

1. Ascending infection This is the most common route of infection. The common pathogenic organisms are inhabitants of the colon and may cause faecal contamination of the urethral orifice, especially in females in reproductive age group. This has been variously attributed to shorter urethra in females liable to faecal contamination, hormonal influences facilitating bacterial adherence to the mucosa, absence of prostatic secretions which have antibacterial properties, and urethral trauma during sexual intercourse. The last named produces what is appropriately labelled as 'honeymoon pyelitis'. Ascending infection may occur in a normal individual but the susceptibility is increased in patients with diabetes mellitus, pregnancy, urinary tract obstruction or instrumentation. Bacteria multiply in the urinary bladder and produce

asymptomatic bacteriuria found in many of these cases. After having caused urethritis and cystitis, the bacteria in susceptible cases ascend further up into the ureters against the flow of urine, extend into the renal pelvis and then the renal cortex. The role of vesico-ureteral reflux is not a significant factor in the pathogenesis of acute pyelonephritis as it is in chronic pyelonephritis.

2. Haematogenous infection Less often, acute pyelonephritis may result from blood-borne spread of infection. This occurs more often in patients with obstructive lesions in the urinary tract, and in debilitated or immunosuppressed patients.

 9. Nephrocalcinosis
 10. Idiopathic interstitial nephritis

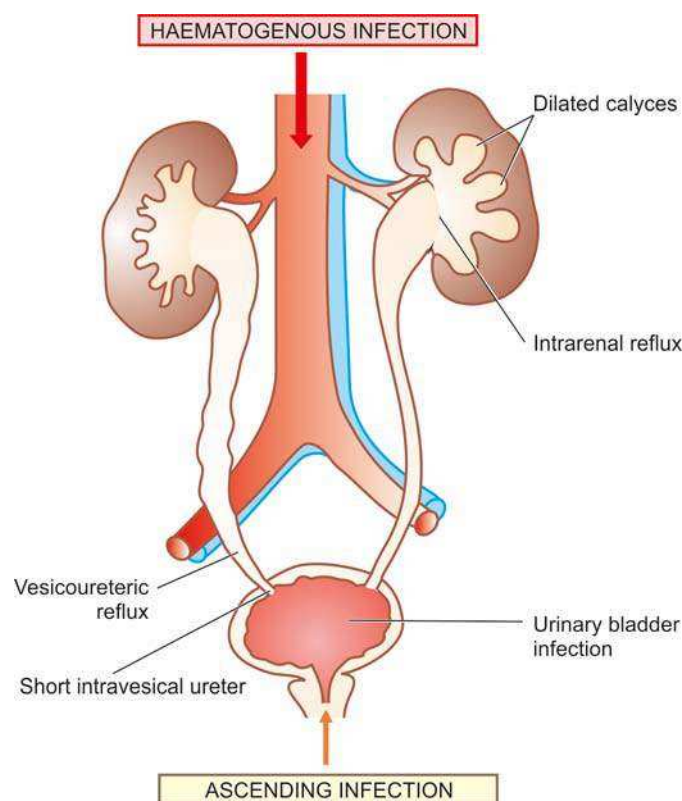

Figure 20.30 Pathogenesis of reflux nephropathy.

MORPHOLOGIC FEATURES *Grossly*, well-developed cases of acute pyelonephritis show enlarged and swollen kidney that bulges on section. The cut surface shows small, yellow-white abscesses with a haemorrhagic rim. These abscesses may be several millimetres across and are situated mainly in the cortex.

Microscopically, acute pyelonephritis is characterised by extensive acute inflammation involving the interstitium and causing destruction of the tubules. Generally, the glomeruli and renal blood vessels show considerable resistance to infection and are spared. The acute inflammation may be in the form of large number of neutrophils in the interstitial tissue and bursting into tubules, or may form focal neutrophilic abscesses in the renal parenchyma.

CLINICAL FEATURES Classically, acute pyelonephritis has an acute onset with chills, fever, loin pain, lumbar tenderness, dysuria and frequency of micturition. Urine will show abundance of bacteria, pus cells and pus cell casts in the urinary sediment. Institution of specific antibiotics, after identification of bacteria by culture followed by sensitivity test, eradicates the infection in majority of patients.

COMPLICATIONS Complications of acute pyelonephritis are encountered more often in patients with diabetes mellitus or with urinary tract obstruction. Following are the three important complications of acute pyelonephritis:

1. Papillary necrosis Papillary necrosis or necrotising papillitis develops more commonly in analgesic abuse nephropathy and in sickle cell disease but may occur as a complication of acute pyelonephritis as well. It may affect one or both kidneys.

Grossly, the necrotic papillae are yellow to grey-white, sharply-defined areas with congested border and resemble infarction. The pelvis may be dilated.

Microscopically, necrotic tissue is separated from the viable tissue by a dense zone of polymorphs. The necrotic area shows characteristic coagulative necrosis as seen in renal infarcts.

2. Pyonephrosis Rarely, the abscesses in the kidney in acute pyelonephritis are extensive, particularly in cases with obstruction. This results in inability of the abscesses to drain and this transforms the kidney into a multilocular sac filled with pus called as pyonephrosis or renal carbuncle (**Fig. 20.31**).

3. Perinephric abscess The abscesses in the kidney may extend through the capsule of the kidney into the perinephric tissue and form perinephric abscess.

Chronic Pyelonephritis

Chronic pyelonephritis is a chronic tubulointerstitial disease resulting from repeated attacks of inflammation and scarring.

ETIOPATHOGENESIS Depending upon the etiology and pathogenesis, two types of chronic pyelonephritis are described—reflux nephropathy and obstructive pyelonephritis (**Fig. 20.32**):

1. Reflux nephropathy Reflux of urine from the bladder into one or both the ureters during micturition is the major cause

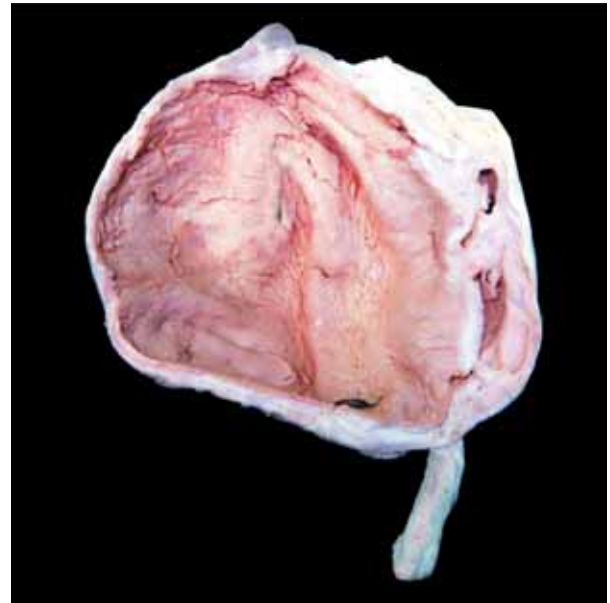

Figure 20.31 Pyonephrosis. The kidney is enlarged and has increased perinephric fat in the hilum. Sectioned surface shows markedly dilated pelvis and calyces having irregular and ragged inner surface and containing necrotic debris and pus.

of chronic pyelonephritis. *Vesicoureteric reflux* is particularly common in children, especially in girls, due to congenital absence or shortening of the intravesical portion of the ureter so that ureter is not compressed during the act of micturition. Reflux results in increase in pressure in the renal pelvis so that the urine is forced into renal tubules which is eventually followed by damage to the kidney and scar formation (see **Fig. 20.30**). Vesicoureteric reflux is more common in patients with urinary tract infection, whether symptomatic or asymptomatic, but reflux of sterile urine can also cause renal damage.

2. Obstructive pyelonephritis Obstruction to the outflow of urine at different levels predisposes the kidney to infection (page 672). Recurrent episodes of such obstruction and infection result in renal damage and scarring. Rarely, recurrent attacks of acute pyelonephritis may cause renal damage and scarring.

MORPHOLOGIC FEATURES *Grossly*, the kidneys show rather characteristic appearance. The kidneys are usually small and contracted (weighing less than 100 gm) showing unequal reduction, which distinguishes it from other forms of contracted kidney. The surface of the kidney is irregularly scarred; the capsule can be stripped off with difficulty due to adherence to scars. These scars are of variable size and show characteristic U-shaped depressions on the cortical surface. There is generally blunting and dilatation of calyces (*calyectasis*) and dilated pelvis of the kidney (**Fig. 20.33**).

Microscopically, predominant changes are seen in interstitium and (**Fig. 20.34**):

i) Interstitium There is chronic interstitial inflammatory reaction, chiefly composed of lymphocytes, plasma cells and macrophages with pronounced interstitial fibrosis. *Xanthogranulomatous pyelonephritis* is an uncommon variant characterised by collection of foamy macrophages admixed with other inflammatory cells and giant cells.

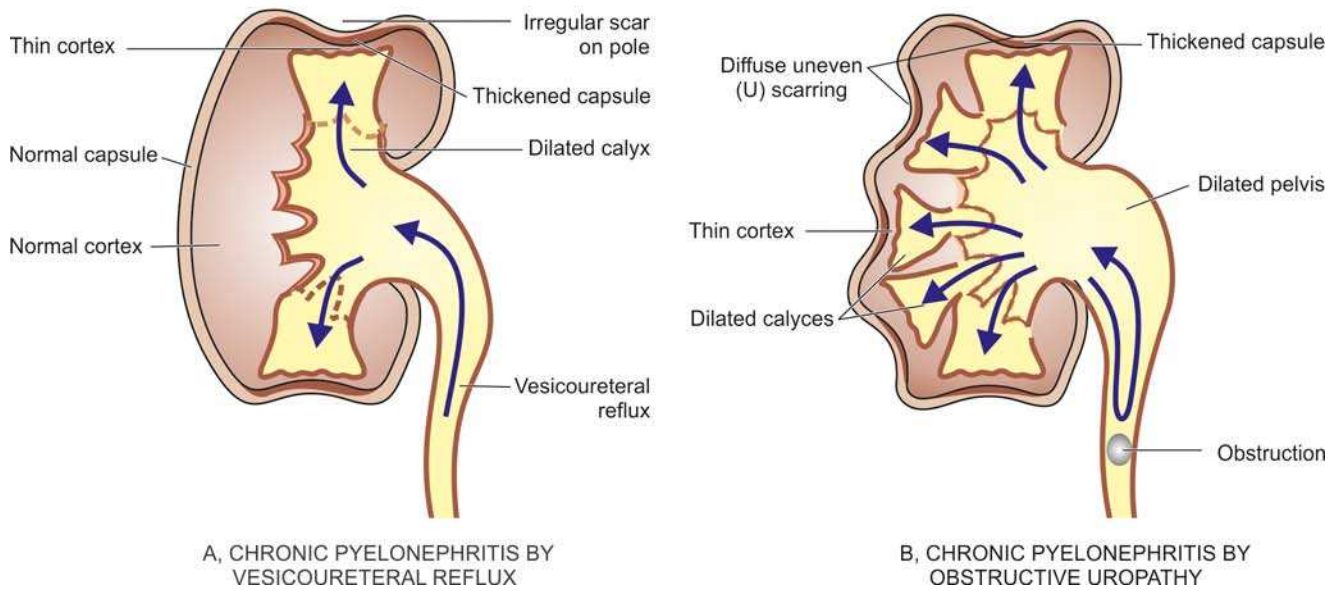

Figure 20.32 The two major types of mechanisms in chronic pyelonephritis. A, *Vesicoureteric reflux* causing infection of peripheral papillae and consequent scars at the poles of the kidney. B, *Obstructive pyelonephritis* due to obstruction of the urinary tract causing high pressure backflow of urine and infection of all the papillae and consequent diffuse scarring of the kidney and thinning of the cortex.

ii) Tubules The tubules show varying degree of atrophy and dilatation. Dilated tubules may contain eosinophilic colloid casts producing thyroïdisation of tubules. A few tubules may contain neutrophils.

iii) Pelvicalyceal system The renal pelvis and calyces are dilated. The walls of pelvis and calyces show marked chronic inflammation and fibrosis. Lymphoid follicles with germinal centres may be present in the pelvicalyceal walls. The lining epithelium may undergo squamous metaplastic change.

iv) Blood vessels Blood vessels entrapped in the scarred areas show obliterative endarteritis. There may be changes of hypertensive hyaline arteriosclerosis.

v) Glomeruli Though glomerular tuft in the scarred area is usually intact, there is often periglomerular fibrosis. In advanced cases, there may be hyalinisation of glomeruli.

CLINICAL FEATURES Chronic pyelonephritis often has an insidious onset. The patients present with clinical picture of chronic renal failure or with symptoms of hypertension. Sometimes, the patients may present with features of acute recurrent pyelonephritis with fever, loin pain, lumbar tenderness, dysuria, pyuria, bacteriuria and frequency of micturition. Diagnosis is made by intravenous pyelography (IVP). Culture of the urine may give positive results.

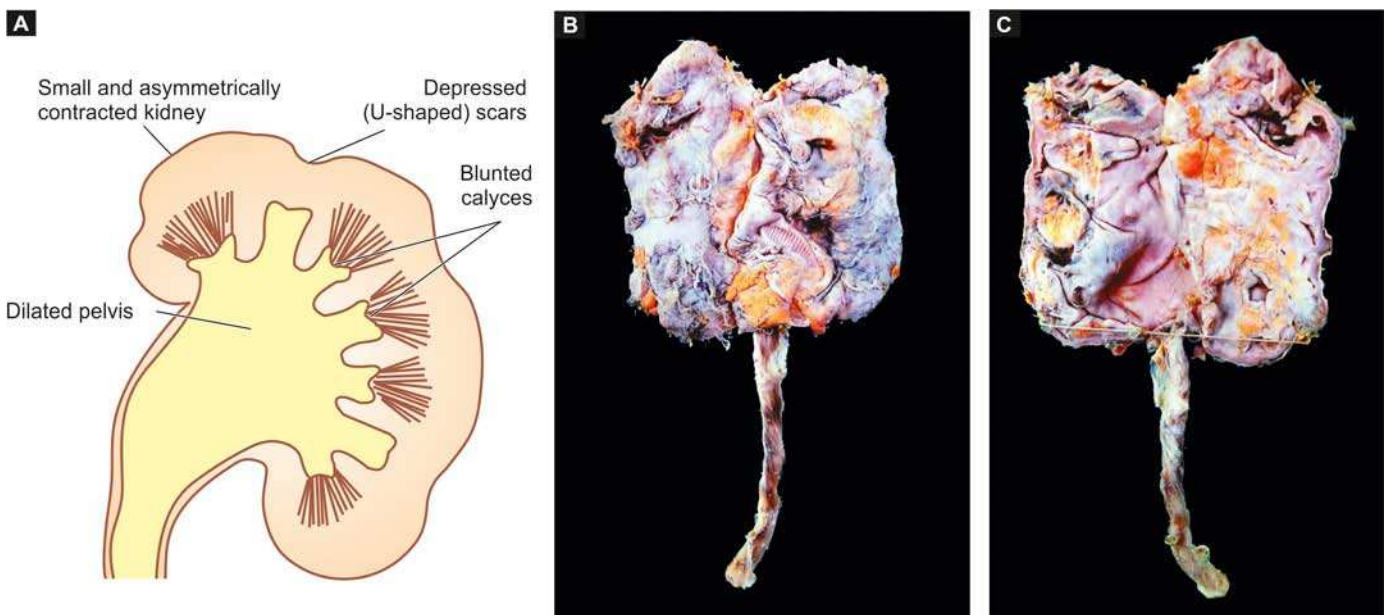

Figure 20.33 Small contracted kidney in chronic pyelonephritis with calyctasis. A, Diagrammatic representation. B, External surface of small and contracted kidney. The kidney is small in size and contracted. The capsule is adherent to the cortex and has irregular scars on the surface. C, Sectioned surface shows dilated pelvi-calyceal system with atrophied and thin peripheral cortex and increased hilar fat extending inside.

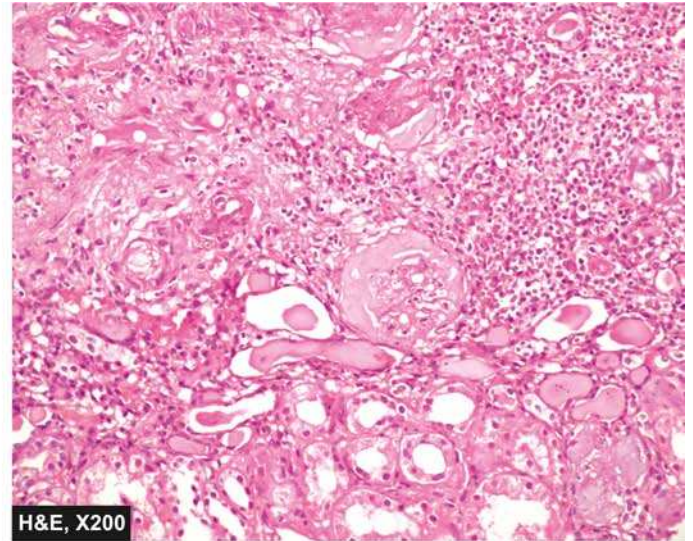

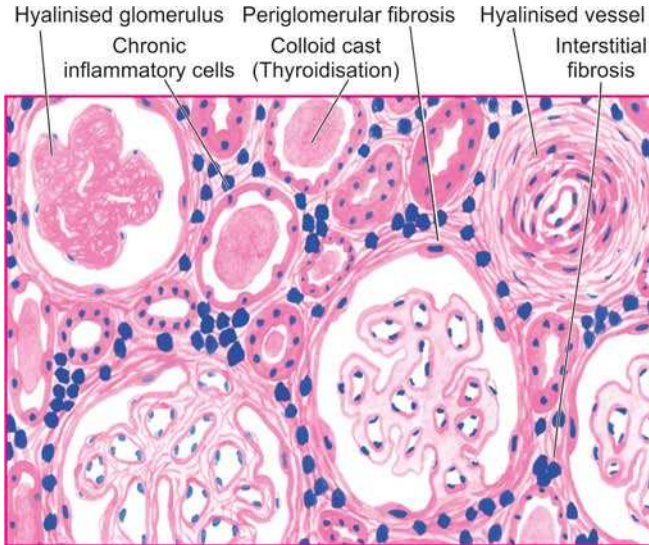

Figure 20.34 Chronic pyelonephritis. The scarred area shows atrophy of some tubules and dilatation of others which contain colloid casts (thyroidisation). The tubules are surrounded by abundant fibrous tissue and chronic interstitial inflammatory reaction. The blood vessels included are thick-walled and the glomeruli show periglomerular fibrosis.

Longstanding cases of chronic pyelonephritis may develop secondary systemic amyloidosis.

Tuberculous Pyelonephritis

Tuberculosis of the kidney occurs due to haematogenous spread of infection from another site, most often from the lungs. Less commonly, it may result from ascending infection from tuberculosis of the genitourinary system such as from epididymis or Fallopian tubes. The renal lesions in tuberculosis may be in the form of tuberculous pyelonephritis or appear as multiple miliary tubercles.

MORPHOLOGIC FEATURES *Grossly*, the lesions in tuberculous pyelonephritis are often bilateral, usually involving the medulla with replacement of the papillae by caseous tissue. Obstruction may result in tuberculous pyonephrosis in which thinned out renal parenchyma surrounds dilated pelvis and calyces filled with caseous material.

Histologically, typical caseating epithelioid cell granulomatous reaction is seen. Acid-fast bacilli can often be demonstrated in the lesions.

CLINICAL FEATURES Most patients are young to middle-aged adults. The clinical presentation is extremely variable but it should always be considered as a possibility in a patient in whom there is persistent sterile pyuria, microscopic haematuria and mild proteinuria after effective antibiotic therapy for urinary tract infection. The diagnosis rests on identification of *M. tuberculosis* by repeated culture of urine on L.J. media.

Myeloma Nephropathy

Renal involvement in multiple myeloma (page 363) is referred to as myeloma nephropathy or myeloma kidney. Functional renal impairment in multiple myeloma is a common manifestation, developing in about 50% of patients. The pathogenesis of myeloma kidney is related to excess filtration

of Bence Jones proteins through the glomerulus, usually *kappa* (*k*) light chains. These light chain proteins are precipitated in the distal convoluted tubules in combination with Tamm-Horsfall proteins, the urinary glycoproteins. The precipitates form tubular casts which are eosinophilic and often laminated. These casts may induce peritubular interstitial inflammatory reaction. Not all light chains are nephrotoxic and their toxicity occurs under acidic pH of the tubular fluid.

MORPHOLOGIC FEATURES *Grossly*, the kidneys may be normal or small and shrunken.

Histologically, there are some areas of tubular atrophy while many other tubular lumina are dilated and contain characteristic bright pink laminated cracked or fractured casts consisting of Bence-Jones proteins called fractured casts. These casts are surrounded by peritubular interstitial inflammatory reaction including the presence of nonspecific inflammatory cells and some multinucleate giant cells induced by tubular casts.

Nephrocalcinosis

Nephrocalcinosis is a diffuse deposition of calcium salts in renal tissue in a number of renal diseases, in hypercalcaemia, hyperphosphataemia and renal tubular acidosis. Most commonly, it develops as a complication of severe hypercalcaemia such as due to hyperparathyroidism, hypervitaminosis D, excessive bone destruction in metastatic malignancy, hyperthyroidism, excessive calcium intake such as in milk-alkali syndrome and sarcoidosis (page 154). Clinically, patients of hypercalcaemia and nephrocalcinosis may have renal colic, band keratopathy due to calcium deposits in the cornea, visceral metastatic calcification, polyuria and renal failure.

MORPHOLOGIC FEATURES Nephrocalcinosis due to hypercalcaemia characteristically shows deposition of calcium in the tubular epithelial cells in the basement membrane, within the mitochondria and in the cytoplasm. These concretions may produce secondary tubular atrophy,

interstitial fibrosis and nonspecific chronic inflammation in the interstitium. As the calcification occurs intracellularly, radiological evidence is usually not present until fairly late in the disease. The calcium deposits become first visible as small opacities in the renal papillae.

**GIST BOX 20.8****Tubular and Tubulointerstitial Diseases**

- ▣ Acute tubular necrosis (ATN) is acute renal failure resulting from destruction of tubular epithelial cells.
- ▣ Based on etiology and morphology, ATN may be ischaemic or toxic.
- ▣ Acute pyelonephritis is an acute suppurative inflammation of the kidney caused by pyogenic bacteria by either ascending infection or by haematogenous route.
- ▣ Chronic pyelonephritis is chronic tubulointerstitial disease resulting from repeated attacks of inflammation and scarring. It may be due to reflux nephropathy or obstruction to the outflow of urine.
- ▣ Other tubulointerstitial diseases include tuberculosis, myeloma, due to drugs etc.

Table 20.14 Causes of obstructive uropathy.

 2. Vesicoureteric obstruction
 3. Urethral stricture
 4. Urethral valves
 5. Inflammation (e.g. phimosis, cystitis etc)
 6. Neuromuscular dysfunction
- C. EXTRAMURAL
 1. Pregnant uterus
 2. Retroperitoneal fibrosis
 3. Tumours (e.g. carcinoma of cervix, rectum, colon, caecum etc)
 4. Prostatic enlargement, prostatic carcinoma and prostatitis
 5. Trauma

OBSTRUCTIVE UROPATHY

Obstruction in the urinary tract is common and important because it increases the susceptibility to infection and stone formation. Obstruction can occur at any age and in either sex. The cause of obstruction may lie at any level of the urinary tract—renal pelvis, ureters, urinary bladder and urethra. The obstruction at any of these anatomic locations may be intraluminal, intramural or extramural. Important causes are listed in **Table 20.14** and illustrated in **Fig. 20.35**.

The obstruction may be unilateral or bilateral, partial or complete, sudden or insidious. Complete bilateral obstruction may result in irreversible renal failure, whereas long-standing chronic partial obstruction may cause various functional abnormalities and anatomic changes. There are three important anatomic sequelae of obstruction, namely: *hydronephrosis*, *hydroureter* and *hypertrophy of the bladder*. Before describing these conditions, an account of the most common and important cause of obstructive uropathy, *nephrolithiasis*, is given first.

NEPHROLITHIASIS

Nephrolithiasis or urolithiasis is formation of urinary calculi at any level of the urinary tract. Urinary calculi are worldwide in distribution but are particularly common in some geographic locations such as in parts of the United States, South Africa, India and South-East Asia. It is estimated that approximately 2% of the population experiences renal stone disease at sometime in their life with male-female ratio of 2:1. The peak incidence is observed in 2nd to 3rd decades of life. Renal calculi are characterised clinically by colicky pain (*renal colic*) as they pass down along the ureter and manifest by haematuria.

Types of Urinary Calculi

There are 4 main types of urinary calculi—calcium containing, mixed (struvite), uric acid and cystine stones, and a few rare types (**Table 20.15**).

1. CALCIUM STONES Calcium stones are the most common comprising about 75% of all urinary calculi. They may

Table 20.15 Salient features of urinary calculi.

| TYPE | INCIDENCE | ETIOLOGY | PATHOGENESIS |
|----------------------------|-----------|---|--|
| 1. Calcium stones | 75% | Hypercalciuria with or without hypercalcaemia; idiopathic | Supersaturation of ions in urine, alkaline pH of urine; low urinary volume, oxaluria and hyperuricosuria |
| 2. Mixed (struvite) stones | 15% | Urinary infection with urea-splitting organisms like <i>Proteus</i> | Alkaline urinary pH produced by ammonia from splitting of urea by bacterially produced urease |
| 3. Uric acid stones | 6% | Hyperuricosuria with or without hyperuricaemia (e.g. in primary and secondary gout) | Acidic urine (pH below 6) decreases the solubility of uric acid in urine and favours its precipitation |
| 4. Cystine stones | 2% | Genetically-determined defect in cystine transport | Cystinuria containing least soluble cystine precipitates as cystine crystals |
| 5. Other types | < 2% | Inherited abnormalities of amino acid metabolism | Xanthinuria |

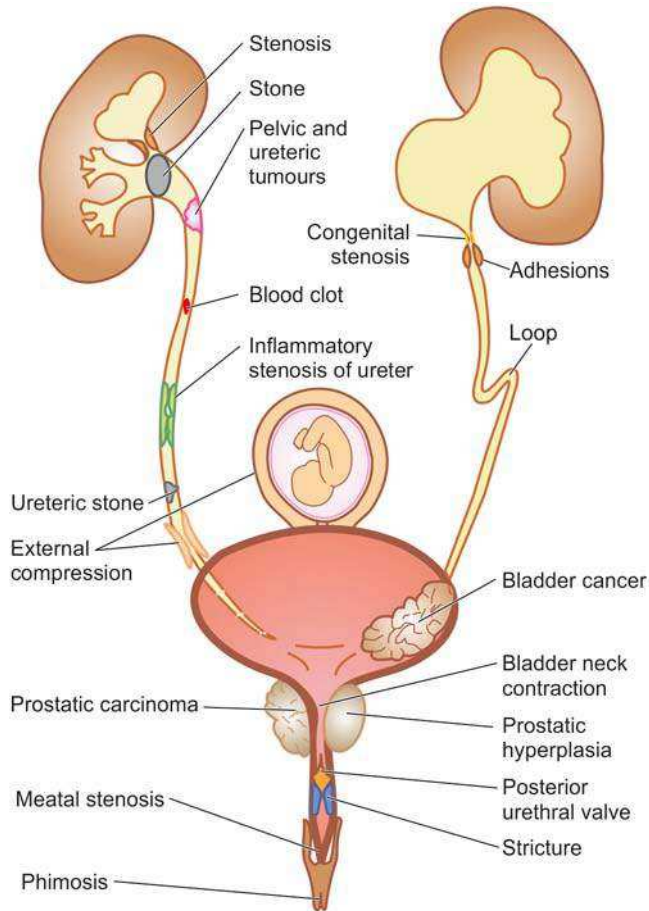

Figure 20.35 Causes of obstructive uropathy.

be pure stones of calcium oxalate (50%) or calcium phosphate (5%), or mixture of calcium oxalate and calcium phosphate (45%).

Etiology Etiology of calcium stones is variable.

- i) About 50% of patients with calcium stones have *idiopathic hypercalciuria without hypercalcaemia*.
- ii) Approximately 10% cases are associated with *hypercalcaemia* and *hypercalciuria*, most commonly due to hyper-

parathyroidism, or a defect in the bowel (i.e. absorptive hypercalciuria), or in the kidney (i.e. renal hypercalciuria).

iii) About 15% of patients with calcium stones have *hyperuricosuria with a normal blood uric acid level* and without any abnormality of calcium metabolism.

iv) In about 25% of patients with calcium stones, the cause is unknown as there is no abnormality in urinary excretion of calcium, uric acid or oxalate and is referred to as '*idiopathic calcium stone disease*'.

Pathogenesis The mechanism of calcium stone formation is explained on the basis of imbalance between the degree of supersaturation of the ions forming the stone and the concentration of inhibitors in the urine. Most likely site where the crystals of calcium oxalate and/or calcium phosphate are precipitated is the tubular lining or around some fragment of debris in the tubule acting as nidus of the stone. The stone grows, as more and more crystals are deposited around the nidus. A number of other predisposing factors contributing to formation of calcium stones are alkaline urinary pH, decreased urinary volume and increased excretion of oxalate and uric acid.

Morphology Calcium stones are usually small (less than a centimeter), ovoid, hard, with granular rough surface. They are dark brown due to old blood pigment deposited in them as a result of repeated trauma caused to the urinary tract by these sharp-edged stones.

2. MIXED (STRUVITE) STONES About 15% of urinary calculi are made of magnesium-ammonium-calcium phosphate, often called *struvite*; hence mixed stones are also called as '*struvite stones*' or '*triple phosphate stones*'.

Etiology Struvite stones are formed as a result of infection of the urinary tract with urea-splitting organisms that produce urease such as by species of *Proteus*, and occasionally *Klebsiella*, *Pseudomonas* and *Enterobacter*. These are, therefore, also known as infection-induced stones. However, *E. coli* does not form urease.

Morphology Struvite stones are yellow-white or grey. They tend to be soft and friable and irregular in shape. 'Staghorn stone' which is a large, solitary stone that takes the shape of the renal pelvis where it is often formed is an example of struvite stone (**Fig. 20.36**).

3. URIC ACID STONES Approximately 6% of urinary calculi are made of uric acid. Uric acid calculi are *radiolucent* unlike radio-opaque calcium stones.

Etiology Uric acid stones are frequently formed in cases with hyperuricaemia and hyperuricosuria such as due to primary gout or secondary gout due to myeloproliferative disorders (e.g. in leukaemias), especially those on chemotherapy, and administration of uricosuric drugs (e.g. salicylates, probenecid). Other factors contributing to their formation are acidic urinary pH (below 6) and low urinary volume.

Pathogenesis The solubility of uric acid at pH of 7 is 200 mg/dl while at pH of 5 is 15 mg/dl. Thus, as the urine becomes more acidic, the solubility of uric acid in urine decreases and precipitation of uric acid crystals increases favouring the formation of uric acid stones. Hyperuricosuria is the most important factor in the production of uric acid stones, while hyperuricaemia is found in about half the cases.

Morphology Uric acid stones are smooth, yellowish-brown, hard and often multiple. On cut section, they show laminated structure.

Table 20.15 Urinary calculi (continued)

| MORPHOLOGY | |
|------------|-----------------------------|
| | Calcium oxalate stones |
| | Struvite ('Staghorn') stone |
| | Uric acid stones |
| | Cystine stones |

Figure facing Table 20.15

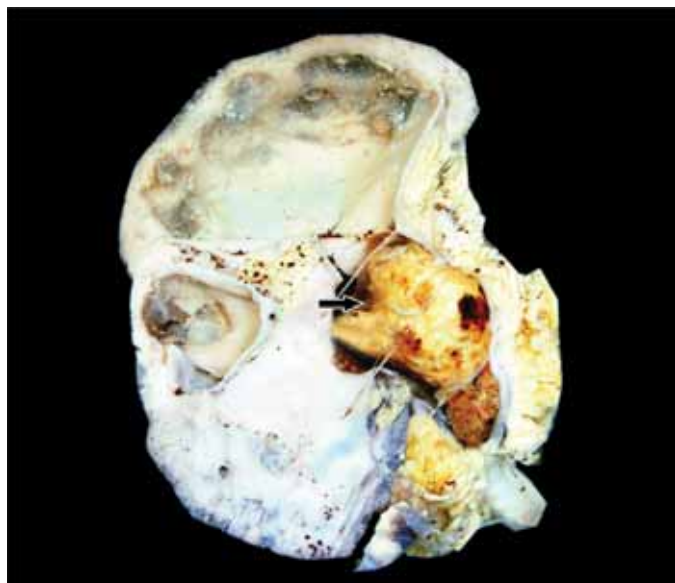

Figure 20.36 Staghorn renal stone with chronic pyelonephritis. The kidney is enlarged and heavy. The capsule is adherent to the cortex and has irregular scars on the surface. Sectioned surface shows dilated pelvi-calyceal system with atrophied and thin peripheral cortex. The pelvis of the kidney contains a single, large, soft yellow white stone taking the contour of the pelvi-calyceal system (arrow).

4. CYSTINE STONES Cystine stones comprise less than 2% of urinary calculi.

Etiology Cystine stones are associated with cystinuria due to a genetically-determined defect in the transport of cystine and other amino acids across the cell membrane of the renal tubules and the small intestinal mucosa.

Pathogenesis The resultant excessive excretion of cystine which is least soluble of the naturally-occurring amino acids leads to formation of crystals and eventually cystine calculi.

Morphology Cystine stones are small, rounded, smooth and often multiple. They are yellowish and waxy.

5. OTHER CALCULI Less than 2% of urinary calculi consist of other rare types such as due to inherited abnormality of enzyme metabolism e.g. hereditary xanthinuria developing xanthine stones.

HYDRONEPHROSIS

Hydronephrosis is the term used for dilatation of renal pelvis and calyces due to partial or intermittent obstruction to the outflow of urine (see Fig. 20.35). Hydronephrosis develops if one or both the pelviureteric sphincters are incompetent, as otherwise there will be dilatation and hypertrophy of the urinary bladder but no hydronephrosis. Hydroureter nearly always accompanies hydronephrosis. Hydronephrosis may be *unilateral or bilateral*.

Unilateral Hydronephrosis

This occurs due to some form of ureteral obstruction at the level of pelviureteric junction (PUJ). The causes are:

- 1. Intraluminal** e.g. a calculus in the ureter or renal pelvis.
- 2. Intramural** e.g. congenital PUJ obstruction, atresia of ureter, inflammatory stricture, trauma, neoplasm of ureter or bladder.

- 3. Extramural** e.g. obstruction of upper part of the ureter by inferior renal artery or vein, pressure on ureter from outside such as carcinoma cervix, prostate, rectum, colon or caecum and retroperitoneal fibrosis.

Bilateral Hydronephrosis

This is generally the result of some form of urethral obstruction but can occur from the various causes listed above if the lesions involve both sides. Based on this, hydronephrosis may be of following types:

- 1. Congenital** e.g. atresia of the urethral meatus, congenital posterior urethral valve.
- 2. Acquired** e.g. bladder tumour involving both ureteric orifices, prostatic enlargement, prostatic carcinoma and prostatitis, bladder neck stenosis, inflammatory or traumatic urethral stricture and phimosis.

MORPHOLOGIC FEATURES The pathologic changes vary depending upon whether the obstruction is sudden and complete, or incomplete and intermittent. The latter situation is more common.

Grossly, the kidneys may have moderate to marked enlargement. Initially, there is *extrarenal hydronephrosis* characterised by dilatation of renal pelvis medially in the form of a sac (Fig. 20.37,A). As the obstruction persists, there is progressive dilatation of pelvis and calyces and pressure atrophy of renal parenchyma. Eventually, the dilated pelvi-calyceal system extends deep into the renal cortex so that a thin rim of renal cortex is stretched over the dilated calyces and the external surface assumes lobulated appearance. This advanced stage is called as *intrarenal hydronephrosis* (Fig. 20.37,B). An important point of distinction between the sectioned surface of advanced hydronephrosis and polycystic kidney disease (page 645) is the direct continuity of dilated cystic spaces (i.e. dilated calyces) with the renal pelvis in the former (Fig. 20.38).

Microscopically, the wall of hydronephrotic sac is thickened due to fibrous scarring and chronic inflammatory cell infiltrate. There is progressive atrophy of tubules and glomeruli alongwith interstitial fibrosis. Stasis of urine in hydronephrosis causes infection (*pyelitis*) resulting in filling of the sac with pus, a condition called *pyonephrosis*.

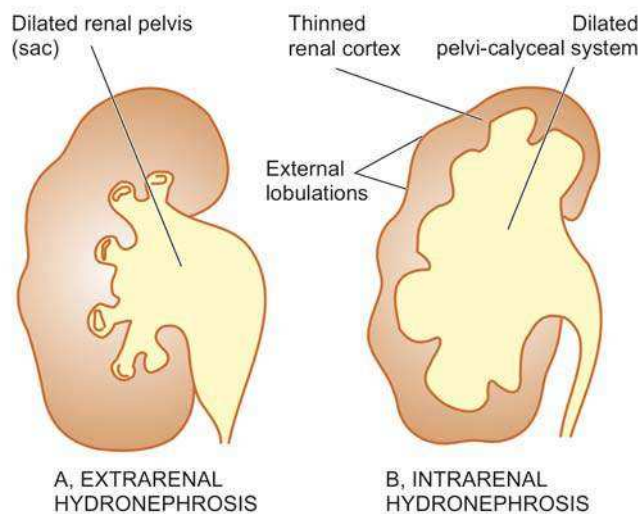

Figure 20.37 Hydronephrosis, stages in its evolution.

Figure 20.38 Hydronephrosis with nephrolithiasis. The kidney is enlarged and heavy. On cut section, the renal pelvis and calyces are dilated and cystic and contain a large stone in the pelvis of the kidney (arrow). The cystic change is seen to extend into renal parenchyma, compressing the cortex as a thin rim at the periphery. Unlike polycystic kidney, however, these cysts are communicating with the pelvi-calyceal system.

GIST BOX 20.9 Obstructive Uropathy

- ▣ There are three important anatomic sequelae of obstruction, namely: hydronephrosis, hydroureter and hypertrophy of the bladder.
- ▣ Nephrolithiasis or urolithiasis is formation of urinary calculi at any level of the urinary tract and is the most common cause of obstructive uropathy.
- ▣ There are 4 main types of urinary calculi—calcium containing, mixed (struvite), uric acid and cystine stones, and a few rare types.
- ▣ Hydronephrosis develops if one or both the pelviureteric sphincters are incompetent. Depending upon etiology, it may be unilateral or bilateral. Hydroureter invariably accompanies it.

RENAL VASCULAR DISEASES

Renal blood vessels which enormously perfuse the kidney are affected secondarily in majority of renal diseases. Renal blood flow is controlled by systemic and local haemodynamic, hormonal and intrinsic intra-renal mechanisms. Diseases which disturb these controlling mechanisms give rise to primary renal vascular lesions. These diseases are as under:

I. Most importantly, *hypertensive vascular disease* and its consequent renal manifestations in the form of benign and malignant nephrosclerosis.

II. *Thrombotic microangiopathy*.

III. *Renal cortical necrosis*.

IV. *Renal infarcts*.

Renal infarcts are already described in Chapter 4 (page 113); other conditions are discussed here.

HYPERTENSIVE VASCULAR DISEASE

An elevated arterial blood pressure is a major health problem, particularly in developed countries. A persistent and

sustained high blood pressure has damaging effects on the heart (e.g. hypertensive heart disease, Chapter 14), brain (e.g. cerebrovascular accident or stroke, Chapter 28) and kidneys (benign and malignant nephrosclerosis).

Definition and Classification

Hypertension is a common disease in industrialised countries and accounts for 6% of death worldwide. Epidemiologic studies have revealed that with elevation in systolic and diastolic blood pressure above normal in adults, there is a continuous increased risk of cardiovascular disease, stroke and renal disease—cardiovascular risk doubles with every 20 mmHg increase in systolic and 10 mmHg increase in diastolic blood pressure above normal levels. Criteria for normal blood pressure, prehypertension and hypertension (stage 1 and stage 2) have been laid by the National Institutes of Health (NIH), US (**Table 20.16**). According to this criteria, normal cut-off values for systolic and diastolic blood pressure are taken as < 120 and < 80 mmHg respectively. As per this criteria, arterial or systemic hypertension in adults is defined clinically as persistent elevation of systolic blood pressure of 140-159 mmHg, or diastolic pressure of 90-99 mmHg as *stage 1 hypertension*, and corresponding values above 160 or above 100 mmHg as *stage 2 hypertension*. Cases falling between upper normal values for systolic and diastolic blood pressure (i.e. above 120/80 mmHg) and those for stage 1 hypertension (120-139/80-89 mmHg) are grouped under *prehypertension* requiring monitoring and follow-up. The diastolic pressure is often considered more significant. Since blood pressure varies with many factors such as age of the patient, exercise, emotional disturbances like fear and anxiety, it is important to measure blood pressure at least twice during two separate examinations under least stressful conditions.

Hypertension is generally classified into 2 types:

1. Primary or essential hypertension in which the cause of increase in blood pressure is unknown. Essential hypertension constitutes about 80-95% patients of hypertension.

2. Secondary hypertension in which the increase in blood pressure is caused by diseases of the kidneys, endocrines or some other organs. Secondary hypertension comprises remaining 5-20% cases of hypertension.

According to the clinical course, both essential and secondary hypertension may be benign or malignant.

◆ **Benign hypertension** is moderate elevation of blood pressure and the rise is slow over the years. About 90-95% patients of hypertension have benign hypertension.

Table 20.16 Clinical classification of hypertension*.

| CATEGORY | SYSTOLIC (mmHg) | DIASTOLIC (mmHg) |
|---------------------------------------|----------------------|----------------------|
| <i>Normal</i> | < 120 | and < 80 |
| <i>Prehypertension</i> | 120-139 | or 80-89 |
| Hypertension | | |
| Stage 1 | 140-159 | or 90-99 |
| Stage 2 | >160 | or >100 |
| <i>Isolated systolic hypertension</i> | ≥140 | and < 90 |
| <i>Malignant hypertension</i> | > 200 (sudden onset) | ≥ 140 (sudden onset) |

*Chobanian et al, JAMA, 2003.

◆ **Malignant hypertension** is marked and sudden increase of blood pressure to 200/140 mmHg or more in a known case of hypertension or in a previously normotensive individual; the patients develop papilloedema, retinal haemorrhages and hypertensive encephalopathy. Less than 5% of hypertensive patients develop malignant hypertension, life expectancy after diagnosis in these patients is generally less than 2 years if not treated effectively.

Etiology and Pathogenesis

The etiology and pathogenesis of secondary hypertension that comprises less than 10% cases has been better understood, whereas the mechanism of essential hypertension, that constitutes about 90% of cases, remains largely obscure. In general, normal blood pressure is regulated by 2 haemodynamic forces—*cardiac output* and *total peripheral vascular resistance*. Factors which alter these two factors result in hypertension. The role of kidney in hypertension, particularly in secondary hypertension, by elaboration of renin and subsequent formation of angiotensin II, is well established (renin-angiotensin system).

With this background knowledge, we next turn to the mechanisms involved in the two forms of hypertension (Table 20.17).

ESSENTIAL (PRIMARY) HYPERTENSION By definition, the cause of essential hypertension is unknown but a number of factors are related to its development. These are as under:

1. Genetic factors The role of heredity in the etiology of essential hypertension has long been suspected. The evidences in support are the familial aggregation, occurrence of hypertension in twins, epidemiologic data, experimental animal studies and identification of hypertension susceptibility gene (angiotensinogen gene).

2. Racial and environmental factors Surveys in the US have revealed higher incidence of essential hypertension in African Americans than in whites. A number of environmental factors have been implicated in the development of hypertension including salt intake, obesity, skilled occupation, higher living standards and individuals under high stress.

3. Risk factors modifying the course of essential hypertension There is sufficient evidence to show that the course of essential hypertension that begins in middle life is modified by a number of factors. These are as under:

Table 20.17 Etiologic classification of hypertension.

| | |
|------|-----------------------------------|
| A. | ESSENTIAL HYPERTENSION (90%) |
| 1. | Genetic factors |
| 2. | Racial and environmental factors |
| 3. | Risk factors modifying the course |
| B. | SECONDARY HYPERTENSION (10%) |
| 1. | <i>Renal</i> |
| i) | Renovascular |
| ii) | Renal parenchymal diseases |
| 2. | <i>Endocrine</i> |
| i) | Adrenocortical hyperfunction |
| ii) | Hyperparathyroidism |
| iii) | Oral contraceptives |
| 3. | <i>Coarctation of Aorta</i> |
| 4. | <i>Neurogenic</i> |

i) **Age** Younger the age at which hypertension is first noted but left untreated, lower the life expectancy.

ii) **Sex** Females with hypertension appear to do better than males.

iii) **Atherosclerosis** Accelerated atherosclerosis invariably accompanies essential hypertension. This could be due to contributory role of other independent factors like cigarette smoking, elevated serum cholesterol, glucose intolerance and obesity.

iv) **Other risk factors** Other factors which alter the prognosis in hypertension include: smoking, excess of alcohol intake, diabetes mellitus, persistently high diastolic pressure above normal and evidence of end-organ damage (i.e. heart, eyes, kidney and nervous system).

Pathogenesis in essential hypertension is explained by many theories. These are as under:

1. **High plasma level of catecholamines.**

2. **Increase in blood volume** i.e. arterial overfilling (volume hypertension) and arteriolar constriction (vasoconstrictor hypertension).

3. **Increased cardiac output.**

4. **Low-renin essential hypertension** found in approximately 20% patients due to altered responsiveness to renin release.

5. **High renin essential hypertension** seen in about 15% cases due to decreased adrenal responsiveness to angiotensin II.

SECONDARY HYPERTENSION Though much less common than essential hypertension, mechanisms underlying secondary hypertension with identifiable cause have been studied more extensively. Based on the etiology, these are described under four headings: renal hypertension, endocrine hypertension, hypertension associated with coarctation of aorta and neurogenic causes.

1. RENAL HYPERTENSION Hypertension produced by renal diseases is called renal hypertension. Renal hypertension is subdivided into 2 groups:

i) **Renal vascular hypertension** e.g. in occlusion of a major renal artery, pre-eclampsia, eclampsia, polyarteritis nodosa and fibromuscular dysplasia of renal artery.

ii) **Renal parenchymal hypertension** e.g. in various types of glomerulonephritis, pyelonephritis, interstitial nephritis, diabetic nephropathy, amyloidosis, polycystic kidney disease and renin-producing tumours.

In either case, renal hypertension can be produced by one of the following 3 inter-related pathogenetic mechanisms:

a) Activation of renin-angiotensin system Renin is a proteolytic enzyme produced and stored in the granules of the juxtaglomerular cells surrounding the afferent arterioles of glomerulus (page 638). The release of renin is stimulated by renal ischaemia, sympathetic nervous system stimulation, depressed sodium concentration, fluid depletion and decreased potassium intake. Released renin is transported through blood stream to the liver where it acts upon substrate angiotensinogen, an α_2 -globulin synthesised in the liver, to form angiotensin I, a decapeptide. Angiotensin I is converted into angiotensin II, an octapeptide, by the action of convertase in the lungs. Angiotensin II is the most potent naturally-occurring vasoconstrictor substance and its pressor action is mainly attributed to peripheral arteriolar vasoconstriction. The other main effect of angiotensin II is to stimulate the

adrenal cortex to secrete aldosterone via AT_1 receptor and thus promotes reabsorption of sodium and water.

Thus, the renin-angiotensin system is concerned mainly with 3 functions:

- i) Control of blood pressure by altering plasma concentration of angiotensin II and aldosterone.
- ii) Regulation of sodium and water content.
- iii) Regulation of potassium balance.

The renin-angiotensin mechanism is summarised in **Fig. 20.39**.

b) Sodium and water retention Blood volume and cardiac output, both of which have a bearing on blood pressure, are regulated by blood level of sodium which is significant for maintaining extracellular fluid volume. Blood concentration of sodium is regulated by 3 mechanisms:

- i) *Release of aldosterone* from activation of renin-angiotensin system, as already explained.
- ii) *Reduction in GFR* due to reduced blood flow as occurs in reduced renal mass or renal artery stenosis. This results in proximal tubular reabsorption of sodium.
- iii) *Release of atriopeptin hormone* from atria of the heart in response to volume expansion. These peptides cause increased GFR and inhibit sodium reabsorption.

c) Release of vasodepressor material A number of vaso-depressor materials and antihypertensives counterbalance the

vasopressor effect of angiotensin II. These substances include: prostaglandins (PGE₂, PGF₂, PGA or medullin) released from interstitial cells of the medulla, urinary kallikrein-kinin system and platelet-activating factor.

2. ENDOCRINE HYPERTENSION A number of hormonal secretions may produce secondary hypertension as follows:

- i) *Adrenal gland*—e.g. in primary aldosteronism, Cushing's syndrome, adrenal virilism and pheochromocytoma.
- ii) *Parathyroid gland*—e.g. hypercalcaemia in hyperparathyroidism.
- iii) *Oral contraceptives*—Oestrogen component in the oral contraceptives stimulates hepatic synthesis of renin substrate.

3. COARCTATION OF AORTA Coarctation of the aorta causes systolic hypertension in the upper part of the body due to constriction itself (page 406). Diastolic hypertension results from changes in circulation.

4. NEUROGENIC Psychogenic, polyneuritis, increased intracranial pressure and section of spinal cord are all uncommon causes of secondary hypertension.

EFFECTS OF HYPERTENSION

Systemic hypertension causes major effects in three main organs—heart and its blood vessels, nervous system, and kidneys. The renal effects in the form of benign and malignant nephrosclerosis are discussed below, whereas hypertensive effects on other organs are described elsewhere in the respective chapters. An important and early clinical marker for renal injury from hypertension and risk factor for cardiovascular disease is *macroalbuminuria* (i.e. albuminuria > 150 mg/day or random urine albumin/creatinine ratio of >300 mg/gm creatinine), or *microalbuminuria* estimated by radioimmunoassay (i.e. microalbumin 30-300 mg/day or random urine microalbumin/creatinine ratio of 30-300 mg/gm creatinine).

Benign Nephrosclerosis

Benign nephrosclerosis is the term used to describe the kidney of benign phase of hypertension. Mild benign nephrosclerosis is the most common form of renal disease in persons over 60 years of age but its severity increases in the presence of hypertension and diabetes mellitus.

MORPHOLOGIC FEATURES *Grossly*, both the kidneys are affected equally and are reduced in size and weight, often weighing about 100 gm or less. The capsule is often adherent to the cortical surface. The surface of the kidney is finely granular and shows V-shaped areas of scarring.* The cut surface shows firm kidney and narrowed cortex (**Fig. 20.40**).

*The various acquired causes of 'small contracted kidney' and their characteristic gross macroscopic appearance may be recollected here. These are: 1. Chronic GN (granular appearance); 2. Chronic pyelonephritis (U-shaped scars); and 3. Benign nephrosclerosis (V-shaped scars). Although granular, U- and V-shaped scars related to corresponding gross patterns, acronym to remember is: '*granular*' for glomerular scars of chronic GN; '*U-scars*' for uneven scars of chronic pyelonephritis; and '*V-scars*' for vascular scars of benign nephrosclerosis. Less common causes are: amyloidosis of the kidney, myeloma kidney and diabetic nephropathy.

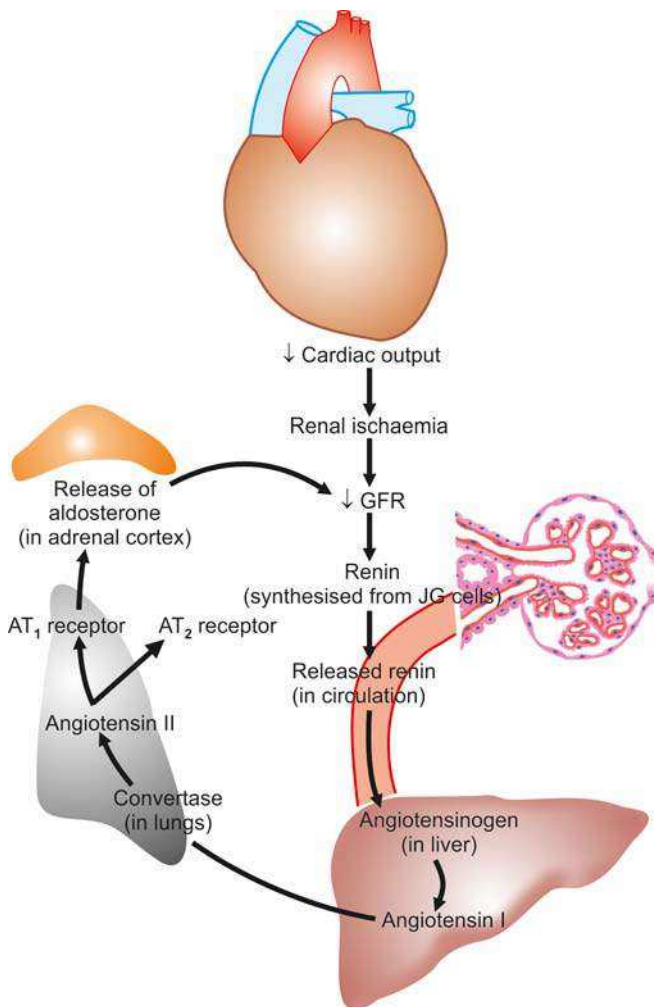

Figure 20.39 The renin-angiotensin mechanism.

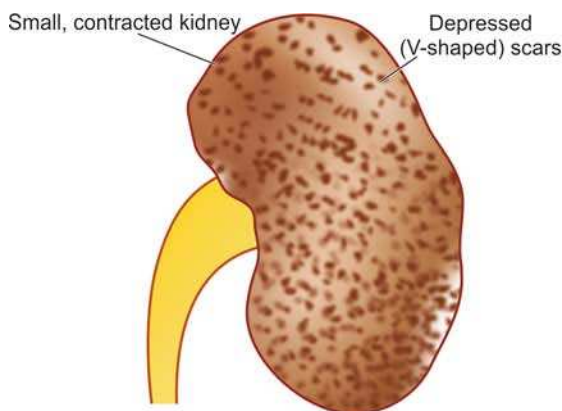

Figure 20.40 Small, contracted kidney in chronic hypertension (benign nephrosclerosis). The kidney is small and contracted. The capsule is adherent to the cortex and has granular depressed scars on the surface.

Microscopically, there are primarily diffuse vascular changes which produce parenchymal changes secondarily as a result of ischaemia. The histologic changes are, thus, described as vascular and parenchymal (**Fig. 20.41,A**):

i) Vascular changes: Changes in blood vessels involve arterioles and arteries up to the size of arcuate arteries. There are 2 types of changes in these blood vessels:

a) *Hyaline arteriosclerosis* that results in homogeneous and eosinophilic thickening of the wall of small blood vessels.

b) *Intimal thickening* due to proliferation of smooth muscle cells in the intima.

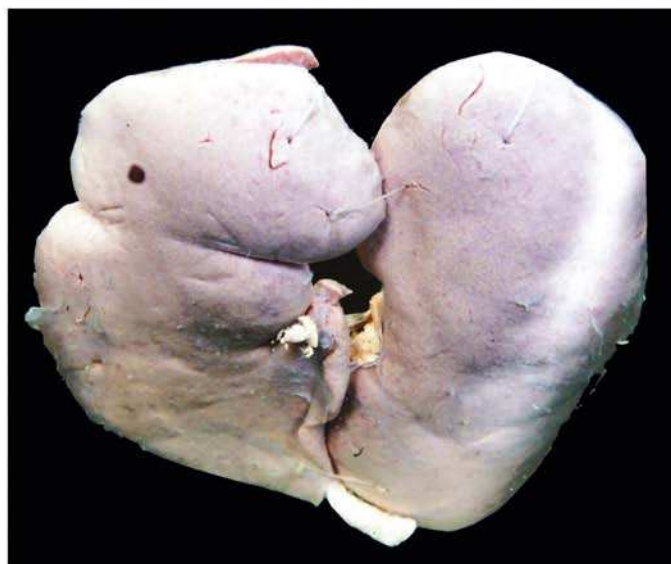

ii) Parenchymal changes: As a consequence of ischaemia, there is variable degree of atrophy of parenchyma. This includes: glomerular shrinkage, deposition of collagen in Bowman's space, periglomerular fibrosis, tubular atrophy and fine interstitial fibrosis.

CLINICAL FEATURES There is variable elevation of the blood pressure with headache, dizziness, palpitation and nervousness. Eye ground changes may be found but papilloedema is absent. Renal function tests and urine examination are normal in early stage. In long-standing cases, there may be mild proteinuria with some hyaline or granular casts. Rarely, renal failure and uraemia may occur.

Malignant Nephrosclerosis

Malignant nephrosclerosis is the form of renal disease that occurs in malignant or accelerated hypertension. Malignant nephrosclerosis is uncommon and usually occurs as a superimposed complication in 5% cases of pre-existing benign essential hypertension or in those having secondary hypertension with identifiable cause such as in chronic renal diseases. However, the pure form of disease also occurs, particularly at younger age with preponderance in males.

MORPHOLOGIC FEATURES *Grossly*, the appearance of the kidney varies. In a case of malignant hypertension superimposed on pre-existing benign nephrosclerosis, the kidneys are small in size, shrunken and reduced in weight

and have finely granular surface. However, the kidneys of a patient who develops malignant hypertension in pure form are enlarged, oedematous and have petechial haemorrhages on the surface producing so called '*flea-bitten kidney*'.* Cut surface shows red and yellow mottled appearance (**Fig. 20.42**).

Microscopically, most commonly the changes are superimposed on benign nephrosclerosis. These changes are as under (**Fig. 20.41,B**):

i) Vascular changes These are more severe and involve the arterioles. The two characteristic vascular changes seen are as under:

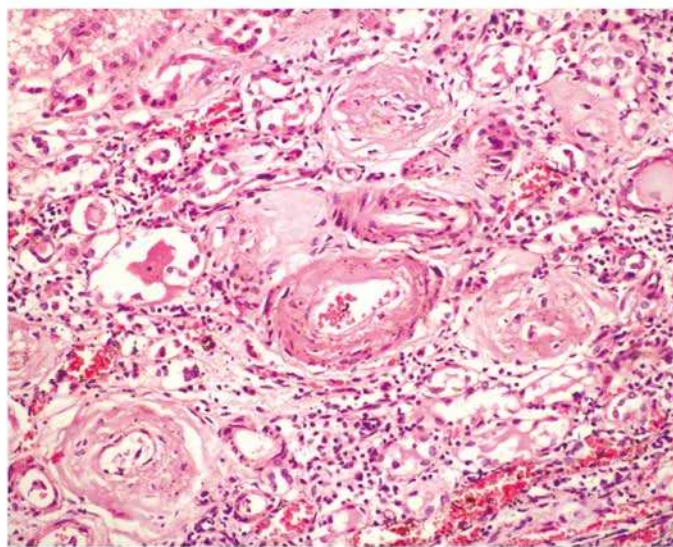

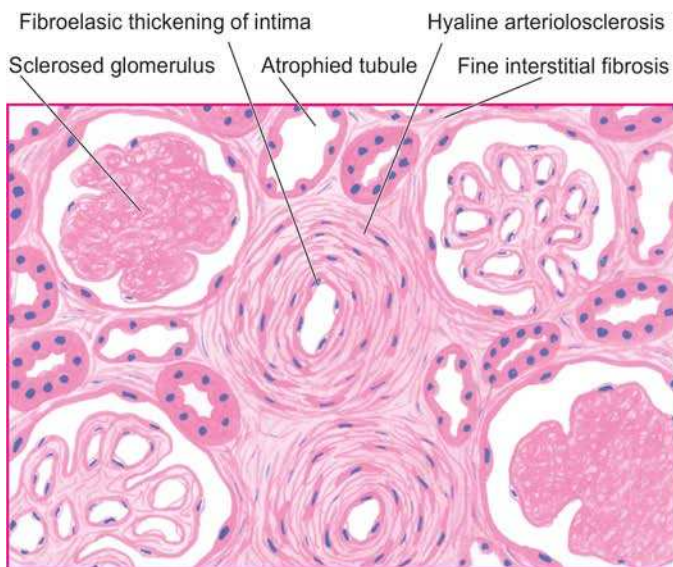

a) *Necrotising arteriolitis* develops on hyaline arteriosclerosis. The vessel wall shows fibrinoid necrosis, a few acute inflammatory cells and small haemorrhages.

b) *Hyperplastic intimal sclerosis* or *onionskin proliferation* is characterised by concentric laminae of proliferated smooth muscle cells, collagen and basement membranes.

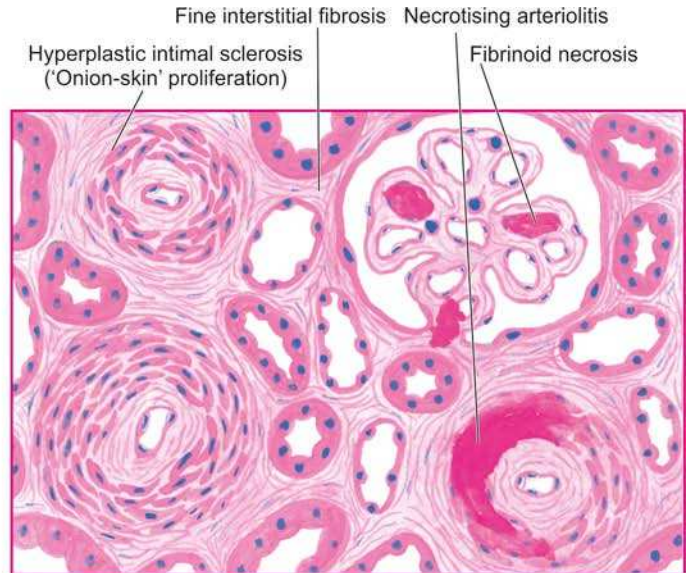

ii) Ischaemic changes The effects of vascular narrowing on the parenchyma include tubular loss, fine interstitial fibrosis and foci of infarction necrosis.

CLINICAL FEATURES The patients of malignant nephrosclerosis have malignant or accelerated hypertension with blood pressure of 200/140 mmHg or higher. Headache, dizziness and impaired vision are commonly found. The presence of papilloedema distinguishes malignant from benign phase of hypertension. The urine frequently shows microscopic haematuria and proteinuria. Renal function tests show deterioration during the course of the illness. Azotaemia (high BUN and serum creatinine) and uraemia develop soon if malignant hypertension is not treated aggressively. Approximately 90% of patients die within one year from causes such as uraemia, congestive heart failure and cerebrovascular accidents.

*Recall the causes of *flea-bitten kidney* here: malignant nephrosclerosis, acute post-streptococcal GN, rapidly progressive GN, haemolytic-uraemic syndrome, thrombotic thrombocytopenic purpura and Hensch-Schonlein purpura.

A, BENIGN NEPHROSCLEROSIS

B, MALIGNANT NEPHROSCLEROSIS

Figure 20.41 Microscopic changes in kidney in hypertension. A, *Benign nephrosclerosis*. The vascular changes are hyaline arteriosclerosis and intimal thickening of small blood vessels in the glomerular tuft. The parenchymal changes include sclerosed glomeruli, tubular atrophy and fine interstitial fibrosis. B, *Malignant nephrosclerosis*. The vascular changes are necrotising arteriolitis and hyperplastic intimal sclerosis or onion-skin proliferation. The parenchymal changes are tubular loss, fine interstitial fibrosis and foci of infarction necrosis.

THROMBOTIC MICROANGIOPATHY

Thrombotic renal disease encompasses a group of diseases having in common the formation of thrombi composed by platelets and fibrin in arterioles and glomeruli of the kidney and culminating clinically in acute renal failure. Causes of thrombotic microangiopathy of renal microvasculature are listed in **Table 20.18**.

Table 20.18 Causes of thrombotic microangiopathy.

1. Infections
(*E. coli*, *Shigella*, *Pseudomonas*)
2. Drugs
(e.g. mitomycin, cisplatin, cyclosporine)
3. Autoimmune disease
(scleroderma, SLE)
4. Thrombotic thrombocytopenic purpura
5. Haemolytic-uraemic syndrome
6. Pregnancy and pre-eclampsia
7. Malignant hypertension

The common clinical manifestations include microangiopathic haemolytic anaemia, thrombocytopenia, DIC, and eventually renal failure.

PATHOGENESIS In all such cases, endothelial injury appears to be the trigger for vascular changes. The injured endothelial surface causes the following effects:

- i) Passage of plasma constituents to the subendothelial zone of microvasculature.
- ii) Promotes thrombosis.

MORPHOLOGIC FEATURES The lesions closely resemble those of malignant nephrosclerosis. The features are as under:

- i) Fibrinoid necrosis of arterioles.
- ii) Thrombi in renal microvasculature.
- iii) Oedema of intima of arterioles.
- iv) Consolidation, necrosis and congestion of glomeruli.

If the renal lesions are massive, the prognosis is generally lethal.

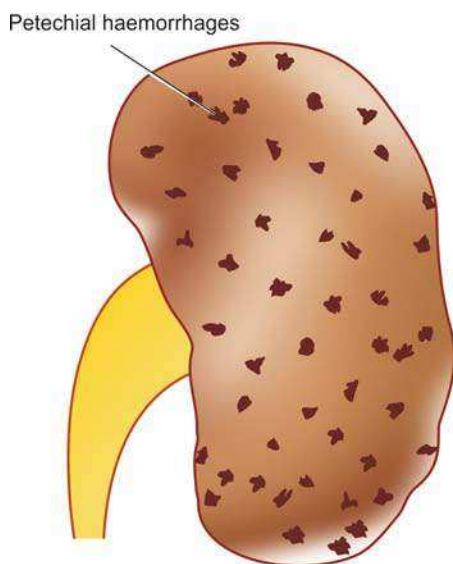

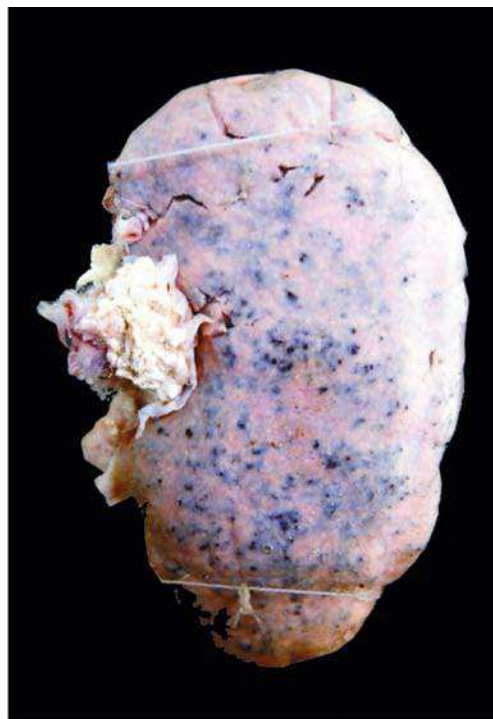

Figure 20.42 Malignant nephrosclerosis. The kidney is enlarged in size and weight. The cortex shows characteristic 'flea bitten kidney' due to tiny petechial haemorrhages on the surface.

RENAL CORTICAL NECROSIS

Renal cortical necrosis is infarction of renal cortex varying from microscopic foci to a situation where most of the renal cortex is destroyed. The medulla, the juxtamedullary cortex and a rim of cortex under the capsule are usually spared. The condition develops most commonly as an obstetrical emergency (e.g. in eclampsia, pre-eclampsia, premature separation of the placenta). Other causes include septic shock, poisoning, severe trauma etc.

The lesions may be focal, patchy or diffuse. The gross and microscopic characteristics of infarcts of cortex are present. Patients present with sudden oliguria or anuria and haematuria. If the process has involved renal cortex extensively, acute renal failure and uraemia develop and prognosis is grave.

GIST BOX 20.10 Renal Vascular Diseases

- ▣ Hypertension may be primary or essential hypertension in which the cause is unknown (about 90% cases) or secondary which is caused by diseases of the kidneys, endocrines or some other organs.
- ▣ Clinically, hypertension may be benign (moderate and slow elevation of blood pressure $\geq 90/140$ mmHg) or malignant hypertension in which there is marked and sudden increase of blood pressure ($\geq 200/140$ mmHg) in a known case of hypertension.
- ▣ Main mechanisms of essential hypertension are activation of renin-angiotensin pathway while secondary hypertension may be due to endocrine, aortic coarctation or neurogenic causes.
- ▣ Systemic hypertension causes major effects in three main organs—heart and its blood vessels (hypertensive heart disease), nervous system (stroke), and kidneys (benign and malignant nephrosclerosis).
- ▣ Thrombotic renal disease, renal cortical necrosis and infarcts are some other diseases of renal blood vessels.

TUMOURS OF KIDNEY

Both benign and malignant tumours occur in the kidney, the latter being more common. These may arise from *renal tubules* (adenoma, adenocarcinoma), *embryonic tissue* (mesoblastic nephroma, Wilms' tumour), *mesenchymal tissue* (angiomyolipoma, medullary interstitial tumour) and from the *epithelium of the renal pelvis* (urothelial carcinoma). Besides these tumours, the kidney may be the site of the secondary tumours.

Table 20.19 provides a list of kidney tumours; the important forms of renal neoplasms are described below.

BENIGN TUMOURS

Benign renal tumours are usually small and are often an incidental finding at autopsy or nephrectomy.

Cortical Adenoma

Cortical tubular adenomas are more common than other benign renal neoplasms. They are frequently multiple and associated with chronic pyelonephritis or benign nephrosclerosis.

Grossly, these tumours may form tiny nodules up to 3 cm in diameter. They are encapsulated and white or yellow.

Microscopically, they are composed of tubular cords or papillary structures projecting into cystic space. The cells of the adenoma are usually uniform, cuboidal with no atypicality or mitosis. However, size of the tumour rather than histologic criteria is considered more significant parameter to predict the behaviour of the tumour—those larger than 3 cm in diameter are potentially malignant and metastasising.

Oncocytoma

Oncocytoma is a benign epithelial tumour arising from collecting ducts.

Table 20.19 Classification of kidney tumours.

| BENIGN | MALIGNANT |
|--|--|
| A. EPITHELIAL TUMOURS OF RENAL PARENCHYMA | |
| Adenoma | Adenocarcinoma |
| Oncocytoma | (hypernephroma, renal cell carcinoma) |
| B. EPITHELIAL TUMOURS OF RENAL PELVIS | |
| Transitional cell papilloma | Transitional cell carcinoma |
| | Others (squamous cell carcinoma, adenocarcinoma of renal pelvis, undifferentiated carcinoma of renal pelvis) |
| C. EMBRYONAL TUMOURS | |
| Mesoblastic nephroma | Wilms' tumour (nephroblastoma) |
| Multicystic nephroma | |
| D. NON-EPITHELIAL TUMOURS | |
| Angiomyolipoma | Sarcomas (rare) |
| Medullary interstitial tumour (fibroma) | |
| E. MISCELLANEOUS | |
| Juxtglomerular cell tumour (Reninoma) | |
| F. METASTATIC TUMOURS | |

Grossly, The tumour is encapsulated and has variable size. Cut section is homogeneous and has characteristic mahogany-brown or tan colour.

Microscopically, the tumour cells are plump with abundant, finely granular, acidophilic cytoplasm and round nuclei. Electron microscopy demonstrates numerous mitochondria in the cytoplasm.

Other Benign Tumours

◆ **Angiomyolipoma** is a hamartoma of the kidney that contains differentiated tissue element derived from blood vessels, smooth muscle and fat. Patients of tuberous sclerosis, a multisystem disease characterised by skin lesions, CNS and renal involvement, frequently have bilateral angiomyolipomas.

◆ **Mesoblastic nephroma** is a congenital benign tumour.

Grossly, the tumour resembles a uterine leiomyoma in having whorled appearance.

Microscopically, it shows cellular growth of spindle cells derived from secondary mesenchyme.

◆ **Multicystic nephroma** is another uncommon tumour of early infancy.

Grossly, it is a solitary, unilateral well demarcated tumour of varying size. Cut surface shows characteristic multilocular appearance.

Microscopically, the cysts are lined by tubular epithelium while the stroma between the cysts contains mesenchymal tissue with some immature blastemal or abortive tubules.

Some authors consider this entity as fully-differentiated variant of Wilms' tumour. However, clinically multicystic nephroma is always benign compared to Wilms' tumour.

◆ **Medullary interstitial cell tumour** is a tiny nodule in the medulla composed of fibroblast-like cells in hyalinised stroma. These tumours used to be called *renal fibromas* but electron microscopy has revealed that the tumour cells are not fibrocytes but are medullary interstitial cells.

◆ **Juxtglomerular tumour or reninoma** is a rare tumour of renal cortex consisting of sheets of epithelioid cells with many small blood vessels. The tumour secretes excessive quantities of renin and, thus, the patients are likely to have hypertension.

MALIGNANT TUMOURS

The two most common primary malignant tumours of the kidney are *adenocarcinoma* and *Wilms' tumour*. A third malignant renal tumour is *urothelial carcinoma* occurring more commonly in the renal pelvis is described in the next section along with other tumours of the lower urinary tract.

Adenocarcinoma of Kidney (Synonyms: Renal Cell Carcinoma, Hypernephroma, Grawitz Tumour)

Hypernephroma is an old misnomer under the mistaken belief that the tumour arises from adrenal rests because of the resemblance of the tumour cells with clear cells of the adrenal cortex. It is now known that the renal cell carcinoma (RCC) is an adenocarcinoma arising from tubular epithelium. This cancer comprises 70 to 80% of all renal cancers and occurs most commonly in 50 to 70 years of age with male preponderance (2:1).

ETIOLOGY AND PATHOGENESIS Various etiologic factors implicated in the etiology of RCC are as follows:

1. Tobacco Tobacco is the major risk factor for RCC, whether chewed or smoked and accounts for 20-30% cases of RCC. Cigarette smokers have two-fold higher risk of developing RCC.

2. Genetic factors Heredity and first-degree relatives of RCC are associated with higher risk. Although majority of cases of RCC are sporadic but about 5% cases are inherited. These cases have following associations:

i) *von Hippel-Lindau (VHL) disease*: It is an autosomal dominant cancer syndrome that includes: haemangioblastoma of the cerebellum, retinal angiomas, multiple RCC (clear cell type), pheochromocytoma and cysts in different organs. Patients of VHL disease have germline mutations of tumour suppressor *VHL* gene located on chromosome 3p, commonly as homozygous loss of *VHL* gene. About 35% cases of VHL develop RCC.

ii) *Hereditary clear cell RCC*: These are cases of clear cell type RCC confined to the kidney without other manifestations of VHL but having autosomal dominant inheritance.

iii) *Papillary RCC*: This form of RCC is characterised by bilteral and multifocal cancer with papillary growth pattern. Genetic abnormality in these cases lies in *MET* gene located on chromosome 7.

iv) *Chromophobe RCC*: These cases have genetic defects in the form of multiple losses of whole chromosomes i.e. they have extreme degree of hypodiploidy.

Table 20.20 Classification of renal cell carcinoma

| TYPE | INCIDENCE | GENETICS | MAIN HISTOLOGY |
|---|-----------|--|--|
| 1. <i>Clear cell type (non-papillary)</i> | 70% | Sporadic and familial (Homozygous loss of <i>VHL</i> gene located on chromosome 3) | Clear cytoplasm (due to glycogen and lipid), well differentiated |
| 2. <i>Papillary type</i> | 15% | Familial and sporadic (Familial cases: mutation in <i>MET</i> gene on chromosome 7; sporadic cases trisomy of chromosome 7, 16, 17 and loss of Y chromosome) | Papillary pattern, psammoma bodies |
| 3. <i>Granular cell type</i> | 8% | Sporadic and familial | Abundant acidophilic cytoplasm, marked atypia |
| 4. <i>Chromophobe type</i> | 5% | Multiple chromosome losses, hypodiploidy | Mixture of pale clear cells with perinuclear halo and granular cells |
| 5. <i>Sarcomatoid type</i> | 1.5% | — | Whorls of atypical anaplastic spindle cells |
| 6. <i>Collecting duct type</i> | 0.5% | — | Tubular and papillary pattern |

3. Cystic diseases of the kidneys Both hereditary and acquired cystic diseases of the kidney have increased risk of development of RCC. Patients on long-term dialysis develop acquired cystic disease which may evolve into RCC and adenomas. Adult polycystic kidney disease and multicystic nephroma is associated with higher occurrence of papillary RCC.

4. Other risk factors Besides above, following other factors are associated with higher incidence of RCC:

- i) Exposure to asbestos, heavy metals and petrochemical products.
- ii) In women, obesity and oestrogen therapy.
- iii) Analgesic nephropathy.
- iv) Tuberous sclerosis.

CLASSIFICATION Based on cytogenetics of sporadic and familial tumours, RCC has been reclassified into clear cell, papillary, granular cell, chromophobe, sarcomatoid and collecting duct type (Table 20.20).

MORPHOLOGIC FEATURES *Grossly*, RCC commonly arises from the poles of the kidney as a solitary and unilateral tumour, more often in the upper pole. The tumour is generally large, golden yellow and circumscribed. Papillary tumours have grossly visible papillae and may be multifocal. About 1% RCC are bilateral. Cut section of the tumour commonly shows large areas of ischaemic necrosis, cystic change and foci of haemorrhages. Another significant characteristic is the frequent presence of tumour thrombus in the renal vein which may extend into the vena cava (Fig. 20.43).

Histologically, the features of various types of RCC are as under:

1. *Clear cell type RCC (70%)*: This is the most common pattern. The clear cytoplasm of tumour cells is due to removal of glycogen and lipid from the cytoplasm during processing of tissues. The tumour cells have a variety of patterns: solid, trabecular and tubular, separated by delicate

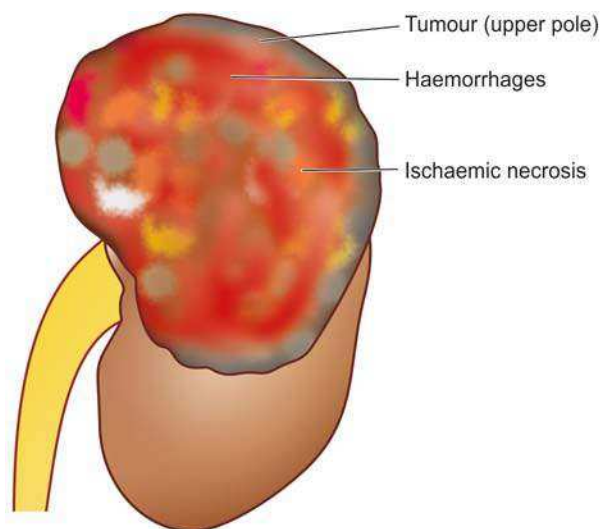

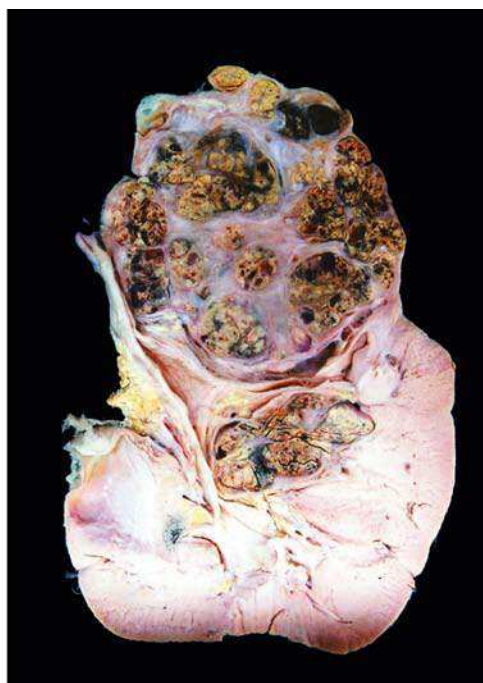

Figure 20.43 Renal cell carcinoma. The upper pole of the kidney shows a large and tan mass while rest of the kidney has reniform contour. Sectioned surface shows irregular, circumscribed, yellowish mass with areas of haemorrhages and necrosis. The residual kidney is compressed on one side and shows obliterated calyces and renal pelvis.

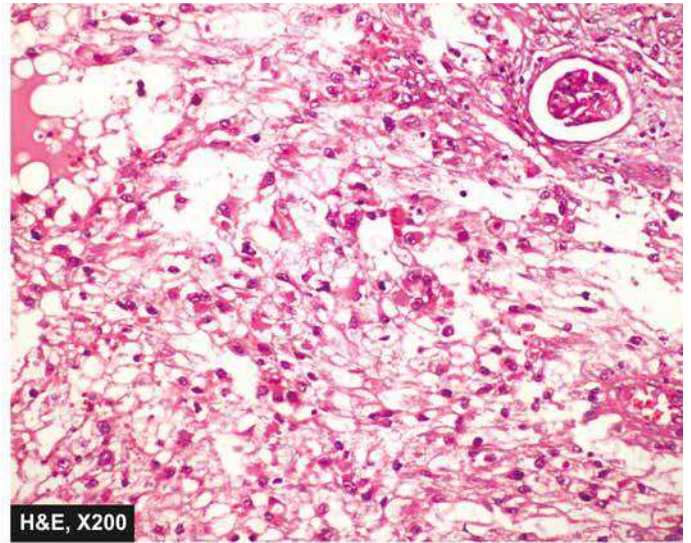

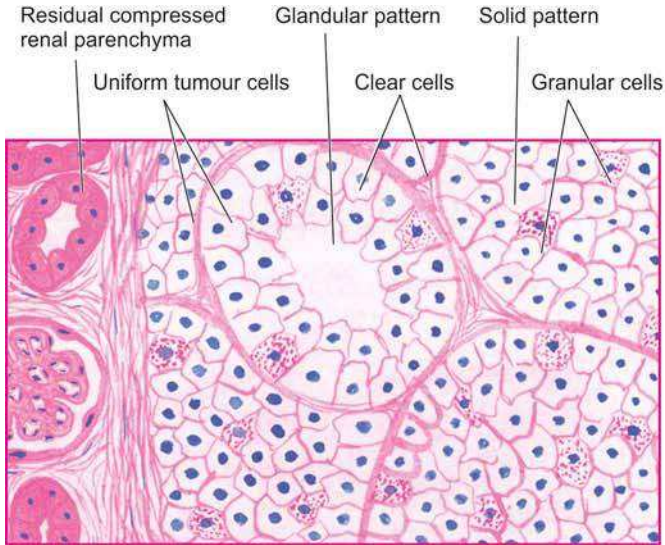

Figure 20.44 Renal cell carcinoma. The tumour shows solid masses and acini of uniform-appearing tumour cells. Clear cells predominate in the tumour while the stroma is composed of fine and delicate fibrous tissue.

vasculature. Majority of clear cell tumours are well differentiated (**Fig. 20.44**).

2. **Papillary type RCC (15%):** The tumour cells are arranged in papillary pattern over the fibrovascular stalks. The tumour cells are cuboidal with small round nuclei. Psammoma bodies may be seen.

3. **Granular cell type RCC (8%):** The tumour cells have abundant acidophilic cytoplasm. These tumours have more marked nuclear pleomorphism, hyperchromatism and cellular atypia.

4. **Chromophobe type RCC (5%):** This type shows admixture of pale clear cells with perinuclear halo and acidophilic granular cells. The cytoplasm of these tumour cells contains many vesicles.

5. **Sarcomatoid type RCC (1.5%):** This is the most anaplastic and poorly differentiated form. The tumour is characterised by whorls of atypical spindle tumour cells.

6. **Collecting duct type RCC (0.5%):** This is a rare type that occurs in the medulla. It is composed of a single layer of cuboidal tumour cells arranged in tubular and papillary pattern.

CLINICAL FEATURES Renal cell carcinoma is generally a slow-growing tumour and the tumour may have been present for years before it is detected. The classical clinical evidence for diagnosis of renal cell carcinoma is the triad of *gross haematuria, flank pain and palpable abdominal mass*. The most common presenting abnormality is haematuria that occurs in about 60% of cases. By the time the tumour is detected, it has spread to distant sites via haematogenous route to the lungs, brain and bone, and locally to the liver and perirenal lymph nodes.

Systemic symptoms of fatigability, weight loss, cachexia and intermittent fever unassociated with evidence of infection are found in many cases at presentation. A number of paraneoplastic syndromes due to ectopic hormone production by the renal cell carcinoma have been described. These include *polycythaemia* (by erythropoietin), *hypercalcaemia* (by parathyroid hormone and prostaglandins), *hypertension*

(by renin), effects of *feminisation* or *masculinisation* (by gonadotropins) and *Cushing's syndrome* (by glucocorticoids).

The **prognosis** in renal cell carcinoma depends upon the extent of tumour involvement at the time of diagnosis. The overall 5-year survival rate is about 70%. Presence of metastases, renal vein invasion and higher nuclear grade of the tumour are some of the predictors of poor prognosis.

Wilms' Tumour (Synonym: Nephroblastoma)

Nephroblastoma or Wilms' tumour is an embryonic tumour derived from primitive renal epithelial and mesenchymal components. It is the most common abdominal malignant tumour of young children, seen most commonly between 1 to 6 years of age with equal sex incidence.

ETIOLOGY AND PATHOGENESIS Wilms' tumour has following etiologic associations:

1. A higher incidence has been seen in monozygotic *twins* and cases with family history.
2. Association of Wilms' tumour with some *other congenital anomalies* has been observed, especially of the genitourinary tract.
3. A few *other malignancies* are known to have higher incidence of Wilms' tumour. These include osteosarcoma, botryoid sarcoma, retinoblastoma, neuroblastoma etc.

Genetic pathogenesis of Wilms' tumour is explained as under:

1. Wilms' tumour associated gene, *WT1* gene, is located on chromosome 11p13. normal function of *WT1* gene is synthesis of protein require for development of kidneys and gonads (ovaries/testes). Mutated form of *WT1* gene is often by deletion in people with Wilms' tumor, aniridia (i.e. absence of iris), genitourinary anomalies, and mental retardation syndrome, known by the acronym WAGR syndrome. As a result of this deletion, affected individuals are missing one copy of the *WT1* gene in each cell and such individuals are prone to develop Wilms' tumour and several other forms of cancers.

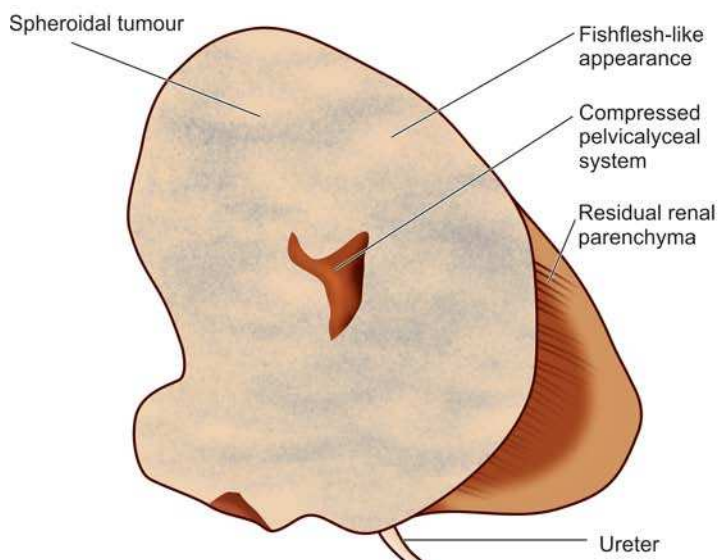

Figure 20.45 Nephroblastoma (Wilms' tumour). The kidney is enlarged and has ovoid and nodular appearance. The sectioned surface shows replacement of almost whole kidney by the tumour leaving a thin strip of compressed renal tissue at lower end (arrow). Cut section of the tumour is gray white, fleshy and has small areas of haemorrhages and necrosis.

2. Due to common genetic mutation, individuals with gonadal dysgenesis are at higher risk of developing Wilms' tumour.
3. Another molecular mechanism for development of sporadic cases of Wilms' tumour is synergism due to common mutation between β -catenin pathway and *WNT* (wingless) signaling pathway.

MORPHOLOGIC FEATURES *Grossly*, the tumour is usually quite large, spheroidal, replacing most of the kidney. It is generally solitary and unilateral but 5-10% cases may have bilateral tumour. On cut section, the tumour shows characteristic variegated appearance—soft, fishflesh-like grey-white to cream-yellow tumour with foci of necrosis and haemorrhages and grossly identifiable myxomatous or cartilaginous elements (**Fig. 20.45**). Invasion into renal vein is grossly evident in half the cases.

Microscopically, nephroblastoma shows mixture of primitive epithelial and mesenchymal elements. Most of the tumour consists of small, round to spindled, anaplastic, sarcomatoid tumour cells. In these areas, abortive tubules and poorly-formed glomerular structures are present (**Fig. 20.46**). Mesenchymal elements such as smooth and skeletal muscle, cartilage and bone, fat cells and fibrous tissue, may be seen.

CLINICAL FEATURES The most common presenting feature is a palpable abdominal mass in a child. Other common abnormalities are haematuria, pain, fever and hypertension. The tumour rapidly spreads via blood, especially to lungs.

The **prognosis** of the tumour with combination therapy of nephrectomy, post-operative irradiation and chemotherapy, has improved considerably and the 5-year survival now is 80-90%.

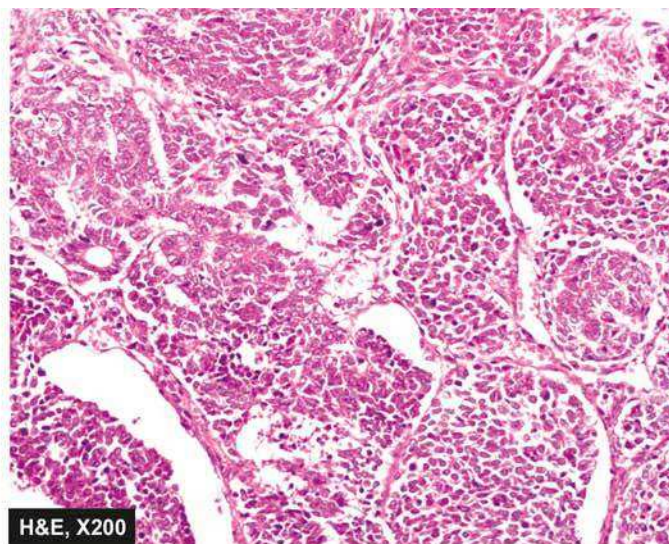

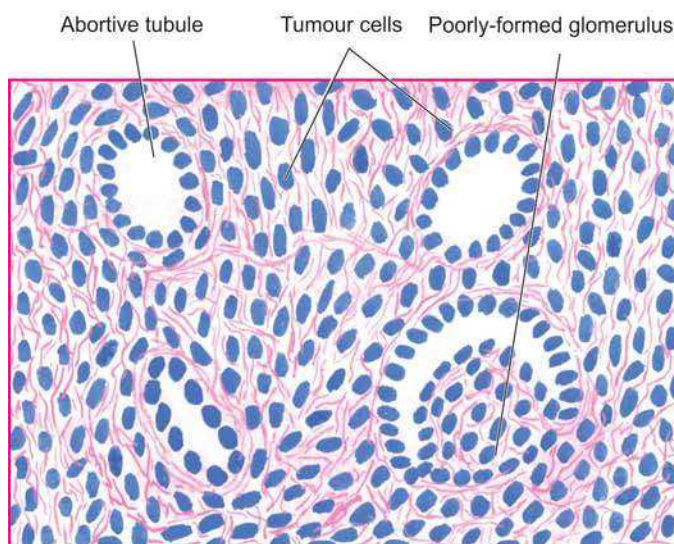

Figure 20.46 Wilms' tumour. There is predominance of small round to spindled sarcomatoid tumour cells. A few abortive tubules and poorly-formed glomerular structures are present in it.

Secondary Tumours

Leukaemic infiltration of the kidneys is a common finding, particularly in chronic myeloid leukaemia. Kidney is a common site for blood-borne metastases from different primary sites, chiefly from cancers of the lungs, breast and stomach.

GIST BOX 20.11 Tumours of Kidneys

- ☐ Benign renal tumours are usually small and are often an incidental finding at autopsy or nephrectomy. These include cortical adenoma, oncocytoma, angiomyolipoma etc.
- ☐ Renal cell carcinoma (RCC) is an adenocarcinoma arising from tubular epithelium and occurs in adults. It is classified into clear cell, papillary, granular cell, chromophobe, sarcomatoid and collecting duct types. Extension of the tumour into renal vein is common.
- ☐ Nephroblastoma or Wilms' tumour is an embryonic tumour derived from primitive renal epithelial and mesenchymal components and occurs in children.
- ☐ Urothelial carcinoma is seen in the renal pelvis in line with lower urinary tract.
- ☐ Kidney is a frequent site for blood-borne metastases from different primary sites.

LOWER URINARY TRACT

NORMAL STRUCTURE

The lower urinary tract consists of *ureters*, *urinary bladder* and *urethra*.

URETERS These are tubular structures, 30 cm in length and half a centimeter in diameter, and extend from the renal pelvis (pelvi-ureteric junction) to the urinary bladder (vesico-ureteric junction). Normally they enter obliquely into the bladder, so that ureter is compressed during micturition, thus preventing vesico-ureteric reflux. Ureters lie retroperitoneally throughout their course.

Histologically, ureter has an outer fibrous investing layer which overlies a thick muscular layer and is lined internally by transitional epithelium or urothelium similar to the lining of the renal pelvis above and bladder below.

URINARY BLADDER It lies extraperitoneally and the peritoneum is reflected on its superior surface. Besides *superior* surface (or dome), the bladder has *posterior surface* (or *base*) and two *lateral surfaces*. The *trigone* is at the base of the bladder and continues as *bladder neck*. Normally, the capacity of bladder is about 400 to 500 ml without over-distension. Micturition is partly a reflex and partly a voluntary act under the control of sympathetic and parasympathetic innervation.

Histologically, the greater part of the bladder wall is made up of muscular layer (detrusor muscle) having 3 coats—internal, middle and external. The *trigone* muscle is derived from the prolongation of the longitudinal muscle layer of each ureter. The inner layer of bladder consists of urothelium 6-7 layers in thickness. The superficial epithelial layer is made of larger cells in the form of a row and have abundant eosinophilic cytoplasm; these cells are called *umbrella cells*.

URETHRA It runs from the bladder up to the external meatus. The *male urethra* consists of 3 parts—prostatic, membranous and penile. It is lined in the prostatic part by urothelium

but elsewhere by stratified columnar epithelium except near its orifice where the epithelium is stratified squamous. The urethral mucosa rests on highly vascular submucosa and outer layer of striated muscle. There are numerous small mucous glands in the urethral mucosa. The *female urethra* is shorter and runs from the bladder parallel with the anterior wall of the vagina. The mucous membrane in female urethra is lined throughout by columnar epithelium except near the bladder where the epithelium is transitional. The other layers and mucous glands are similar to those in male urethra.

CONGENITAL ANOMALIES

Vesicoureteric reflux is the most common anomaly described already on page 669. A few others are considered below.

DOUBLE URETER This is a condition in which the entire ureter or only the upper part is duplicated. Double ureter is invariably associated with a double renal pelvis, *one* in the upper part and the *other* in the lower part of the kidney. If double ureter affects the entire length, then there are two separate openings into the bladder on one side but more commonly they are joined in the intravesical portion and open by a single ureteric orifice.

URETEROCELE Ureterocele is cystic dilatation of the terminal part of the ureter which lies within the bladder wall. The cystic dilatation lies beneath the bladder mucosa and can be visualised by cystoscopy.

ECTOPIA VESICAE (EXSTROPHY) This is a rare condition owing to congenital developmental deficiency of anterior wall of the bladder and is associated with splitting of the overlying anterior abdominal wall. This results in exposed interior of the bladder. There may be prolapse of the posterior wall of the bladder through the defect in the anterior bladder and abdominal wall. The condition in males is often associated with *epispadias* in which the urethra opens on the dorsal aspect of penis. If the defect is not properly repaired, the exposed bladder mucosa gets infected repeatedly and may undergo squamous metaplasia with subsequent increased tendency to develop carcinoma of the bladder.

URACHAL ABNORMALITIES Rarely, there may be persistence of the urachus in which urine passes from the bladder to the umbilicus. More often, part of urachus remains patent which may be the umbilical end, bladder end, or central portion. Persistence of central portion gives rise to *urachal cyst* lined by transitional or squamous epithelium. Adenocarcinoma may develop in urachal cyst. Other abnormalities due to urachal remnants are patent urachus, urachal-umbilical sinus and vesico-urachal diverticulum.

INFLAMMATIONS

Urinary tract infection (UTI) is common, especially in females and has been described already along with its morphologic consequences (page 668). Inflammation of the tissues of lower urinary tract (ureteritis, cystitis and urethritis) is considered here.

URETERITIS

Infection of the ureter is almost always secondary to pyelitis above, or cystitis below. Ureteritis is usually mild but repeated and longstanding infection may give rise to chronic ureteritis.

Inflammation of the urinary bladder is called cystitis. Primary cystitis is rare since the normal bladder epithelium is quite resistant to infection. Cystitis may occur by spread of infection from upper urinary tract as seen following renal tuberculosis, or may spread from the urethra such as in instrumentation. Cystitis is caused by a variety of bacterial and fungal infections as discussed in the etiology of pyelonephritis (page 667). The most common pathogenic organism in UTI is *E. coli*, followed in decreasing frequency by *Enterobacter*, *Klebsiella*, *Pseudomonas* and *Proteus*. Infection with *Candida albicans* may occur in the bladder in immunosuppressed patients. Besides bacterial and fungal organisms, parasitic infestations such as with *Schistosoma haematobium* is common in the Middle-East countries, particularly in Egypt. *Chlamydia* and *Mycoplasma* may occasionally cause cystitis. In addition, radiation, direct exposure to chemical irritant, foreign bodies and local trauma may all initiate cystitis.

Cystitis, like UTI, is more common in females than in males because of the shortness of urethra which is liable to faecal contamination and due to mechanical trauma during sexual intercourse. In males, prostatic obstruction is a frequent cause of cystitis. All forms of cystitis are clinically characterised by a *triad* of symptoms—*frequency* (repeated urination), *dysuria* (painful or burning micturition) and *low abdominal pain*. There may, however, be systemic manifestations of bacteraemia such as fever, chills and malaise.

MORPHOLOGIC FEATURES Cystitis may be acute or chronic.

ACUTE CYSTITIS *Grossly*, the bladder mucosa is red, swollen and haemorrhagic. There may be suppurative exudate or ulcers on the bladder mucosa.

Microscopically, this form of cystitis is characterised by intense neutrophilic exudate admixed with lymphocytes and macrophages. There is oedema and congestion of mucosa.

CHRONIC CYSTITIS Repeated attacks of acute cystitis lead to chronic cystitis.

Grossly, the mucosal epithelium is thickened, red and granular with formation of polypoid masses. Long-standing cases result in thickened bladder wall and shrunken cavity.

Microscopically, there is patchy ulceration of the mucosa with formation of granulation tissue in the regions of polypoid masses. Submucosa and muscular coat show fibrosis and infiltration by chronic inflammatory cells. A form of chronic cystitis characterised by formation of lymphoid follicles in the bladder mucosa is termed *cystitis follicularis*.

A few other special forms of cystitis having distinct clinical and morphological appearance are described below.

INTERSTITIAL CYSTITIS (HUNNER'S ULCER) This variant of cystitis occurs in middle-aged women. The patients get repeated attacks of severe and excruciating pain on distension of the bladder, frequency of micturition and great decrease in bladder capacity. Cystoscopy often reveals a localised ulcer. The *etiology* of the condition is unknown but it is thought to be neurogenic in origin.

Microscopically, the submucosa and muscle coat show increased fibrosis and chronic inflammatory infiltrate, chiefly lymphocytes, plasma cells and eosinophils.

CYSTITIS CYSTICA As a result of long-standing chronic inflammation, there occurs a downward projection of epithelial nests known as *Brunn's nests* from the deeper layer of bladder mucosa. These epithelial cells may appear as small cystic inclusions in the bladder wall, or may actually develop columnar metaplasia with secretions in the lumen of cysts.

MALAKOPLAKIA This is a rare condition most frequently found in the urinary bladder but can occur in the ureters, kidney, testis and prostate, and occasionally in the gut. The *etiology* of the condition is unknown but it probably results from persistence of chronic inflammation with defective phagocytic process by the macrophages. Malakoplakia occurs more frequently in immunosuppressed patients and in recipients of transplants.

Grossly, the lesions appear as soft, flat, yellowish, slightly raised plaques on the bladder mucosa. They may vary from 0.5 to 5 cm in diameter.

Microscopically, the plaques are composed of massive accumulation of foamy macrophages with occasional multinucleate giant cells and some lymphocytes. These macrophages have granular PAS-positive cytoplasm and some of them contain cytoplasmic laminated concretions of calcium phosphate called *Michaelis-Gutmann bodies*. These bodies ultrastructurally represent lysosomes filled with partly digested debris of bacteria phagocytosed by macrophages which have not been digested fully by them due to defective phagocytosis.

POLYPOID CYSTITIS Polypoid cystitis is characterised by papillary projections on the bladder mucosa due to submucosal oedema and can be confused with transitional cell carcinoma. The condition occurs due to indwelling catheters and infection.

URETHRITIS

Urethritis may be *gonococcal* or *non-gonococcal*.

◆ **Gonococcal (gonorrhoeal) urethritis** is an acute suppurative condition caused by gonococci (*Neisseria gonorrhoeae*). The mucosa and submucosa are eventually converted into granulation tissue which becomes fibrosed and scarred resulting in urethral stricture.

◆ **Non-gonococcal urethritis** is more common and is most frequently caused by *E. coli*. The infection of urethra often accompanies cystitis in females and prostatitis in males. Urethritis is one of the components in the triad of Reiter's syndrome which comprises arthritis, conjunctivitis and urethritis. The pathologic changes are similar to inflammation of the lower urinary tract elsewhere but strictures are less common than following gonococcal infection of the urethra.

TUMOURS

Majority of lower urinary tract tumours are epithelial. Both benign and malignant tumours occur; the latter being more

Table 20.21 WHO classification of urinary bladder tumours.

EPITHELIAL TUMOURS

- A. *Urothelial (transitional cell) tumours (90%)*
1. Transitional cell papilloma (exophytic, Inverted)
 2. Papillary urothelial neoplasms of low malignant potential (PUNLMP)
 3. Carcinoma in situ (CIS, or flat non-invasive urothelial carcinoma)
 4. Transitional cell carcinoma (low grade, high grade)
- B. *Squamous cell carcinoma (5%)*
- C. *Adenocarcinoma (Rare)*
- D. *Small cell carcinoma (Rare)*
- E. *Mixed carcinoma (5%)*

NON-EPITHELIAL TUMOURS (Rare)

Benign (leiomyoma, granular cell myoblastoma, neurilemmoma, haemangioma)

Malignant (Sarcomas)

common. About 90% of malignant tumours of the lower urinary tract occur in the urinary bladder, 8% in the renal pelvis and remaining 2% are seen in the urethra or ureters.

TUMOURS OF THE BLADDER

The tumours of urinary bladder are divided into epithelial and non-epithelial, the latter being uncommon. Thus, epithelial tumours are the main tumours, vast majority of which are of transitional cell type (urothelial) tumours (Table 20.21).

Urothelial (Transitional Cell) Bladder Tumours

More than 90% of bladder tumours arise from transitional epithelial (urothelium) lining of the bladder in continuity with the epithelial lining of the renal pelvis, ureters, and the major part of the urethra.

Bladder cancer comprises about 3% of all cancers. Most of the cases appear beyond 5th decade of life with 3-times higher preponderance in males than females.

ETIOPATHOGENESIS Urothelial tumours in the urinary tract are typically multifocal and the pattern of disease becomes apparent over a period of years. A number of environmental and host factors are associated with increased risk of bladder cancer. These are as under:

1. **Smoking** Tobacco smoking is associated with 2 to 4 fold increased risk of developing bladder cancer, probably due to increased urinary excretion of carcinogenic substances.
2. **Industrial occupations** Workers in industries that produce aniline dyes, rubber, plastic, textiles, and cable have high incidence of bladder cancer. Bladder cancer may occur in workers in these factories after a prolonged exposure of about 20 years. The carcinogenic substances responsible for bladder cancer in these cases are the metabolites of β -naphthylamine and benzene.
3. **Schistosomiasis** There is increased risk of bladder cancer, particularly squamous cell carcinoma, in patients having bilharzial infestation (*Schistosoma haematobium*) of the bladder. Schistosomiasis is common in Egypt and Sudan and accounts for high incidence of bladder cancer in these countries. It is thought to induce local irritant effect and initiate squamous metaplasia followed by squamous cell carcinoma.

4. **Dietary factors** Certain carcinogenic metabolites of tryptophan are excreted in urine of patients with bladder cancer. These metabolites have been shown to induce bladder cancer in experimental animals. The role of artificial sweeteners like saccharin, coffee or caffeine and chronic alcoholism in the etiology of bladder cancer in man is controversial.

5. **Local lesions** A number of local lesions in the bladder predispose to the development of bladder cancer. These include ectopia vesicae (extrophied bladder), vesical diverticulum, leukoplakia of the bladder mucosa and urinary diversion in defunctionalised bladder. All these conditions are associated with squamous metaplasia and high incidence of bladder cancer.

6. **Drugs** Immunosuppressive therapy with cyclophosphamide and patients having analgesic-abuse (phenacetin-) nephropathy have high risk of developing bladder cancer.

7. **Prior irradiation** Patients who have received prior irradiation for some other pelvic cancers have higher risk of developing bladder cancer.

Multicentric nature of urothelial cancer and high rate of recurrence has led to the hypothesis that a *field effect* in the urothelium is responsible for this form of cancer. This is responsible for polychronotropism in bladder cancer i.e. the tumour tends to recur with time and develops at new locations within the urinary tract.

Several cytogenetic abnormalities have been seen in bladder cancer. These include several mutations: fibroblast growth factor receptor 3, *p53*, *RB* gene and *p21* gene. These mutations are associated with higher rate of recurrences and metastasis.

MORPHOLOGIC FEATURES *Grossly*, urothelial tumours may be single or multiple. About 90% of the tumours are papillary (non-invasive or invasive), whereas the remaining 10% are flat indurated (non-invasive or invasive) (Fig. 20.47). Most common location in the bladder is lateral walls, followed by posterior wall and region of trigone. The papillary tumours have free floating fern-like arrangement with a broad or narrow pedicle. The non-papillary tumours are bulkier with ulcerated surface (Fig. 20.48). More common locations for either of the two types are the trigone, the region of ureteral orifices and on the lateral walls.

Histologically, most common epithelial tumours of the bladder are urothelial (90%); others are squamous cell, glandular, small cell and mixed.

UROTHELIAL (TRANSITIONAL CELL) TUMOURS The WHO and ISUP (International Society of Urologic Pathology), in 1998 have proposed consensus histologic criteria to categorise urothelial tumours into papillomas (exophytic, inverted), carcinoma in situ (CIS), papillary urothelial neoplasms of low malignant potential (PUNLMP), and urothelial carcinoma (low grade and high grade). The salient histologic features of this categorisation are summed up in Table 20.22 and briefly given below:

1. **Urothelial papilloma** Papillomas may occur singly or may be multiple. These may be exophytic or inverted.

Exophytic papillomas are generally small, less than 2 cm in diameter, having delicate papillae. Each papilla is composed of fibrovascular stromal core covered by normal-

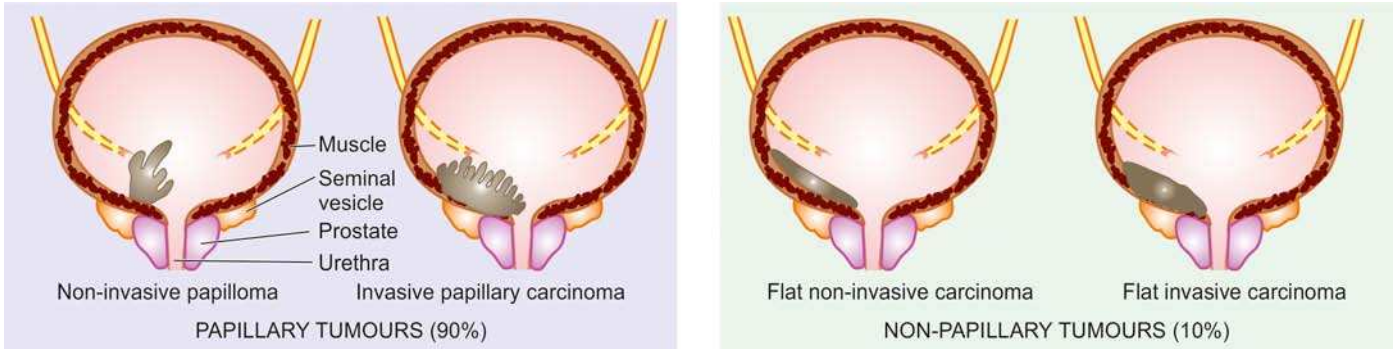

Figure 20.47 Gross patterns of epithelial bladder tumours.

looking transitional cells having normal number of layers (upto 6-7) in thickness. The individual cells resemble the normal transitional cells and do not vary in size and shape. Mitoses are absent and basal polarity is retained. Patients of exophytic papillomas may sometimes develop recurrences and require long-term follow up.

Inverted papillomas have an endophytic growth pattern and are benign tumours.

2. Carcinoma *in situ* (CIS) (Flat urothelial carcinoma)

Carcinoma *in situ* is characterised by anaplastic malignant cells confined to layers superficial to basement membrane of the bladder mucosa. These flat lesions have cytologic features similar to high-grade urothelial carcinoma such as lack of cohesiveness, nuclear pleomorphism, and mitoses. If left untreated, these cases progress to invasive bladder cancer in vast majority of cases (50-75%).

3. Papillary urothelial neoplasms of low malignant potential (PUNLMP) These cases have many features

similar to papillomas with additional features such as increase in the number of epithelial layers, having round to oval nuclei and diffuse nuclear enlargement. PUNLMP is unassociated with invasion and may have recurrences.

4. Papillary urothelial (Transitional cell) carcinoma Histologic criteria for categorising these tumours are based on *architecture, cytologic features and invasiveness*.

i) *Architecture* takes into consideration the type of papillae and relationship of cell layers with basement membrane as regards polarity.

ii) *Cytologic criteria* of neoplasm are the extent of resemblance with normal cells, crowding, variation in nuclear size, shape, chromatin, nucleoli (their presence and type), and mitotic figures.

iii) *Criteria for invasion* in papillary as well as non-papillary tumours are penetration of the basement membrane of bladder mucosa and presence or absence of invasion by neoplastic cells in the muscle.

Table 20.22 Histologic criteria for classifying urothelial tumours as per WHO/ISUP.

| FEATURE | PAPILLOMA | PUNLMP | LOW-GRADE TCC | HIGH-GRADE TCC |
|------------------------------|-----------|---------------------------|-----------------------------------|---------------------------------|
| I. ARCHTECTURE | | | | |
| 1. Papillae | Delicate | Delicate | Fused, branching | Fused, branching |
| 2. Cellular organisation | | | | |
| i) Resemblance to normal | Yes | Generally yes | Orderly | Mainly disordered |
| ii) Thickness | Normal | Any thickness | Any thickness | Any thickness |
| iii) Loss of polarity | No | No | Minimal | Frequent |
| iv) Cohesiveness | Yes | Yes | Yes | Often lost |
| v) Crowding | No | No | Minimal | Yes |
| II. CELLULAR FEATURES | | | | |
| 1. Nuclear size | Normal | May be uniformly enlarged | Enlarged with variation in size | Enlarged with variation in size |
| 2. Nuclear shape | Normal | Elongated, uniform | Roud-to-oval, slight pleomorphism | Moderate to marked pleomorphism |
| 3. Nuclear chromatin | Fine | Fine | Mild variation | Moderate to marked variation |
| 4. Nucleoli | Absent | Rare | Inconspicuous, small, regular | Conspicuous, multiple |
| 5. Mitosis | Absent | Rare, basal | Occasional, any level | Frequent, any level |
| 6. Umbrella cells | Present | Present | Usually present | May be absent |

WHO/ISUP=WHO-International Society for Urologic Pathology, 2004; PUNLMP=Papillary urothelial neoplasm of low malignant potential; TCC=Transitional cell (urothelial) carcinoma

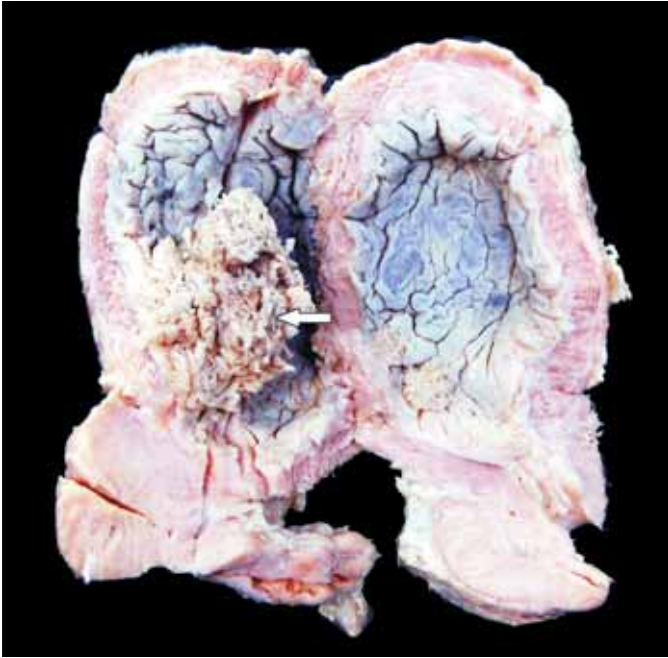

Figure 20.48 Carcinoma urinary bladder. The mucosal surface shows papillary tumour floating in the lumen (arrow).

Based on these salient features, the characteristics of two grades are as under:

Papillary urothelial carcinoma, low grade: These tumours show fused and branching papillary pattern but overall there is an orderly arrangement of layers of cells. These cells are cohesive and show mild variation in polarity, nuclear size, chromatin and shape (round to oval), and inconspicuous small and regular nucleoli. Mitotic figures are infrequent and are seen in lower half (**Fig. 20.49**).

Papillary urothelial carcinoma, high grade: High-grade tumours have increased thickness and have fused and branching papillae which show quite disorderly arrangement. The tumour cells show nuclear enlargement, moderate to marked variation in nuclear size, shape,

hyperchromatism, and multiple prominent nucleoli. Mitoses are frequent and atypical and seen at any level in the epithelial layers.

Invasive urothelial carcinoma Any grade of papillary urothelial carcinoma may show invasion into lamina propria or further into muscularis propria (detrusor).

Foci of squamous or glandular metaplasia may be seen in any grade of the tumour.

OTHER VARIANTS Although urothelial carcinoma is most common, a few less common histologic types are seen in the bladder as under:

Squamous cell carcinoma Squamous cell carcinoma comprises about 5% of the bladder carcinomas. Unlike TCC which is mostly papillary and non-ulcerating, most squamous carcinomas of the bladder are sessile, nodular, infiltrating and ulcerating. Association of squamous carcinoma and schistosomiasis has already been highlighted. The carcinoma may be well-differentiated with keratin pearl formation, or may be anaplastic.

Adenocarcinoma Adenocarcinoma of the bladder is rare. Adenocarcinoma has association with exostrophy of the bladder with glandular metaplasia, or may arise from urachal rests, periurethral and periprostatic glands, or from cystitis cystica. The tumour is characterised by glandular and tubular pattern with or without mucus production.

Small cell carcinoma This variant has morphologic resemblance with small cell carcinoma of the lung or other neuroendocrine carcinomas and has a worse outcome.

Mixed carcinoma Occasionally, combination of more than one histologic types are seen.

STAGING OF BLADDER CANCER The clinical behaviour and prognosis of bladder cancer can be assessed by the following simple staging system:

Stage 0: Carcinoma confined to the mucosa.

Stage A: Carcinoma invades the lamina propria but not the muscularis.

Stage B1: Carcinoma invades the superficial muscle layer.

Stage B2: Carcinoma invades the deep muscle layer.

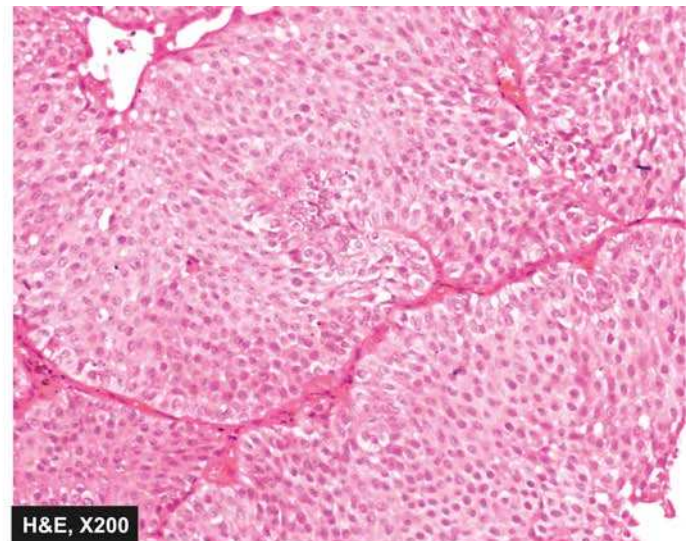

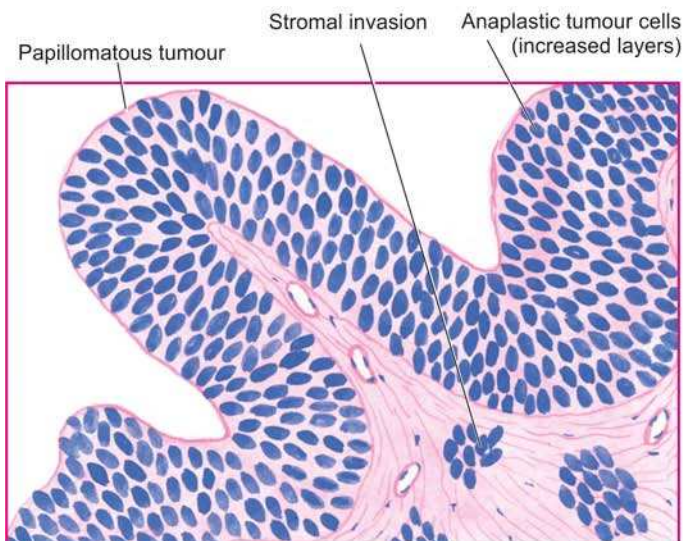

Figure 20.49 Urothelial (Transitional cell) carcinoma, low grade. There is increase in the number of layers of epithelium in an orderly manner and slight loss of polarity. The cells show slight nuclear enlargement and mild variation in nuclear size and shape and infrequent mitosis.

Stage C: Carcinoma invades the perivesical tissues.
Stage D1: Carcinoma shows regional metastases.
Stage D2: Carcinoma shows distant metastases.

Non-epithelial Bladder Tumours

Mesenchymal tumours of the bladder are less common and may be benign or malignant.

BENIGN Benign mesenchymal tumour of the bladder is uncommon but most common is leiomyoma. Other less common examples are neurofibroma, haemangioma and granular cell myoblastoma.

MALIGNANT Rhabdomyosarcoma is the most frequent malignant mesenchymal tumour. It exists in 2 forms:

Adult form occurring in adults over 40 years of age and resembles the rhabdomyosarcoma of skeletal muscle.

Childhood form occurring in infancy and childhood and appears as large polypoid, soft, fleshy, grapelike mass and is also called *sarcoma botryoides* or *embryonal rhabdomyosarcoma*. It is morphologically characterised by masses of embryonic mesenchyme consisting of masses of highly pleomorphic stellate cells in myxomatous background. Similar tumours occur in the female genital tract (page 713).

TUMOURS OF RENAL PELVIS AND URETERS

Almost all the tumours of the renal pelvis and ureters are of epithelial origin. They are of the same types as are seen in the urinary bladder. However, tumours in the ureters are quite rare.

TUMOURS OF URETHRA

Tumours of the urethra are rare except for the urethral caruncle which is a tumour-like lesion.

URETHRAL CARUNCLE Urethral caruncle is not uncommon. It is an inflammatory lesion present on external urethral meatus in elderly females.

Grossly, the caruncle appears as a solitary, 1 to 2 cm in diameter, pink or red mass, protruding from urethral meatus. It is quite friable and ulcerated.

Microscopically, the mass may be covered by squamous or transitional epithelium or there may be ulcerated surface. The underlying tissues show proliferating blood vessels, fibroblastic connective tissue and intense acute and chronic inflammatory infiltrate. Thus, the histologic appearance closely resembles a *pyogenic granuloma*.

URETHRAL CARCINOMA Carcinoma of the urethra is uncommon. In most cases it occurs in the distal urethra near the external meatus and thus is commonly squamous cell carcinoma. Less often, there may be transitional cell carcinoma or adenocarcinoma arising from periurethral glands.

GIST BOX 20.12 Diseases of Lower Urinary Tract

- ☐ Vesicoureteric reflux, ectopia vesicae and urachal abnormalities are some of the congenital anomalies of lower urinary tract.
- ☐ Ureteritis and cystitis may accompany pyelitis.
- ☐ Urethritis may be gonococcal and non-gonococcal.
- ☐ Epithelial tumours are the main tumours, vast majority of which are of transitional cell type (urothelial) tumours.
- ☐ Urothelial tumours include papillomas (exophytic, inverted), carcinoma in situ, papillary urothelial neoplasms of low malignant potential (PUNLMP), and urothelial carcinoma (low grade and high grade).
- ☐ Urethral caruncle is an inflammatory lesion on external urethral meatus in elderly females.

CLINICAL CASE 20

A 5 years old male child is brought by the mother to Paediatric Outpatient with chief complaints of puffiness of face, particularly more marked in the morning, and pitting oedema on both legs for about one month. The child is passing smoky urine but no oliguria. There is history of appearance of multiple boils repeatedly on the skin of both legs which remained neglected and partly healed.

On examination, the blood pressure is 150/110 mmHg, pulse rate 90/min, respiration rate 22/min. pallor+, pedal oedema+. There is no cyanosis, lymphadenopathy or icterus. Systemic examination did not show any abnormality in respiratory system, abdomen, CVS and CNS.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 911 (Appendix II)

CLINICAL CASE 21

A 50 years old man presents to General Surgery Outpatient with complaints of gross painless haematuria and pain in right flank. There is also history of loss of 10 kg weight in the last 6 months.

On physical examination, a right-sided flank mass is palpable on bimanual examination.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 912 (Appendix II)

The Male Reproductive System and Prostate

TESTIS AND EPIDIDYMIS

NORMAL STRUCTURE

Contents of the scrotal sac include the testicle and epididymis along with lower end of the spermatic cord and the tunica vaginalis that forms the outer serous investing layer. The epididymis is attached to body of the testis posteriorly. Thus, the testicle and epididymis may be regarded as one organ.

Structurally, the main components of the testicle are the seminiferous tubules which when uncoiled are of considerable length.

Histologically, the seminiferous tubules are formed of a lamellar connective tissue membrane and contain several layers of cells (**Fig. 21.1,A**). In the adult, the cells lining the seminiferous tubules are of 2 types:

1. *Spermatogonia* or germ cells which produce spermatocytes (primary and secondary), spermatids and mature spermatozoa.
2. *Sertoli cells* which are larger and act as supportive cells to germ cells, produce mainly androgen (testosterone) and little oestrogen.

The seminiferous tubules drain into collecting ducts which form the rete testis from where the secretions pass into the vasa efferentia. Vasa efferentia opens at the upper end of the epididymis. The lower end of the epididymis is prolonged into a thick muscular tube, the vas deferens, that transports the secretions into the urethra.

The fibrovascular stroma present between the seminiferous tubules contains varying number of *interstitial cells of Leydig*. Leydig cells have abundant cytoplasm containing lipid granules and elongated Reinke's crystals. These cells are the main source of testosterone and other androgenic hormones in males. Thus, Sertoli and Leydig cells are hormone-producing cells homologous to their ovarian counterparts (granulosa-theca cells) and are termed *specialised stromal cells* of the gonads.

Thus, the main *functions* of the testis are to produce sperms and testosterone.

DEVELOPMENTAL DISORDERS

CRYPTORCHIDISM

Cryptorchidism or undescended testis is a condition in which the testicle is arrested at some point along its descent. Its incidence is about 0.2% in adult male population. In 70% of cases, the undescended testis lies in the inguinal ring, in 25% in the abdomen and, in the remaining 5%, it may be present at other sites along its descent from intra-abdominal location to the scrotal sac.

ETIOLOGY The exact etiology is not known in majority of cases. However, a few apparent causes associated with cryptorchidism are as under:

1. **Mechanical factors** e.g. short spermatic cord, narrow inguinal canal, adhesions to the peritoneum.
2. **Genetic factors** e.g. trisomy 13, maldevelopment of the scrotum or cremaster muscles.
3. **Hormonal factors** e.g. deficient androgenic secretions.

MORPHOLOGIC FEATURES Cryptorchidism is unilateral in 80% cases and bilateral in the rest.

Grossly, the cryptorchid testis is small in size, firm and fibrotic.

Histologically, contrary to previous beliefs, the changes of atrophy begin to appear by about 2 years of age. These changes are as under (**Fig. 21.1,B**):

1. *Seminiferous tubules*: There is progressive loss of germ cell elements so that the tubules may be lined by only spermatogonia and spermatids but foci of spermatogenesis are discernible in 10% of cases. The tubular basement membrane is thickened. Advanced cases show hyalinised tubules with a few Sertoli cells only, surrounded by prominent basement membrane.
2. *Interstitial stroma*: There is usually increase in the interstitial fibrovascular stroma and conspicuous presence of Leydig cells, seen singly or in small clusters.

CLINICAL FEATURES As such, cryptorchidism is completely asymptomatic and is discovered only on physical examination. However, if surgical correction by orchiopexy is not undertaken by about 2 years of age, or certainly in the prepubertal period, following significant adverse clinical outcome may result:

1. **Sterility-infertility** Bilateral cryptorchidism is associated with sterility while unilateral disease may result in infertility.
2. **Inguinal hernia** A concomitant inguinal hernia is frequently present along with cryptorchidism.
3. **Malignancy** Cryptorchid testis is at 30-50 times increased risk of developing testicular malignancy, most commonly seminoma and embryonal carcinoma, than a normally descended testis. The risk of malignancy is greater in intra-abdominal testis than in testis in the inguinal canal for the simple reason that the neoplastic process in the testis in scrotal location is detected earlier than intra-abdominal site.

MALE INFERTILITY

The morphologic pattern of testicular atrophy described above for cryptorchidism can result from various other congenital or acquired causes of male infertility. These causes can be divided into 3 groups: pre-testicular, testicular and post-testicular.

A. Pre-Testicular Causes

1. **Hypopituitarism** Pre-pubertal or post-pubertal hypopituitarism such as from tumour, trauma, infarction, cyst and genetic deficiency of FSH and LH secretion.

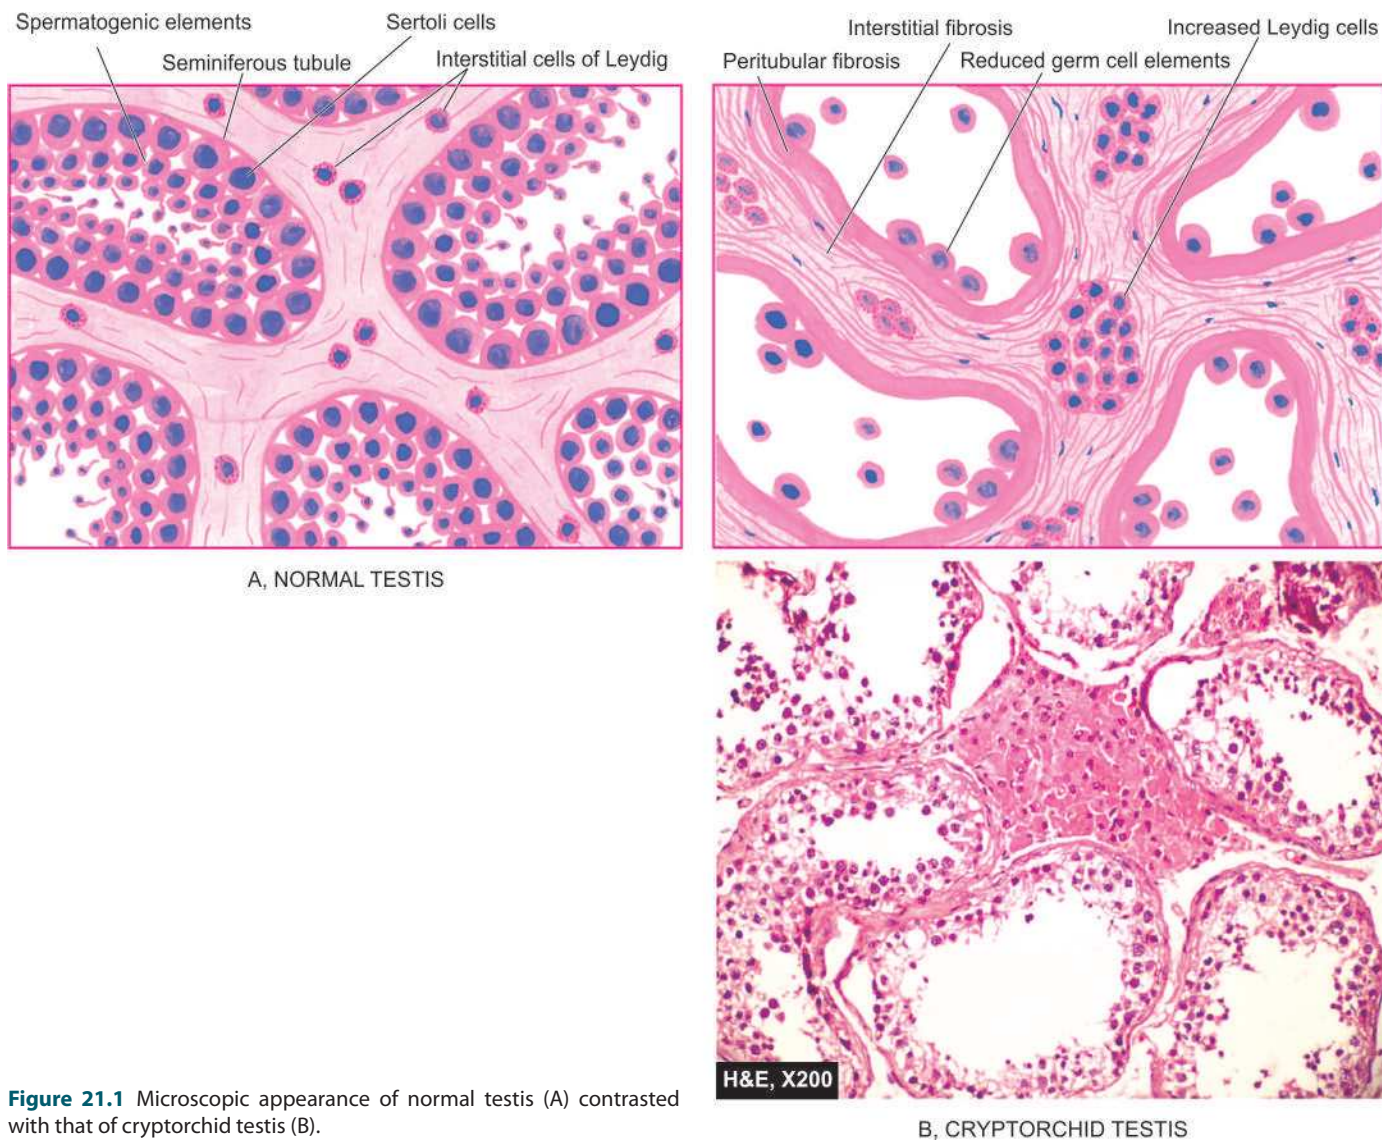

Figure 21.1 Microscopic appearance of normal testis (A) contrasted with that of cryptorchid testis (B).

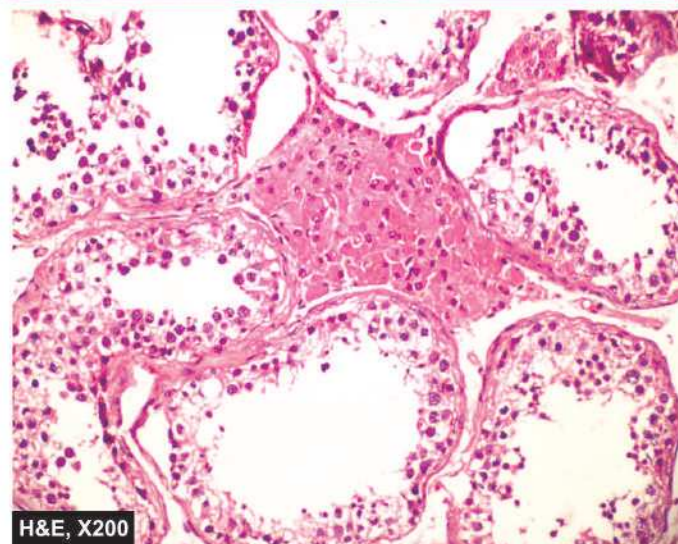

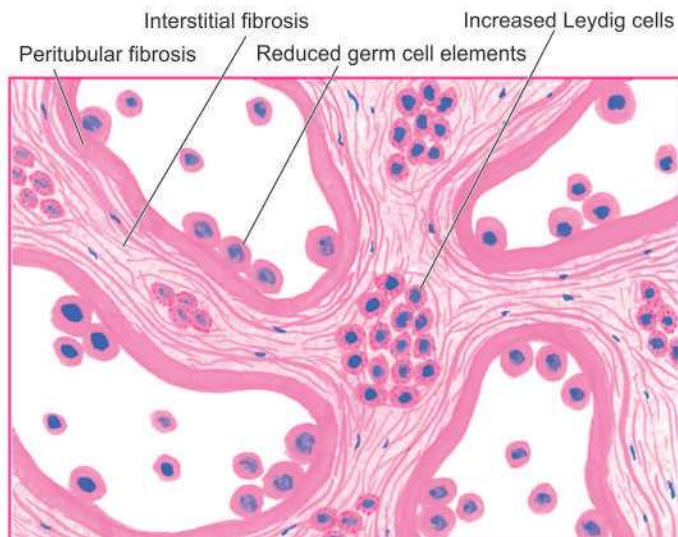

2. Oestrogen excess *Endogenous* excess such as from hepatic cirrhosis, adrenal tumour, Sertoli and Leydig cell tumour; or *exogenous* excess such as in the treatment of carcinoma of the prostate.

3. Glucocorticoid excess *Endogenous* excess may occur in Cushing's syndrome while *exogenous* excess may occur in the treatment of ulcerative colitis, bronchial asthma, rheumatoid arthritis etc.

4. Other endocrine disorders Hypothyroidism and diabetes mellitus are associated with hypospermatogenesis.

B. Testicular Causes

- 1. Agonadism** i.e. total absence of the testes.
- 2. Cryptorchidism** or undescended testis described above.
- 3. Maturation arrest** i.e. failure of spermatogenesis beyond one of the immature stages.
- 4. Hypospermatogenesis** i.e. presence of all the maturation stages of spermatogenesis but in decreased number.
- 5. Sertoli cell-only syndrome** in which there is congenital or acquired absence of all germ cells so that the seminiferous tubules are lined by Sertoli cells only.

6. Klinefelter's syndrome in which there is an XXY intersexuality characterised by primary hypogonadism, azoospermia, gynecomastia, eunuchoid built and subnormal intelligence.

7. Mumps orchitis occurring as a complication of parotitis (page 515).

8. Irradiation damage resulting in permanent germ cell destruction.

C. Post-Testicular Causes

- 1. Congenital block** e.g. absence or atresia of vas deferens.
- 2. Acquired block** e.g. due to gonorrhoea and surgical intervention.
- 3. Impaired sperm motility** in the presence of normal sperm counts e.g. immotile cilia syndrome (page 465).

INFLAMMATIONS

Inflammation of the testis is termed as orchitis and of epididymis is called as epididymitis; the latter being more common. A combination epididymo-orchitis may also occur. A few important types are described here.

NON-SPECIFIC EPIDIDYMITIS AND ORCHITIS

Non-specific epididymitis and orchitis, or their combination, may be acute or chronic. The common routes of spread of infection are via the vas deferens, or via lymphatic and haematogenous routes. Most frequently, the infection is caused by urethritis, cystitis, prostatitis and seminal vesiculitis. Other causes are mumps, smallpox, dengue fever, influenza, pneumonia and filariasis. The common infecting organisms in sexually-active men under 35 years of age are *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, whereas in older individuals the common organisms are urinary tract pathogens like *Escherichia coli* and *Pseudomonas*.

MORPHOLOGIC FEATURES *Grossly*, in acute stage the testicle is firm, tense, swollen and congested. There may be multiple abscesses, especially in gonorrhoeal infection. In chronic cases, there is usually variable degree of atrophy and fibrosis.

Histologically, acute orchitis and epididymitis are characterised by congestion, oedema and diffuse infiltration by neutrophils, lymphocytes, plasma cells and macrophages or formation of neutrophilic abscesses. Acute inflammation may resolve, or may progress to chronic form. In chronic epididymo-orchitis, there is focal or diffuse chronic inflammation, disappearance of seminiferous tubules, fibrous scarring and destruction of interstitial Leydig cells. Such cases usually result in permanent sterility.

GRANULOMATOUS (AUTOIMMUNE) ORCHITIS

Non-tuberculous granulomatous orchitis is a peculiar type of unilateral, painless testicular enlargement in middle-aged men that may resemble a testicular tumour clinically. The exact etiology and pathogenesis of the condition are not known though an autoimmune basis is suspected.

MORPHOLOGIC FEATURES *Grossly*, the affected testis is enlarged with thickened tunica. Cut section of the testicle is greyish-white to tan-brown.

Histologically, there are circumscribed non-caseating granulomas lying within the seminiferous tubules. These granulomas are composed of epithelioid cells, lymphocytes, plasma cells, some neutrophils and multinucleate giant cells. The origin of the epithelioid cells is from Sertoli cells lining the tubules. The tubules show peritubular fibrosis which merges into the interstitial tissue that is infiltrated by lymphocytes and plasma cells.

TUBERCULOUS EPIDIDYMO-ORCHITIS

Tuberculosis invariably begins in the epididymis and spreads to involve the testis. Tuberculous epididymo-orchitis is generally secondary tuberculosis from elsewhere in the body. It may occur either by direct spread from genitourinary tuberculosis such as tuberculous seminal vesiculitis, prostatitis and renal tuberculosis, or may reach here by haematogenous spread of infection such as from tuberculosis of the lungs. Primary genital tuberculosis may occur rarely.

MORPHOLOGIC FEATURES *Grossly*, discrete, yellowish, caseous necrotic areas are seen.

Figure 21.2 Tuberculous epididymo-orchitis. The interstitium contains several epithelioid cell granulomas with central areas of caseation necrosis. These granulomas are surrounded by Langhans' giant cells and mantle of lymphocytes.

Microscopically, numerous tubercles which may coalesce to form large caseous mass are seen. Characteristics of typical tubercles such as epithelioid cells, peripheral mantle of lymphocytes, occasional multinucleate giant cells and central areas of caseation necrosis are seen (**Fig. 21.2**). Numerous acid-fast bacilli can be demonstrated by Ziehl-Neelsen staining. The lesions produce extensive destruction of the epididymis and may form chronic discharging sinuses on the scrotal skin. In late stage, the lesions heal by fibrous scarring and may undergo calcification.

SPERMATIC GRANULOMA

Spermatic granuloma is the term used for development of inflammatory lesions due to invasion of spermatozoa into the stroma. Spermatic granuloma may develop due to trauma, inflammation and loss of ligature following vasectomy.

MORPHOLOGIC FEATURES *Grossly*, the sperm granuloma is a small nodule, 3 mm to 3 cm in diameter, firm, white to yellowish-brown.

Histologically, it consists of a granuloma composed of histiocytes, epithelioid cells, lymphocytes and some neutrophils. Characteristically, the centre of spermatic granuloma contains spermatozoa and necrotic debris. The late lesions have fibroblastic proliferation at the periphery and hyalinisation.

ELEPHANTIASIS

Elephantiasis is enormous thickening of the scrotal skin resembling the elephant's hide and results in enlargement of the scrotum. The condition results from filariasis in which the adult worm lives in the lymphatics, while the larvae travel in

the blood. The most important variety of filaria is *Wuchereria bancrofti*. The condition is common in all tropical countries. The vector is generally the *Culex* mosquito. The patients may remain asymptomatic or may manifest with fever, local pain, swelling, rash, tender lymphadenopathy and blood eosinophilia. An asthma-like respiratory complaint may develop in some cases.

MORPHOLOGIC FEATURES *Grossly*, the affected leg and scrotum are enormously thickened with enlargement of regional lymph nodes. The affected area of skin may show dilated dermal lymphatics and varicosities.

Histologically, the changes begin with lymphatic obstruction by the adult worms. The worm in alive, dead or calcified form may be found in the dilated lymphatics or in the lymph nodes. Dead or calcified worm in lymphatics is usually followed by lymphangitis with intense infiltration by eosinophils. Sometimes, granulomatous reaction may be evident. In advanced cases, chronic lymphoedema with tough subcutaneous fibrosis and epidermal hyperkeratosis develops which is termed elephantiasis.

MISCELLANEOUS LESIONS

TORSION OF TESTIS

Torsion of the testicle may occur either in a fully-descended testis or in an undescended testis. The latter is more common and more severe. It results from sudden cessation of venous drainage and arterial supply to the testis, usually following sudden muscular effort or physical trauma. Torsion is common in boys and young men.

MORPHOLOGIC FEATURES The pathologic changes vary depending upon the duration and severity of vascular occlusion. There may be coagulative necrosis of the testis and epididymis, or there may be haemorrhagic infarction. The inflammatory reaction is generally not so pronounced.

VARICOCELE

Varicocele is the dilatation, elongation and tortuosity of the veins of the pampiniform plexus in the spermatic cord. It is of 2 types: primary (idiopathic) and secondary.

◆ **Primary or idiopathic form** is more frequent and is more common in young unmarried men. It is nearly always on the left side as the loaded rectum presses the left vein. Besides, the left spermatic vein enters the renal vein at right angles while the right spermatic vein enters the vena cava obliquely.

◆ **Secondary form** occurs due to pressure on the spermatic vein by enlarged liver, spleen or kidney. It is commoner in middle-aged people.

HYDROCELE

A hydrocele is abnormal collection of serous fluid in the tunica vaginalis. It may be acute or chronic, congenital or acquired. The usual causes are trauma, systemic oedema such as in cardiac failure and renal disease, and as a complication of gonorrhoea, syphilis and tuberculosis.

The hydrocele fluid is generally clear and straw-coloured but may be slightly turbid or haemorrhagic. The hydrocele sac may have single loculus or may have multiple loculi. The wall of

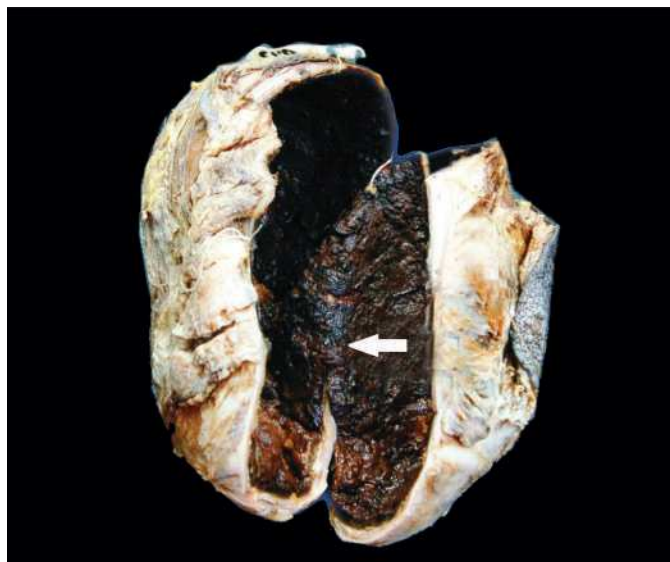

Figure 21.3 Haematocele testis. Sectioned surface of the sac shows thick wall coated internally by brownish, tan and necrotic material which is organised blood clot (arrow).

the hydrocele sac is composed of fibrous tissue infiltrated with lymphocytes and plasma cells.

HAEMATOCELE

Haematocele is haemorrhage into the sac of the tunica vaginalis. It may result from direct trauma, from injury to a vein by the needle, or from haemorrhagic diseases.

In recent haematocele, the blood coagulates and the wall is coated with ragged deposits of fibrin. In long-standing cases, the tunica vaginalis is thickened with dense fibrous tissue coated with brownish material due to old organised haemorrhage and occasionally may get partly calcified (**Fig. 21.3**).

GIST BOX 21.1

Miscellaneous Diseases of Testis

- ▣ Cryptorchidism or undescended testis is a condition in which the testicle is arrested congenitally at some point along its descent.
- ▣ Testicular atrophy can also result from various other congenital or acquired causes of pre-testicular, testicular and post-testicular origin and cause male infertility.
- ▣ Orchitis, epididymitis and epididymo-orchitis are inflammations of these tissues and may be non-specific, granulomatous (autoimmune) or caseating tuberculous inflammation.
- ▣ Torsion of the testicle is sudden cessation of venous drainage and arterial supply to the testis, following sudden muscular effort or physical trauma.
- ▣ Varicocele is the dilatation and tortuosity of the veins of the pampiniform plexus in the spermatic cord.
- ▣ Hydrocele and haematocele are abnormal collection of serous fluid or blood respectively in the tunica vaginalis.

TESTICULAR TUMOURS

Testicular tumours are the cause of about 1% of all cancer deaths. They are more frequent in white male population but

Table 21.1 Classification of testicular tumours.

| 2. | Rare tumours |

are less common in Africans and Asians. They have *trimodal* age distribution—a peak during infancy, another during late adolescence and early adulthood, and a third peak after 60 years of age.

CLASSIFICATION

The most widely accepted classification is the histogenetic classification proposed by the World Health Organisation (**Table 21.1**). Based on this, all testicular tumours are divided into 3 groups: *germ cell tumours*, *sex cord-stromal tumours* and *mixed forms*. Vast majority of the testicular tumours (95%) arise from germ cells or their precursors in the seminiferous tubules, while less than 5% originate from sex cord-stromal components of the testis. From clinical point of view, germ cell tumours of the testis are categorised into 2 main groups—seminomatous and non-seminomatous which need to be distinguished (**Table 21.2**).

ETIOLOGIC FACTORS

Exact etiology of testicular germ cell tumours is unknown, but the following factors have been implicated:

1. Cryptorchidism The probability of a germ cell tumour developing in an undescended testis is 30-50 times greater than in a normally-descended testis. About 10% of testicular germ cell tumours are associated with cryptorchidism. The high incidence is attributed to higher temperature to which the undescended testis in the groin or abdomen is exposed. Intra-abdominal testis is at greater risk than the inguinal testis. There is increased incidence of tumour in the contralateral normally-descended testis. There are no data to confirm or deny whether surgical repositioning or orchiopexy of a cryptorchid testis alters the incidence of testicular tumour. However, surgical correction is still helpful since it is easier to detect the tumour in scrotal testis than in an abdominal or inguinal testis.

2. Other developmental disorders Dysgenetic gonads associated with endocrine abnormalities such as androgen insensitivity syndrome have higher incidence of development of germ cell tumours.

3. Genetic factors Genetic factors play a role in the development of germ cell tumours supported by the observation of high incidence in first-degree family members, twins and in white male populations while blacks in Africa have a very low incidence. However, no definite pattern of inheritance has been recognised.

4. Other factors A few less common factors include the following:

i) Orchitis A history of mumps or other forms of orchitis may be given by the patient with germ cell tumour.

ii) Trauma Many patients give a history of trauma prior to the development of the tumour but it is not certain how trauma initiates the neoplastic process. Instead, possibly it brings the patient to attention of the physician.

iii) Carcinogens A number of carcinogens such as use of certain drugs (e.g. LSD, hormonal therapy for sterility, copper, zinc etc), exposure to radiation and endocrine abnormalities may play a role in the development of testicular tumours.

HISTOGENESIS

Pathogenesis of testicular tumours remains controversial except that vast majority of these tumours originate from germ cells. Based on current concepts on histogenesis of testicular tumours, following agreements and disagreements have emerged (**Fig. 21.4**):

Table 21.2 Distinguishing features of seminomatous (SGCT) and non-seminomatous (NSGCT) germ cell tumours of testis.

| FEATURE | SGCT | NSGCT |
|---------------------------------|---|---|
| 1. <i>Primary tumour</i> | Larger, confined to testis for sufficient time; testicular contour retained | Smaller, at times indistinct; testicular contour may be distorted |
| 2. <i>Metastasis</i> | Generally to regional lymph nodes | Haematogenous spread early |
| 3. <i>Response to radiation</i> | Radiosensitive | Radioresistant |
| 4. <i>Serum markers</i> | hCG; generally low levels | hCG, AFP, or both; high levels |
| 5. <i>Prognosis</i> | Better | Poor |

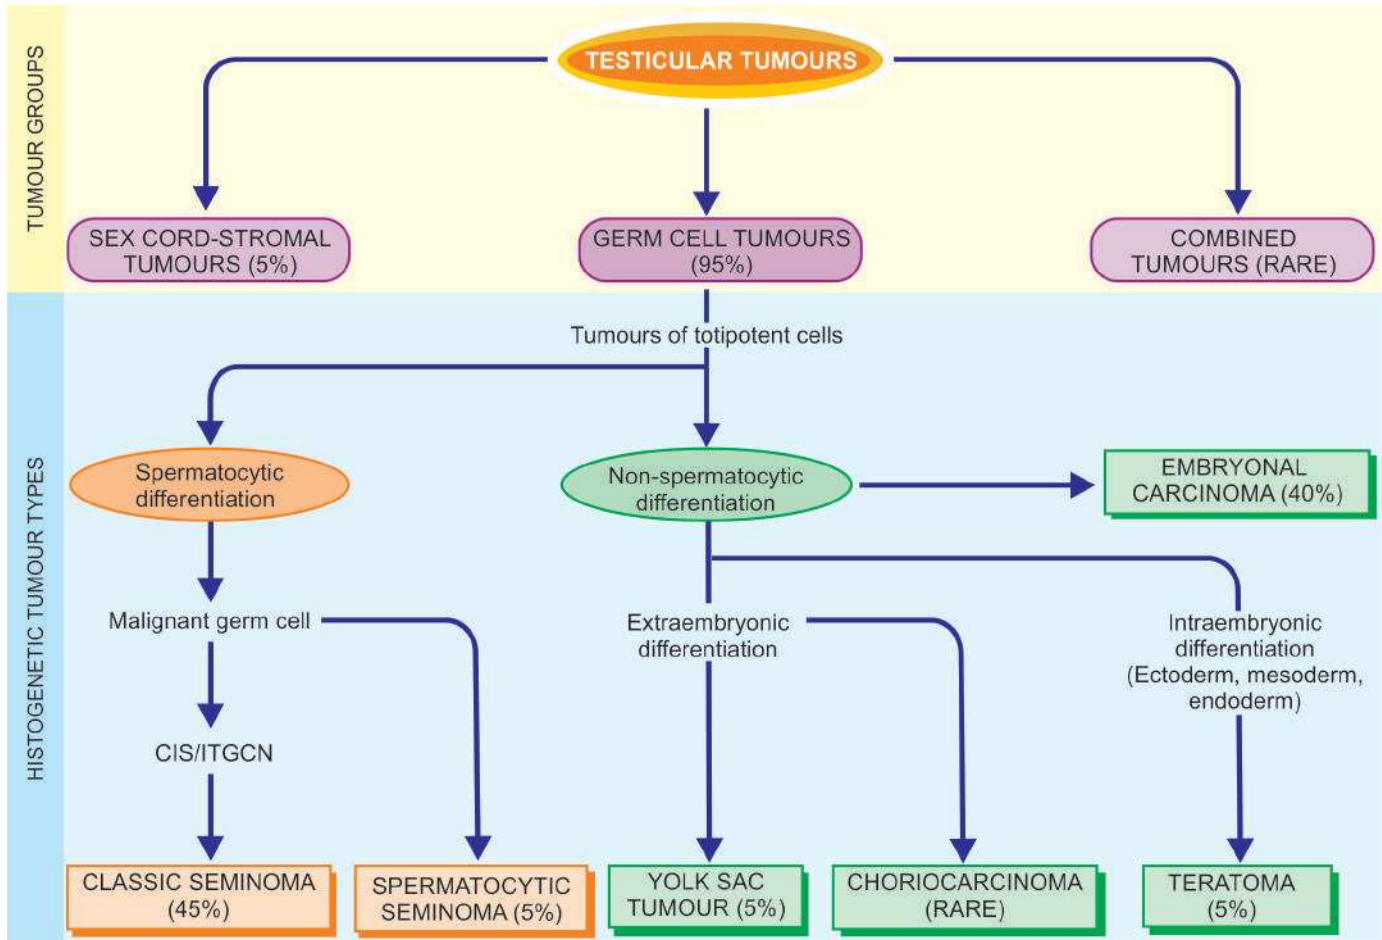

Figure 21.4 Classification, incidence and histogenesis of testicular tumours.

1. Developmental disorders Disorders such as cryptorchidism, gonadal dysgenesis and androgen insensitivity syndrome are high risk factors for development of testicular germ cell tumours. These observations point to developmental defect in gonadogenesis.

2. Molecular genetic features Testicular germ cell tumours have been found to have several genetic abnormalities suggesting a common molecular pathogenesis of all germ cell tumours:

- i) *Hyperdiploidy* is almost a constant feature of all germ cell tumours of the testis.
- ii) In more than 90% of testicular germ cell tumours irrespective of histologic type (as also ovarian germ cell tumours), an isochromosome of short arm of chromosome 12, abbreviated as *i(12p)*, is found.
- iii) Similarly, deletion of long arm of chromosome 12 abbreviated as *del(12q)*, is present.
- iv) *Telomerase activity* is present in all germ cell tumours of the testis.
- v) Other mutations include *p53*, *cyclin E* and *FAS* gene.

3. CIS/ITGCN A preinvasive stage of carcinoma *in situ* (CIS) termed *intratubular germ cell neoplasia (ITGCN)* generally precedes the development of most of the invasive testicular germ cell tumours in adults. CIS originates from spermatogenic elements. Areas of CIS are found in seminiferous tubules adjacent to most seminomas, embryonal carcinomas and other mixed germ cell tumours. However, CIS is not found in seminiferous tubules adjoining yolk sac carcinoma of childhood, benign teratoma in children and adolescents, and

spermatocytic seminoma indicating their different pathogenetic mechanisms.

4. 'Three hit' process Germ cells in seminiferous tubules undergo activation (*'first hit'*) before undergoing malignant transformation confined to seminiferous tubules (CIS) (*'second hit'*) and eventually into invasive stage by some epigenetic phenomena (*'third hit'*). Though this sequential tumorigenesis explains the development of seminomatous tumours, it is yet not clear whether non-seminomatous germ cell tumours develop directly or through intermediate stage.

CLINICAL FEATURES AND DIAGNOSIS

The usual presenting clinical symptoms of testicular tumours are gradual gonadal enlargement and a dragging sensation in the testis. Metastatic involvement may produce secondary symptoms such as pain, lymphadenopathy, haemoptysis and urinary obstruction.

SPREAD Since testicular germ cell tumours originate from totipotent germ cells, it is not unusual to find metastases of histologic types different from the primary growth. Testicular tumours may spread by both lymphatic and haematogenous routes:

1. Lymphatic spread occurs to retroperitoneal para-aortic lymph nodes, mediastinal lymph nodes and supraclavicular lymph nodes.

2. Haematogenous spread primarily occurs to the lungs, liver, brain and bones.

TUMOUR MARKERS Germ cell tumours of the testis secrete polypeptide hormones and certain enzymes which can be detected in the blood. Two tumour markers widely used in the diagnosis, staging and monitoring the follow-up of patients with testicular tumours are: human chorionic gonadotropin (hCG) and alpha-foetoprotein (AFP). In addition, carcinoembryonic antigen (CEA), human placental lactogen (HPL), placental alkaline phosphatase, testosterone, oestrogen and luteinising hormone may also be elevated.

1. **hCG** is synthesised by placental syncytio-trophoblast such as in various non-seminomatous germ cell tumours of the testis (e.g. in choriocarcinoma, yolk sac tumour and embryonal carcinoma). However, ectopic hCG production may occur in a variety of non-testicular non-germ cell tumours as well.

2. **AFP** is normally synthesised by the foetal liver cells, yolk sac and foetal gut. Its levels are elevated in testicular tumours associated with yolk sac components. However, elevated serum AFP levels are also found in liver cell carcinoma.

PROGNOSIS For selecting post-orchietomy treatment (radiation, surgery, chemotherapy or all the three) and for monitoring prognosis, 3 clinical stages are defined:

Stage I: tumour confined to the testis.

Stage II: distant spread confined to retroperitoneal lymph nodes below the diaphragm.

Stage III: distant metastases beyond the retroperitoneal lymph nodes.

Seminomas tend to remain localised to the testis (stage I) while non-seminomatous germ cell tumours more often present with advanced clinical disease (stage II and III). Seminomas are extremely radiosensitive while non-seminomatous germ cell tumours are radio-resistant. In general, seminomas have a better prognosis with 90% cure rate while the non-seminomatous tumours behave in a more aggressive manner and have poor prognosis.

After these general comments, specific testicular tumours are described below.

GERM CELL TUMOURS

Germ cell tumours comprise approximately 95% of all testicular tumours and are more frequent before the age of 45 years. *Testicular germ cell tumours are almost always malignant.*

Nearly half of them contain more than one histologic type. Besides their counterparts in the female gonads, germ cell tumours are also found at the extragonadal sites such as the retroperitoneum, mediastinum, base of the brain, coccyx etc (page 185).

Intratubular Germ Cell Neoplasia

The term intratubular germ cell neoplasia (ITGCN) is used to describe the preinvasive stage of germ cell tumours, notably intratubular seminoma and intratubular embryonal carcinoma. Others have used carcinoma *in situ* (CIS) stage of germ cell tumours as synonymous term.

Histologically, the malignant atypical tumour cells are restricted to the seminiferous tubules without evident invasion into the interstitium. Areas of ITGCN are frequently found in the vicinity of germ of cell tumours.

Classic Seminoma

Seminoma is the commonest malignant tumour of the testis and corresponds to dysgerminoma in the female (page 737). It constitutes about 45% of all germ cell tumours, and in another 15% comprises the major component of mixed germ cell tumour. Seminoma is divided into 2 main categories: classic and spermatocytic. Classic seminoma comprises about 95% of all seminomas and has a peak incidence in the 4th decade of life and is rare before puberty. Undescended testis harbours seminoma more frequently as compared to other germ cell tumours. About 10% pure seminomas are associated with elevated hCG levels in serum.

MORPHOLOGIC FEATURES *Grossly*, the involved testis is enlarged up to 10 times its normal size but tends to maintain its normal contour since the tumour rarely invades the tunica. The larger tumour replaces the entire testis, whereas the smaller tumour appears as circumscribed mass in the testis. Cut section of the affected testis shows homogeneous, grey-white lobulated appearance (Fig. 21.5). Necrosis and haemorrhage in the tumour are rare.

Microscopically, the tumour has the following characteristics (Fig. 21.6):

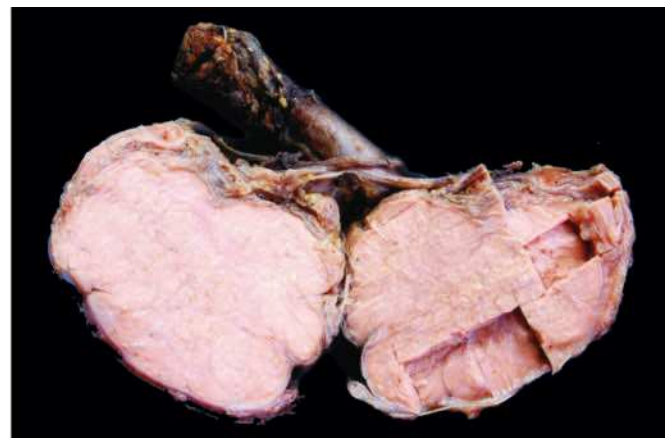

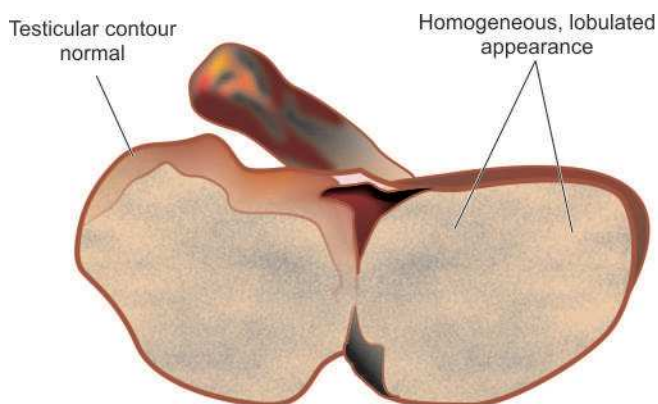

Figure 21.5 Seminoma testis. The testis is enlarged but without distorting its contour. Sectioned surface shows replacement of the entire testis by lobulated, homogeneous, grey-white mass.

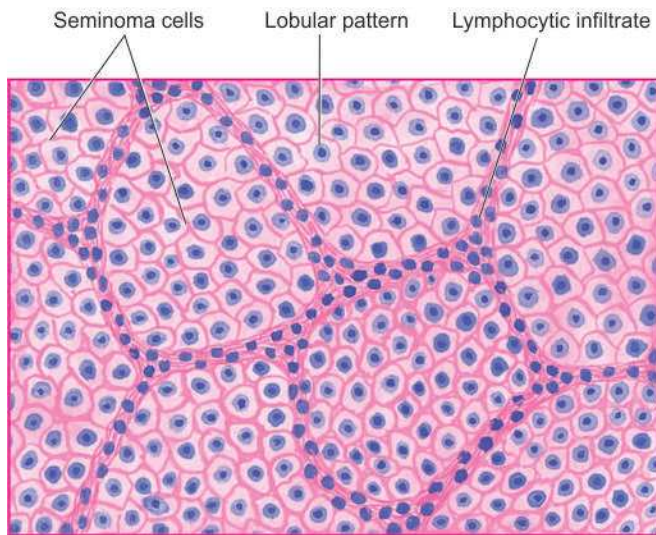

Figure 21.6 Seminoma testis. Microscopy of the tumour shows lobules of monomorphic seminoma cells separated by delicate fibrous stroma containing lymphocytic infiltration.

1. Tumour cells The seminoma cells generally lie in cords, sheets or columns forming lobules. Typically, in a classic seminoma, the tumour cells are fairly uniform in size with clear cytoplasm and well-defined cell borders. The cytoplasm contains variable amount of glycogen that stains positively with PAS reaction. The nuclei are centrally located, large, hyperchromatic and usually contain 1-2 prominent nucleoli. Tumour giant cells may be present. Mitotic figures are infrequent. However, about 10% of seminomas have increased mitotic activity and have aggressive behaviour and are categorised as *anaplastic seminomas*.

2. Stroma The stroma of seminoma is delicate fibrous tissue which divides the tumour into lobules. The stroma shows a characteristic lymphocytic infiltration, indicative of immunologic response of the host to the tumour. About 20% of the tumours show granulomatous reaction in the stroma.

The *prognosis* of classic seminoma is better than other germ cell tumours. The tumour is highly radiosensitive. Natural history of anaplastic seminoma, however, is unclear—perhaps it represents an advanced stage of classic seminoma with a more aggressive behaviour.

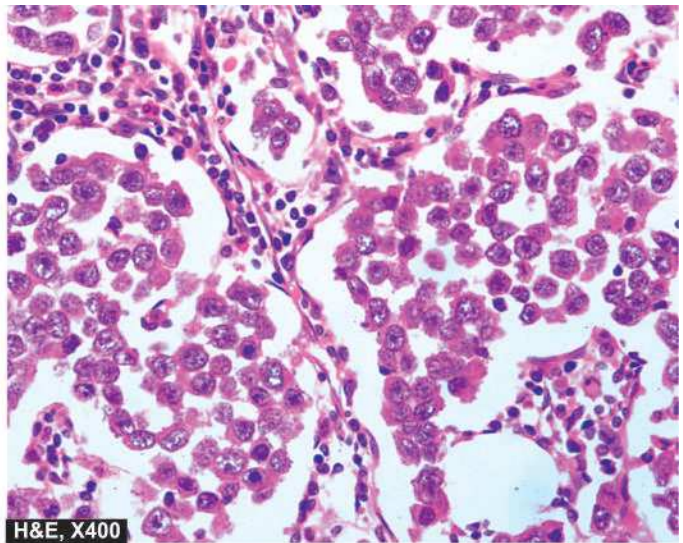

Spermatocytic Seminoma

Spermatocytic seminoma is both clinically and morphologically a distinctive tumour from classic seminoma and is, therefore, classified separately in the WHO classification. It is an uncommon tumour having an incidence of about 5% of all germ cell tumours. Spermatocytic seminoma usually occurs in older patients, generally in 6th decade of life. The tumour is bilateral in 10% of patients.

MORPHOLOGIC FEATURES *Grossly*, spermatocytic seminoma is homogeneous, larger, softer and more yellowish and gelatinous than the classic seminoma.

Histologically, the distinctive features are as under:

1. Tumour cells The tumour cells vary considerably in size from lymphocyte-like to huge mononucleate or

multinucleate giant cells. Majority of the tumour cells are, however, of intermediate size. The cells have eosinophilic cytoplasm devoid of glycogen. The nuclei of intermediate and large cells have filamentous pattern. Mitoses are often frequent.

2. Stroma The stroma lacks lymphocytic and granulomatous reaction seen in classic seminoma.

The *prognosis* of spermatocytic seminoma is excellent compared and better than classic seminoma since the tumour is slow-growing and rarely metastasises. The tumour is radiosensitive.

Embryonal Carcinoma

Pure embryonal carcinoma constitutes 30% of germ cell tumours but areas of embryonal carcinoma are present in 40% of various other germ cell tumours. These tumours are more common in 2nd to 3rd decades of life. About 90% cases are associated with elevation of AFP or hCG or both. They are more aggressive than the seminomas.

MORPHOLOGIC FEATURES *Grossly*, embryonal carcinoma is usually a small tumour in the testis. It distorts the contour of the testis as it frequently invades the tunica and the epididymis. Cut surface of the tumour is grey-white, soft with areas of haemorrhages and necrosis.

Microscopically, the following features are seen:

1. The tumour cells are arranged in a variety of *patterns*—glandular, tubular, papillary and solid.
2. The *tumour cells* are highly anaplastic carcinomatous cells having large size, indistinct cell borders, amphophilic cytoplasm and prominent hyperchromatic nuclei showing considerable variation in nuclear size. Mitotic figures and tumour giant cells are frequently present. Haemorrhage and necrosis are common.
3. The *stroma* is not as distinct as in seminoma and may contain variable amount of primitive mesenchyme.

Embryonal carcinoma is more aggressive and less radioresistant than seminoma. Chemotherapy is more effective in treating this tumour.

Yolk Sac Tumour

(Synonyms: Endodermal Sinus Tumour, Orchioblastoma, Infantile Embryonal Carcinoma)

This characteristic tumour is the most common testicular tumour of infants and young children up to the age of 4 years. In adults, however, yolk sac tumour in pure form is rare but may be present as the major component in 40% of germ cell tumours. AFP levels are elevated in 100% cases of yolk sac tumours.

MORPHOLOGIC FEATURES *Grossly*, the tumour is generally soft, yellow-white, mucoid with areas of necrosis and haemorrhages.

Microscopically, yolk sac tumour has the following features (Fig. 21.7):

1. The tumour cells form a variety of *patterns*—loose reticular network, papillary, tubular and solid arrangement.
2. The *tumour cells* are flattened to cuboid epithelial cells with clear vacuolated cytoplasm.
3. The tumour cells may form distinctive perivascular structures resembling the yolk sac or endodermal sinuses of the rat placenta called *Schiller-Duval bodies*.
4. There may be presence of both intracellular and extracellular PAS-positive *hyaline globules*, many of which contain AFP.

Polyembryoma

Polyembryoma is defined as a tumour composed predominantly of embryoid bodies. Embryoid bodies are structures containing a disc and cavities surrounded by loose mesenchyme simulating an embryo of about 2 weeks' gestation.

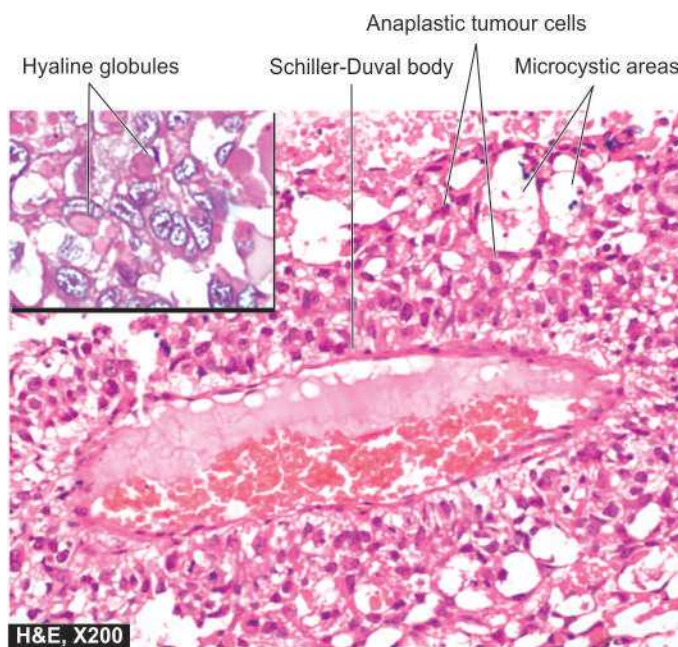

Figure 21.7 Yolk sac tumour testis. The tumour has microcystic pattern and has highly anaplastic tumour cells. Several characteristic Schiller-Duval bodies are present. Inset shows intra- and extracellular hyaline globules.

Polyembryoma is extremely rare but embryoid bodies may be present with embryonal carcinoma and teratoma.

Choriocarcinoma

Pure choriocarcinoma is a highly malignant tumour composed of elements consisting of syncytiotrophoblast and cytotrophoblast.

However, pure form is extremely rare and occurs more often in combination with other germ cell tumours. The patients are generally in their 2nd decade of life. The primary tumour is usually small and the patient may manifest initially with symptoms of metastasis. The serum and urinary levels of hCG are greatly elevated in 100% cases.

MORPHOLOGIC FEATURES *Grossly*, the tumour is usually small and may appear as a soft, haemorrhagic and necrotic mass.

Microscopically, the characteristic feature is the identification of intimately related syncytiotrophoblast and cytotrophoblast without formation of definite placental-type villi.

- i) *Syncytiotrophoblastic cells* are large with many irregular and bizarre nuclei and abundant eosinophilic vacuolated cytoplasm which stains positively for hCG. These cells often surround masses of cytotrophoblastic cells.
- ii) *Cytotrophoblastic cells* are polyhedral cells which are more regular and have clear or eosinophilic cytoplasm with hyperchromatic nuclei.

Teratoma

Teratomas are complex tumours composed of tissues derived from more than one of the three germ cell layers—endoderm, mesoderm and ectoderm. Testicular teratomas are more common in infants and children and constitute about 40% of testicular tumours in infants, whereas in adults they comprise 5% of all germ cell tumours. However, teratomas are found in combination with other germ cell tumours (most commonly with embryonal carcinoma) in about 45% of mixed germ cell tumours. About half the teratomas have elevated hCG or AFP levels or both.

MORPHOLOGIC FEATURES Testicular teratomas are classified into 3 types:

1. Mature (differentiated) teratoma
2. Immature teratoma
3. Teratoma with malignant transformation.

Grossly, most teratomas are large, grey-white masses enlarging the involved testis. Cut surface shows characteristic variegated appearance—grey-white solid areas, cystic and honey-combed areas, and foci of cartilage and bone (Fig. 21.8). Dermoid tumours commonly seen in the ovaries are rare in testicular teratomas.

Microscopically, the three categories of teratomas show different appearances:

- 1. Mature (differentiated) teratoma** Mature teratoma is composed of disorderly mixture of a variety of well-differentiated structures such as cartilage, smooth muscle, intestinal and respiratory epithelium, mucus glands, cysts lined by squamous and transitional epithelium, neural

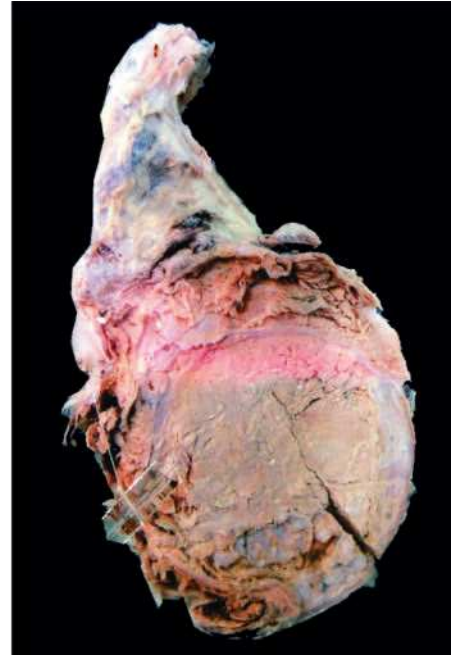

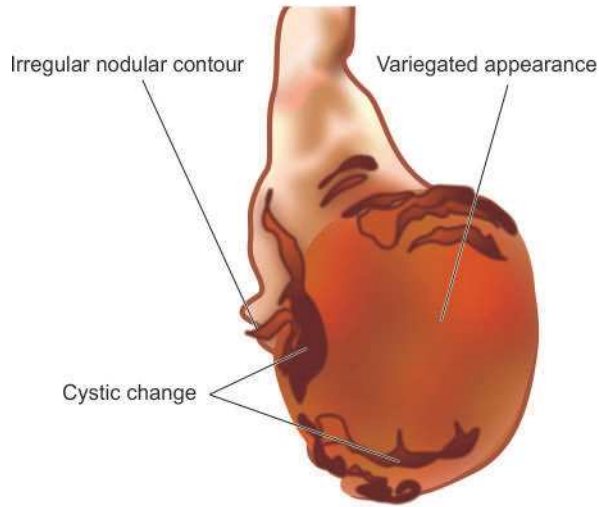

Figure 21.8 Immature teratoma testis. The testis is enlarged and nodular distorting the testicular contour. Sectioned surface shows replacement of the entire testis by variegated mass having grey-white solid areas, cystic areas, honey-combed areas and foci of cartilage and bone.

tissue, fat and bone. This type of mature or differentiated teratoma is the most common, seen more frequently in infants and children and has favourable prognosis. However, similar mature and benign-appearing tumour in adults is invariably associated with small hidden foci of immature elements so that their clinical course in adults is unpredictable. It is believed that *all testicular teratomas in the adults are malignant*.

As mentioned earlier, dermoid cysts similar to those of the ovary are rare in the testis.

2. Immature teratoma Immature teratoma is composed of incompletely differentiated and primitive or embryonic tissues along with some mature elements (**Fig. 21.9**). Primitive or embryonic tissue commonly present are poorly-formed cartilage, mesenchyme, neural tissues, abortive eye, intestinal and respiratory tissue elements etc. Mitoses are usually frequent.

3. Teratoma with malignant transformation This is an extremely rare form of teratoma in which one or more of the tissue elements show malignant transformation. Such malignant change resembles morphologically with typical malignancies in other organs and tissues and commonly includes rhabdomyosarcoma, squamous cell carcinoma and adenocarcinoma.

Mixed Germ Cell Tumours

About 60% of germ cell tumours have more than one of the above histologic types (except spermatocytic seminoma) and are called mixed germ cell tumours. The clinical behaviour of these tumours is worsened by inclusion of more aggressive tumour component in a less malignant tumour. Interestingly, metastases of the mixed germ cell tumours may not exactly reproduce the histologic types present in the primary tumour.

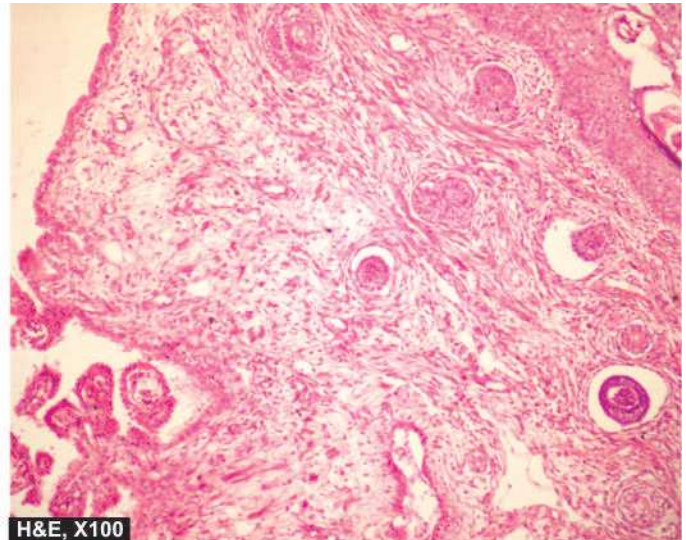

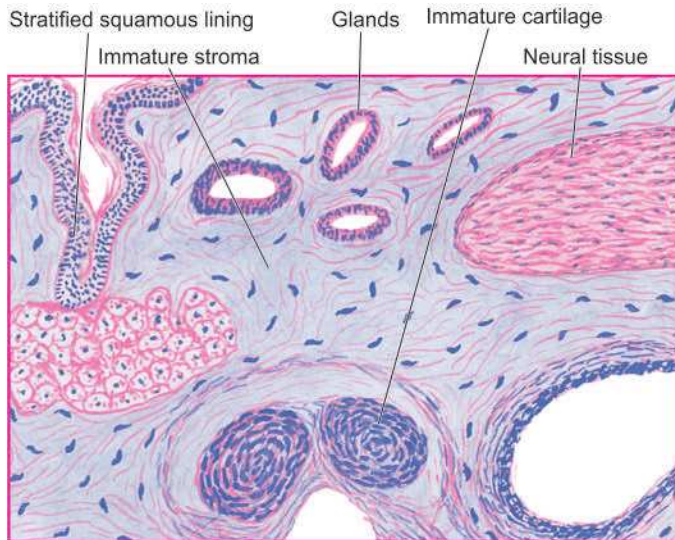

Figure 21.9 Immature teratoma testis. Microscopy shows a variety of incompletely differentiated tissue elements.

The most common combinations of mixed germ cell tumours are as under:

1. Teratoma, embryonal carcinoma, yolk sac tumour and syncytiotrophoblast.
2. Embryonal carcinoma and teratoma (teratocarcinoma).
3. Seminoma and embryonal carcinoma.

SEX CORD-STROMAL TUMOURS

Tumours arising from specialised gonadal stroma are classified on the basis of histogenesis. The primitive mesenchyme which forms the specialised stroma of gonads in either sex gives rise to theca, granulosa and lutein cells in the female, and Sertoli and interstitial Leydig cells in the male. Since the cell of origin of primitive mesenchyme is identical, Sertoli and interstitial Leydig cell tumours may also occur in the ovaries (in addition to theca cell, granulosa cell and lutein cell tumours). Likewise, the latter three tumours may occur in the testis (in addition to Sertoli cell and Leydig cell tumours). All these tumours secrete various hormones. The biologic behaviour of these tumours generally cannot be determined on histological grounds alone but is related to clinical parameters and hormonal elaboration by these tumours.

Leydig (Interstitial) Cell Tumour

Leydig cell tumours are quite uncommon. They may occur at any age but are more frequent in the age group of 20 to 50 years. Characteristically, these cells secrete androgen, or both androgen and oestrogen, and rarely corticosteroids. Bilateral tumours may occur typically in congenital adrenogenital syndrome.

MORPHOLOGIC FEATURES *Grossly*, the tumour appears as a small, well-demarcated and lobulated nodule. Cut surface is homogeneously yellowish or brown.

Histologically, the tumour is composed of sheets and cords of normal-looking Leydig cells. These cells contain abundant eosinophilic cytoplasm and Reinke's crystals and a small central nucleus.

Most of Leydig cell tumours are benign. Only about 10% may invade and metastasise.

Sertoli Cell Tumours (Androblastoma)

Sertoli cell tumours correspond to arrhenoblastoma of the ovary. They may occur at all ages but are more frequent in infants and children. These tumours may elaborate oestrogen or androgen and may account for gynaecomastia in an adult, or precocious sexual development in a child.

MORPHOLOGIC FEATURES *Grossly*, the tumour is fairly large, firm, round, and well circumscribed. Cut surface of the tumour is yellowish or yellow-grey.

Microscopically, Sertoli cell tumour is composed of benign Sertoli cells arranged in well-defined tubules.

Majority of Sertoli cell tumours are benign but about 10% may metastasise to regional lymph nodes.

Granulosa Cell Tumour

This is an extremely rare tumour in the testis and resembles morphologically with its ovarian counterpart (page 738).

MIXED GERM CELL-SEX CORD STROMAL TUMOURS

An example of combination of both germ cells and sex cord stromal components is gonadoblastoma.

Gonadoblastoma

Dysgenetic gonads and undescended testis are predisposed to develop such combined proliferations of germ cells and sex cord-stromal elements. The patients are commonly intersexuals, particularly phenotypic females. Most of the gonadoblastomas secrete androgen and therefore produce virilisation in female phenotype. A few, however, secrete oestrogen.

MORPHOLOGIC FEATURES *Grossly*, the tumour is of variable size, yellowish-white and soft.

Microscopically, gonadoblastoma is composed of 2 principal cell types—large germ cells resembling seminoma cells, and small cells resembling immature Sertoli, Leydig and granulosa cells. Call-Exner bodies of a granulosa cell tumour may be present.

Prognosis largely depends upon the malignant potential of the type of germ cell components included.

OTHER TUMOURS

Malignant Lymphoma

Malignant lymphomas comprises 5% of testicular malignancies and is the most common testicular tumour in the elderly. Bilaterality is seen in half the cases. Most common are large cell non-Hodgkin's lymphoma of B cell type.

Rare Tumours

In addition to the testicular tumours described above, some other uncommon tumours in this location include: plasmacytoma, leukaemic infiltration, carcinoid tumour, haemangioma, primary sarcomas and metastatic tumours.

GIST BOX 21.2 Testicular Tumours

- ☐ Testicular tumours are divided into 3 groups: germ cell tumours (95%), sex cord-stromal tumours (~5%) and mixed forms (rare).
- ☐ Cryptorchidism and dysgenetic gonads are implicated in the etiology of testicular tumours.
- ☐ AFP and hCG are commonly used as tumour markers in their diagnosis, staging and monitoring.
- ☐ Testicular tumours may spread by lymphatic and haematogenous route.
- ☐ Seminoma is the commonest malignant tumour of the testis; spermatocytic seminoma is a variant with better prognosis.
- ☐ Teratomas are composed of tissues derived from three germ cell layers—endoderm, mesoderm and ectoderm. They may be mature, immature and with malignant change.
- ☐ Other primary germ cell tumors are yolk sac tumour seen in children, embryonal carcinoma in young adults and choriocarcinoma, a highly malignant tumour.
- ☐ Leydig cell, Sertoli cell and granular cell tumours are uncommon sex-cord stromal tumours.

NORMAL STRUCTURE

The penis is covered by skin, foreskin (prepuce) and stratified squamous mucosa. The structure of penis consists of 3 masses of erectile tissue—two corpora cavernosa, one on each side dorsally, and the corpus spongiosum ventrally through which the urethra passes. The expanded free end of the corpus spongiosum forms the glans.

The lumen of the urethra in sectioned surface of the penis appears as an irregular cleft in the middle of the corpus spongiosum. In the prostatic part, it is lined by transitional epithelium, but elsewhere it is lined by columnar epithelium except near its orifice where stratified squamous epithelium lines it.

DEVELOPMENTAL AND INFLAMMATORY DISORDERS

Glans and prepuce are frequently involved in inflammation in a number of specific and non-specific conditions. The specific inflammations include various sexually-transmitted diseases such as hard chancre in syphilis, chancroid caused by *Haemophilus ducreyi*, gonorrhoea caused by gonococci, herpes progeneralis, granuloma inguinale (donovanosis), and lymphopathia venereum caused by *Chlamydia trachomatis*.

PHIMOSIS

Phimosis is a condition in which the prepuce is too small to permit its normal retraction behind the glans. It may be congenital or acquired. *Congenital phimosis* is a developmental anomaly whereas *acquired phimosis* may result from inflammation, trauma or oedema leading to narrowing of preputial opening. In either case, phimosis interferes with cleanliness and predisposes to the development of secondary infection, preputial calculi and squamous cell carcinoma.

Paraphimosis is a condition in which the phimotic prepuce is forcibly retracted resulting in constriction over the glans penis and subsequent swelling.

HYPOSPADIAS AND EPISPADIAS

Hypospadias is a developmental defect of the urethra in which the urethral meatus fails to reach the end of the penis, but instead, opens on the ventral surface of the penis. Similar developmental defect with resultant urethral opening on the dorsal surface of the penis is termed *epispadias*. Hypospadias and epispadias may cause urethral constriction with consequent infection and may also interfere with normal ejaculation and insemination. Both these urethral anomalies are more frequently associated with cryptorchidism.

BALANOPOSTHITIS

Balanoposthitis is the term used for non-specific inflammation of the inner surface of the prepuce (*balanitis*) and adjacent surface of the glans (*posthitis*). It is caused by a variety of microorganisms such as staphylococci, streptococci, coliform bacilli and gonococci. Balanoposthitis usually results from lack of cleanliness resulting in accumulation of secretions and smegma. It is a common accompaniment of phimosis. The

type of inflammation may be acute or chronic, sometimes with ulceration on the mucosal surface of the glans.

BALANITIS XEROTICA OBLITERANS

Balanitis xerotica obliterans is a white atrophic lesion on the glans penis and the prepuce and is a counterpart of the *lichen sclerosus et atrophicus* in the vulva described on page 710.

TUMOURS

Benign and malignant tumours as well as certain premalignant lesions may occur on the penis.

BENIGN TUMOURS

Condyloma Acuminatum

Condyloma acuminatum or anogenital wart is a benign tumour caused by human papilloma virus (HPV) types 6 and 11. The tumour may occur singly, or there may be conglomerated papillomas. A more extensive, solitary, exophytic and cauliflower-like warty mass is termed *giant condyloma* or *Buschke-Löwenstein tumour* or *verrucous carcinoma*.

MORPHOLOGIC FEATURES The condyloma is commonly located on the coronal sulcus on the penis or the perineal area.

Grossly, the tumour consists of solitary or multiple, warty, cauliflower-shaped lesions of variable size with exophytic growth pattern.

Histologically, the lesions are essentially like common warts (*verruca vulgaris*). The features include formation of papillary villi composed of connective tissue stroma and covered by squamous epithelium which shows hyperkeratosis, parakeratosis, and hyperplasia of prickle cell layer. Many of the prickle cells show clear vacuolisation of the cytoplasm (*koilocytosis*) indicative of HPV infection.

Giant condyloma shows upward as well as downward growth of the tumour but is otherwise histologically identical to condyloma acuminatum. Though histologically benign, clinically the giant condyloma is associated with recurrences and behaves as intermediate between truly benign condyloma acuminatum and squamous cell carcinoma.

PREMALIGNANT LESIONS (CARCINOMA IN SITU)

In the region of external male genitalia, three lesions display cytological changes of malignancy confined to epithelial layers only without evidence of invasion. These conditions are: Bowen's disease, erythroplasia of Queyrat and bowenoid papulosis.

Bowen's Disease

Bowen's disease is located on the shaft of the penis and the scrotum besides the sun-exposed areas of the skin (page 773).

Grossly, it appears as a solitary, circumscribed plaque lesion with ulceration.

Histologically, the changes are superficial to the dermo-epidermal border. The epithelial cells of the epidermis show hyperplasia, hyperkeratosis, parakeratosis and scattered bizarre dyskeratotic cells.

A fair proportion of cases of Bowen's disease are associated with internal visceral cancers.

Erythroplasia of Queyrat

The lesions of erythroplasia of Queyrat appear on the penile mucosa.

Grossly, the lesions are pink, shiny and velvety soft.

Histologically, the thickened and acanthotic epidermis shows variable degree of dysplasia.

Unlike Bowen's disease, there is no relationship between erythroplasia of Queyrat and internal malignancy.

Bowenoid Papulosis

The lesions of bowenoid papulosis appear on the penile shaft and adjacent genital skin.

Grossly, they are solitary or multiple, shiny, red-brown papular lesions.

Histologically, there is orderly maturation of epithelial cells in hyperplastic epidermis with scattered hyperchromatic nuclei and dysplastic cells.

MALIGNANT TUMOURS

Squamous Cell Carcinoma

The incidence of penile carcinoma shows wide variation in different populations. In the United States, the overall incidence of penile cancer is less than 1% of all cancers in males but it is 3-4 times more common in blacks than in whites. In some Asian, African and Latin American countries, its incidence is about 10% of all cancers. Relationship of penile cancer with HPV has been well supported; high-risk HPV types 16 and 18 are strongly implicated and their DNA has been documented in the nuclei of malignant cells. Carcinoma of the penis is quite rare in Jews and Muslims who undergo a ritual of circumcision early in life. In India, cancer of the penis is rare in Muslims who practice circumcision as a religious rite in infancy, whereas Hindus who are normally not circumcised have a

higher incidence. Circumcision provides protection against penile cancer due to prevention of accumulation of smegma which is believed to be carcinogenic. The greatest incidence of penile cancer is between 45 and 60 years.

MORPHOLOGIC FEATURES **Grossly**, the tumour is located, in decreasing frequency, on frenum, prepuce, glans and coronal sulcus. The tumour may be cauliflower-like and papillary, or flat and ulcerating (**Fig. 21.10**).

Histologically, squamous cell carcinoma of both fungating and ulcerating type is generally well differentiated to moderately-differentiated type which resembles in morphology to similar cancer elsewhere in the body (**Fig. 21.11**).

The tumour metastasises via lymphatics to regional lymph nodes. Visceral metastases by haematogenous route are uncommon and occur in advanced cases only.

GIST BOX 21.3 Diseases of Penis

- ☐ Phimosis in which there is narrowed preputial opening, and hypospadias in which urethral meatus opens on the ventral surface of the penis, are developmental anomalies.
- ☐ Balanoposthitis is inflammation of the inner surface of the prepuce (balanitis) and adjacent surface of the glans (posthitis).
- ☐ Balanitis xerotica obliterans is a white atrophic lesion on the glans penis and the prepuce.
- ☐ Penile tumours may be benign (e.g. condyloma acuminatum), few premalignant conditions (Bowen's disease, bowenoid papulosis) and squamous cell carcinoma.

PROSTATE

NORMAL STRUCTURE

The prostate gland in the normal adult weighs approximately 20 gm. It surrounds the commencement of the male urethra and is composed of 5 lobes during embryonic development—

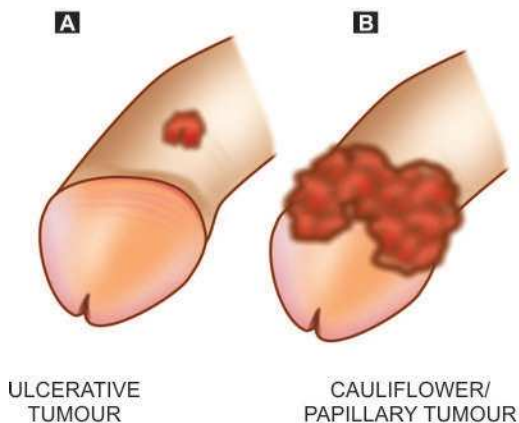

Figure 21.10 Carcinoma of the penis. Diagrammatic representation of flat-ulcerating (A) and cauliflower papillary (B) patterns of growth at common locations. C, Amputated specimen of the penis shows a cauliflower growth on the coronal sulcus (arrow). The surface of the growth is ulcerated and is chalky-white in appearance.

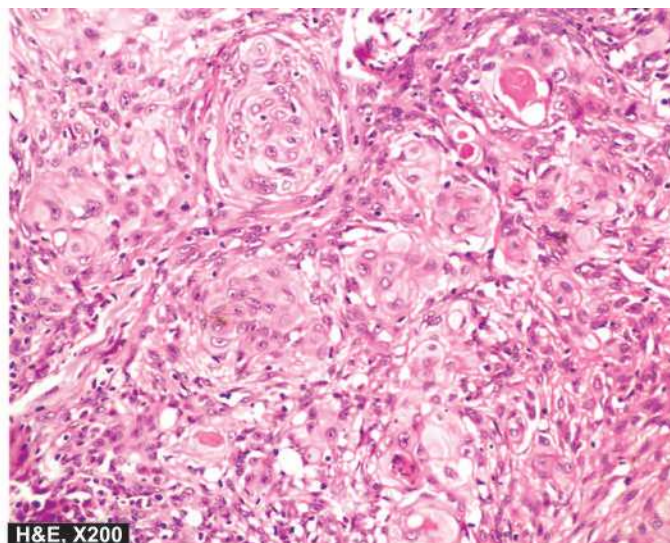

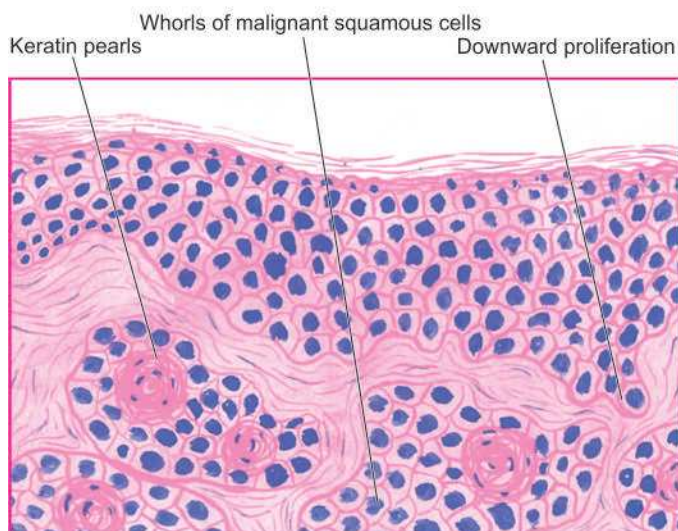

Figure 21.11 Squamous cell carcinoma penis. Microscopy shows whorls of malignant squamous cells with central keratin pearls.

anterior, middle, posterior and two lateral lobes. But at birth, the five lobes fuse to form 3 distinct lobes—two major lateral lobes and a small median lobe (**Fig. 21.12,A**).

Histologically, the prostate is composed of tubular alveoli (acini) embedded in fibromuscular tissue mass. The glandular epithelium forms infoldings and consists of 2 layers—a basal layer of low cuboidal cells and an inner layer of mucus-secreting tall columnar cells. The alveoli are separated by thick fibromuscular septa containing abundant smooth muscle fibres.

The prostate has numerous blood vessels and nerves. In addition to nervous control, the prostate is an endocrine-dependent organ. Based on hormonal responsiveness, the prostate is divided into 2 separate parts:

1. *Inner periurethral female part* which is sensitive to oestrogen and androgen.
2. *Outer subcapsular true male part* which is sensitive to androgen.

Prostate is involved in 3 important pathologic processes: prostatitis, nodular hyperplasia and carcinoma. While benign nodular hyperplasia occurs in the periurethral part distorting and compressing the centrally located urethral lumen, the prostatic carcinoma usually arises from the outer

subcapsular part in which case it does not compress the urethra (**Figs. 21.12, B, C**).

PROSTATITIS

Inflammation of the prostate or prostatitis may be acute, chronic and granulomatous types. Acute or chronic prostatitis may superimpose on nodular hyperplasia.

ACUTE PROSTATITIS

Acute focal or diffuse suppurative inflammation of the prostate is not uncommon. It occurs most commonly due to ascent of bacteria from the urethra, less often by descent from the upper urinary tract or bladder, and occasionally by lymphogenous or haematogenous spread from a distant focus of infection. The infection may occur spontaneously or may be a complication of urethral manipulation such as by catheterisation, cystoscopy, urethral dilatation and surgical procedures on the prostate. The common pathogens are those which cause UTI, most frequently *E. coli*, and others such as *Klebsiella*, *Proteus*, *Pseudomonas*, *Enterobacter*, gonococci, staphylococci and streptococci. The diagnosis is made by culture of urine specimen.

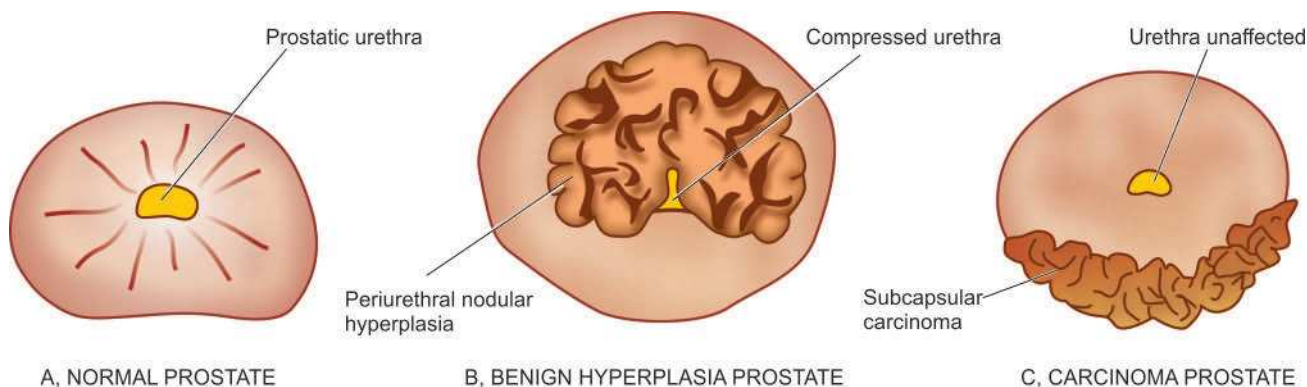

Figure 21.12 Normal prostate, benign nodular hyperplasia and prostatic carcinoma. The nodule in case of benign nodular hyperplasia (B) is located in the inner periurethral part and compresses the prostatic urethra while prostatic carcinoma (C) generally arises in the peripheral glands and, thus, does not compress the urethra.

MORPHOLOGIC FEATURES *Grossly*, the prostate is enlarged, swollen and tense. Cut section shows multiple abscesses and foci of necrosis.

Histologically, the prostatic acini are dilated and filled with neutrophilic exudate. There may be diffuse acute inflammatory infiltrate. Oedema, hyperaemia and foci of necrosis frequently accompany acute inflammatory involvement.

CHRONIC PROSTATITIS

Chronic prostatitis is more common and foci of chronic inflammation are frequently present in the prostate of men above 40 years of age. Chronic prostatitis is usually asymptomatic but may cause allergic reactions, iritis, neuritis or arthritis.

Chronic prostatitis is of 2 types—bacterial and abacterial.

◆ **Chronic bacterial prostatitis** is caused in much the same way and by the same organisms as the acute prostatitis. It is generally a consequence of recurrent UTI. Diagnosis is made by detection of more than 10-12 leucocytes per high power field in expressed prostatic secretions, and by positive culture of urine specimen and prostatic secretions. This condition is more difficult to treat since antibiotics penetrate the prostate poorly.

◆ **Chronic abacterial prostatitis** is more common. There is no history of recurrent UTI and culture of urine and prostatic secretions is always negative, though leucocytosis is demonstrable in prostatic secretions. The pathogens implicated are *Chlamydia trachomatis* and *Ureaplasma urealyticum*.

MORPHOLOGIC FEATURES Pathologic changes in both bacterial and abacterial prostatitis are similar.

Grossly, the prostate may be enlarged, fibrosed and shrunken.

Histologically, the diagnosis of chronic prostatitis is made by foci of lymphocytes, plasma cells, macrophages and neutrophils within the prostatic substance. Corpora amylacea, prostatic calculi and foci of squamous metaplasia in the prostatic acini may accompany inflammatory changes. Seminal vesicles are invariably involved.

GRANULOMATOUS PROSTATITIS

Granulomatous prostatitis is a variety of chronic prostatitis, probably caused by leakage of prostatic secretions into the tissue, or could be of autoimmune origin.

MORPHOLOGIC FEATURES *Grossly*, the gland is firm to hard, giving the clinical impression of prostatic carcinoma on rectal examination.

Histologically, the inflammatory reaction consists of macrophages, lymphocytes, plasma cells and some multinucleate giant cells. The condition may be confused with tuberculous prostatitis.

NODULAR HYPERPLASIA

Non-neoplastic tumour-like enlargement of the prostate, commonly termed benign nodular hyperplasia (BNH) or

benign enlargement of prostate (BEP), is a very common condition in men and considered by some as normal ageing process. It becomes increasingly more frequent above the age of 50 years and its incidence approaches 75-80% in men above 80 years. However, symptomatic BEP producing urinary tract obstruction and requiring surgical treatment occurs in 5-10% of cases only.

ETIOLOGY The cause of BEP has not been fully established. However, a few etiologic factors such as *endocrinologic*, *racial*, *inflammation* and *arteriosclerosis* have been implicated but endocrine basis for hyperplasia has been more fully investigated and considered a strong possibility in its genesis. It has been found that both sexes elaborate androgen and oestrogen, though the level of androgen is high in males and that of oestrogen is high in females. With advancing age, there is decline in the level of androgen and a corresponding rise of oestrogen in the males. The periurethral inner prostate which is primarily involved in BEP is responsive to the rising level of oestrogen, whereas the outer prostate which is mainly involved in the carcinoma is responsive to androgen. A plausible hypothesis suggested is that there is synergistic stimulation of the prostate by both hormones—the *oestrogen* acting to sensitise the prostatic tissue to the growth promoting effect of *dihydroxy-testosterone* derived from plasma testosterone.

MORPHOLOGIC FEATURES *Grossly*, the enlarged prostate is nodular, smooth and firm and weighs 2-4 times its normal weight i.e. may weigh up to 40-80 gm. The appearance on cut section varies depending upon whether the hyperplasia is predominantly of the glandular or fibromuscular tissue (**Fig. 21.13**). In *primarily glandular BEP* the tissue is yellow-pink, soft, honey-combed, and milky fluid exudes, whereas in *mainly fibromuscular BEP* the cut surface is firm, homogeneous and does not exude milky fluid. The hyperplastic nodule forms a mass mainly in the inner periurethral prostatic gland so that the surrounding prostatic tissue forms a false capsule which

Figure 21.13 Nodular enlargement of the prostate. Sectioned surface of enlarged prostate shows soft to firm, grey-white, nodularity with microcystic areas.

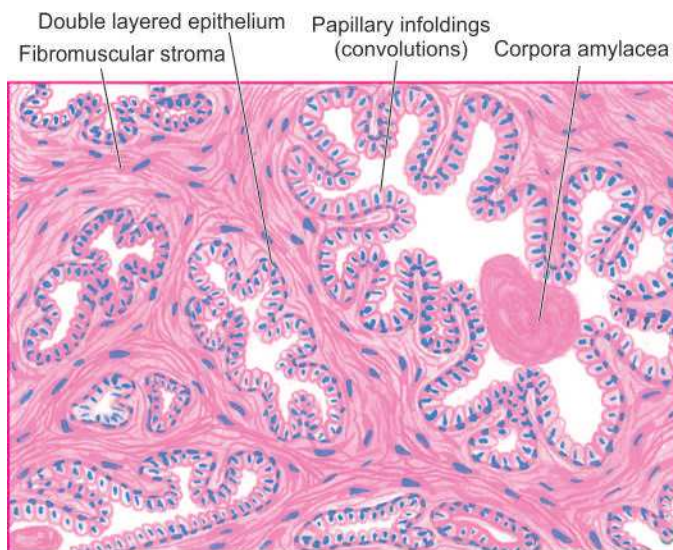

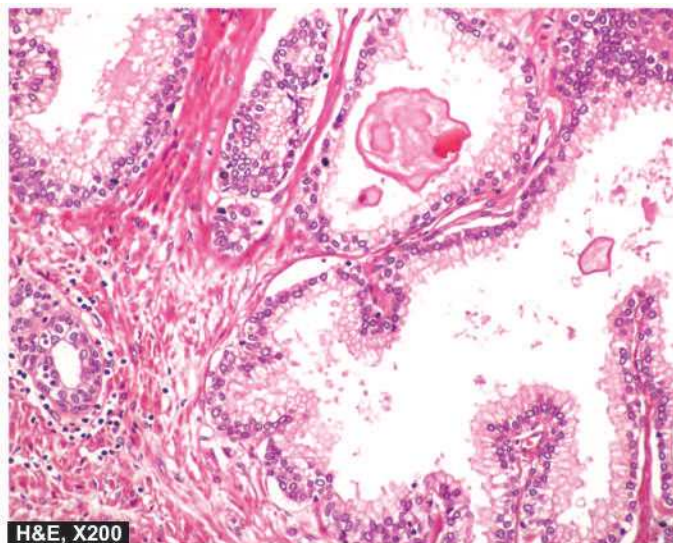

Figure 21.14 Nodular hyperplasia of the prostate. There is hyperplasia of fibromuscular elements. There are areas of intra-acinar papillary infoldings (convolutions) lined by two layers of epithelium with basal polarity of nuclei.

enables the surgeon to enucleate the nodular masses. The left-over peripheral prostatic tissue may sometimes undergo recurrent nodular enlargement or may develop carcinoma later.

Histologically, in every case, there is hyperplasia of all three tissue elements in varying proportions—glandular, fibrous and muscular (**Fig. 21.14**):

◆ **Glandular hyperplasia** predominates in most cases and is identified by exaggerated intra-acinar papillary infoldings with delicate fibrovascular cores. The lining epithelium is two-layered: the inner tall columnar mucus-secreting with poorly-defined borders, and the outer cuboidal to flattened epithelium with basal nuclei.

◆ **Fibromuscular hyperplasia** when present as dominant component appears as aggregates of spindle cells forming an appearance akin to fibromyoma of the uterus.

In addition to glandular and/or fibromuscular hyperplasia, other histologic features frequently found include foci of lymphocytic aggregates, small areas of infarction, corpora amylacea and foci of squamous metaplasia.

CLINICAL FEATURES Clinically, the symptomatic cases develop symptoms due to complications such as urethral obstruction and secondary effects on the bladder (e.g. hypertrophy, cystitis), ureter (e.g. hydroureter) and kidneys (e.g. hydronephrosis). The presenting features include frequency, nocturia, difficulty in micturition, pain, haematuria and sometimes, the patients present with acute retention of urine requiring immediate catheterisation.

CARCINOMA OF PROSTATE

Cancer of the prostate is the second most common form of cancer in males, followed in frequency by lung cancer. It is a disease of men above the age of 50 years and its prevalence increases with increasing age so that more than 50% of men 80 years old have asymptomatic (latent) carcinoma of the prostate. Many a times, carcinoma of the prostate is small and

detected as microscopic foci in a prostate removed for BEP or found incidentally at autopsy. Thus, it is common to classify carcinoma of the prostate into the following 4 types:

- 1. Latent carcinoma** This is found unexpectedly as a small focus of carcinoma in the prostate during autopsy studies in men dying of other causes. Its incidence in autopsies has been variously reported as 25-35%.
- 2. Incidental carcinoma** About 15-20% of prostatectomies done for BEP reveal incidental carcinoma of the prostate.
- 3. Occult carcinoma** This is the type in which the patient has no symptoms of prostatic carcinoma but shows evidence of metastases on clinical examination and investigations.
- 4. Clinical carcinoma** Clinical prostatic carcinoma is the type detected by rectal examination and other investigations and confirmed by pathologic examination of biopsy of the prostate.

ETIOLOGY The cause of prostatic cancer remains obscure. However, a few factors have been suspected. These are as under:

1. Endocrinologic factors Androgens are considered essential for development and maintenance of prostatic epithelium. But how androgens are responsible for causing malignant transformation is not yet clear. However, the etiologic role of androgens is supported by the following indirect evidences:

- Orchiectomy causes arrest of metastatic prostatic cancer disease (testis being the main source of testosterone).
- Administration of oestrogen causes regression of prostatic carcinoma.
- Cancer of the prostate is extremely rare in eunuchs and in patients with Klinefelter's syndrome.
- Cancer of the prostate begins at the stage of life when androgen levels are high. However, the cancer may remain latent with decline in androgen level with advancing age.

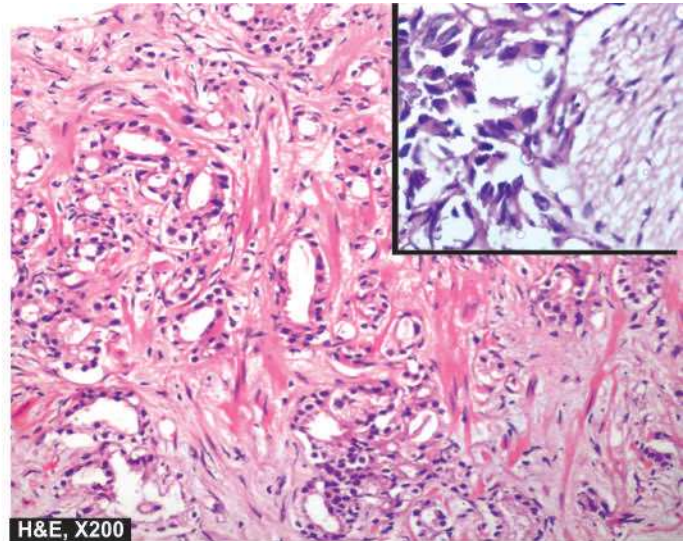

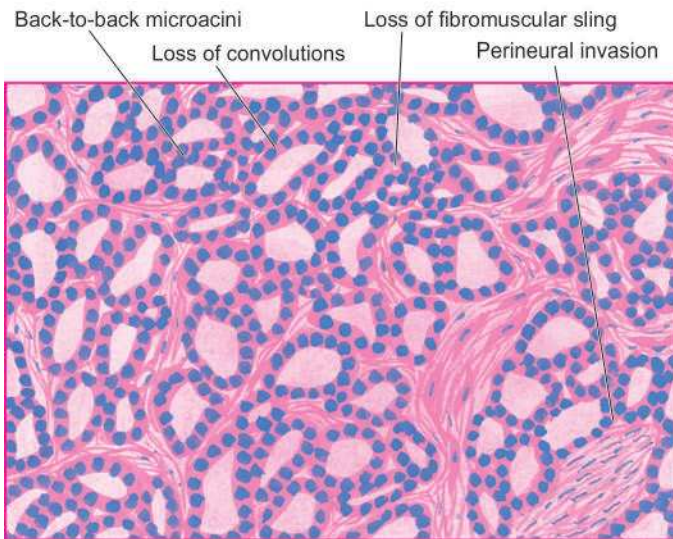

Figure 21.15 Carcinoma of the prostate. The field shows microacini of small malignant cells infiltrating the prostatic stroma. Inset in the photomicrograph shows perineural invasion by prostatic adenocarcinoma.

2. Racial and geographic influences There are some racial and geographic differences in the incidence of prostatic cancer. It is uncommon in Japanese and Chinese, while the prevalence is high in Americans. African Americans have a markedly higher incidence as compared to whites which may be related to genetic variation in androgen receptor gene.

3. Environmental influences Some common environmental factors and carcinogens have been identified with high risk to development of prostatic cancer. These include high dietary fat, and exposure to polycyclic aromatic hydrocarbons. Flavonoids, antioxidants and selenium may reduce the risk.

4. Nodular hyperplasia Though nodular prostatic hyperplasia has been suggested by some as precursor for development of prostatic cancer, it is considered unlikely. Most prostatic cancers develop in the periphery of the gland while BEP occurs in the periurethral part of the gland. Any concomitant occurrence of the two diseases may be considered as ageing process. Approximately 15-20% of nodular hyperplastic prostates harbour carcinoma.

5. Heredity The possibility of inherited polymorphism of prostatic cancer has been suggested by the observations of familial clustering and 2-fold higher frequency in first-degree relatives. Men with prostatic cancer susceptibility gene, BRCA2, have 20-times increased risk of prostatic cancer.

HISTOGENESIS Histogenesis of prostatic adenocarcinoma has been documented as a multistep process arising from premalignant stage of *prostatic intraepithelial neoplasia (PIN)*. PIN refers to multiple foci of cytologically atypical luminal cells overlying diminished number of basal cells in prostatic ducts and is a forerunner of invasive prostatic carcinoma. Based on cellular atypia, PIN may be low grade to high grade. PIN of high-grade progresses to prostatic adenocarcinoma. At genetic level, following epigenetic phenomenon and acquired somatic mutations have been reported in development of prostatic cancer:

i) *Epigenetic phenomenon*: Hypermethylation of *GSTP1* (glutathione 5-transferase) gene promoter causing loss of function of the gene that detoxifies carcinogens.

ii) *Somatic mutation*: Gene rearrangement in coding sequence of *ETS* family of transcription factor gene that places the mutated gene close to *TMPRSS2* promoter gene, resulting in formation of *TMPRSS2-ETS* fusion gene in prostatic cancer (*ETS*= E26 transformation specific; *TMPRSS2* gene= transmembrane protease serine 2 gene).

MORPHOLOGIC FEATURES *Grossly*, the prostate may be enlarged, normal in size or smaller than normal. In 95% of cases, prostatic carcinoma is located in the peripheral zone, especially in the posterior lobe. The malignant prostate is firm and fibrous. Cut section is homogeneous and contains irregular yellowish areas.

Microscopically, 4 histologic types are described—adenocarcinoma, transitional cell carcinoma, squamous cell carcinoma and undifferentiated carcinoma. However, *adenocarcinoma* is the most common type found in 96% of cases and is the one generally referred to as carcinoma of the prostate. The other three histologic types are rare and resemble in morphology with similar malignant tumours elsewhere in the body.

The histologic characteristics of adenocarcinoma of the prostate are as under (**Fig. 21.15**):

1 Architectural disturbance In contrast to convoluted appearance of the glands seen in normal and hyperplastic prostate, there is loss of intra-acinar papillary convolutions. The groups of acini are either closely packed in back-to-back arrangement without intervening stroma or are haphazardly distributed.

2. Stroma Normally, fibromuscular sling surrounds the acini, whereas malignant acini have little or no stroma between them. The tumour cells may penetrate and replace the fibromuscular stroma.

3. Gland pattern Most frequently, the glands in well-differentiated prostatic adenocarcinoma are small or medium-sized, lined by a single layer of cuboidal or low columnar cells. Moderately-differentiated tumours have cribriform or fenestrated glandular appearance. Poorly-differentiated tumours have little or no glandular arrangement but instead show solid or trabecular pattern.

4. Tumour cells The outer basal layer seen in the normal or benign acini is lost. The tumour cells may be clear, dark and eosinophilic cells. *Clear cells* have foamy cytoplasm, *dark cells* have homogeneous basophilic cytoplasm, and *eosinophilic cells* have granular cytoplasm. The cells may show varying degree of anaplasia and nuclear atypia but is generally slight.

5. Invasion One of the important diagnostic features of malignancy in prostate is the early and frequent occurrence of invasion of intra-prostatic *perineural spaces*. Lymphatic and vascular invasion may be present but are difficult to detect.

SPREAD The tumour spreads within the gland by direct extension, and to distant sites by blood and lymphatic route.

Direct spread Direct extension of the tumour occurs into the prostatic capsule and beyond. In late stage, the tumour may extend into the bladder neck, seminal vesicles, trigone and ureteral openings.

Metastases Distant spread occurs by both lymphatic and haematogenous routes. The rich lymphatic network surrounding the prostate is the main mode of spread to the sacral, iliac and para-aortic lymph nodes. The earliest metastasis occur to the obturator lymph node. Haematogenous spread leads most often to characteristic osteoblastic *osseous metastases*, especially to pelvis, and lumbar spine; other sites of metastases are lungs, kidneys, breast and brain. The route of blood-borne metastases may be retrograde spread by prostatic venous plexus or via systemic circulation.

CLINICAL FEATURES AND DIAGNOSIS In symptomatic cases, clinical features are: urinary obstruction with dysuria, frequency, retention of urine, haematuria, and in 10% of cases pain in the back due to skeletal metastases. By the time symptoms appear, the carcinoma of prostate is usually palpable on digital rectal examination (DRE) as a hard and nodular gland fixed to the surrounding tissues.

Two biochemical serum *tumour markers* employed for diagnosis and monitoring the prognosis of prostatic carcinoma are as under:

1. *Prostatic acid phosphatase (PAP)* is secreted by prostatic epithelium. Elevation of serum level of PAP is found in cases of prostatic cancer which have extended beyond the capsule or have metastasised. PAP can also be demonstrated in the normal prostatic tissues.

2. *Prostate-specific antigen (PSA)* can be detected by immunohistochemical method in the malignant prostatic epithelium as well as estimated in the serum. A reading between 4 and 10 ng/ml (normal 0-4 ng/ml) is highly suspicious (10% risk) but value above 10 is diagnostic of prostatic carcinoma. PSA assay is also helpful in distinguishing high-grade prostatic cancer from urothelial carcinoma, colonic carcinoma, lymphoma and

prostatitis. PSA level is generally higher in low-grade tumours than in high-grade tumours. PSA immunohistochemistry is useful in deciding whether the metastasis originated from the prostate or not.

The diagnosis of prostatic carcinoma can be made by clinical, biochemical, radiologic, ultrasonographic, cytologic (FNA) and histopathologic methods (core biopsy, TUR specimen, or radical prostatectomy). However, for a definite diagnosis, triple approach is most commonly followed: i) DRE, ii) serum PSA determination, and iii) transrectal ultrasound (TRUS)-guided core needle biopsy.

HISTOLOGIC GRADING AND CLINICAL STAGING Clinical staging has good correlation with histologic grading and, thus, has a prognostic significance.

Gleason's histologic grading Mostofi's (WHO) histologic grading categorising prostate cancer into grade I (well-differentiated), grade II (moderately-differentiated) and grade III (poorly-differentiated) has largely been replaced with Gleason's microscopic *grading system* which is based on two features:

- i) Degree of glandular differentiation and distribution.
- ii) Growth pattern of the tumour in relation to the stroma.

Based on above, the microscopic features are assessed by low-power examination of the prostatic tissue and two types of *scores* (primary for predominant grade and secondary for the other pattern) are assigned on a scale of 1-5. The sum total of both primary and secondary scores is expressed as a *grade* out of 10.

TNM staging For clinical staging of prostate cancer, TNM system is considered international standard. This system of staging for prostate cancer takes into account cases with abnormal PSA and findings of DRE. Based on these parameters, clinical stages of prostate cancer are given in **Table 21.3**.

Treatment of prostatic carcinoma consists of surgery, radiotherapy and hormonal therapy. The hormonal dependence of prostate cancer consists of depriving the tumour cells of growth-promoting influence of testosterone. This can be achieved by bilateral orchiectomy followed by administration of oestrogen. Surgical approaches for prostate cancer include transurethral resection (TUR), radical prostatectomy and transurethral US-guided laser-induced prostatectomy (TULIP).

Table 21.3 TNM staging of prostate cancer.

| STAGE | DESCRIPTION |
|-------|--|
| T1a | Nonpalpable, ≤5% resected tissue involved |
| T1b | Nonpalpable, >5% resected tissue involved |
| T1c | Nonpalpable, detected due to elevated PSA |
| T2a | Palpable, ≤50% of one lobe |
| T2b | Palpable, >50% of one lobe |
| T2c | Palpable, involves both lobes |
| T3a | palpable, unilateral extracapsular involvement |
| T3b | Palpable, bilateral extracapsular involvement |
| T3c | Tumour invades seminal vesicle |
| M1 | Distant metastases |

- ▣ Prostate is divided into inner periurethral female part (sensitive to oestrogen and androgen) and outer subcapsular true male part (sensitive to androgen).
- ▣ Inflammation of the prostate or prostatitis may be acute, chronic and granulomatous types.
- ▣ Nodular hyperplasia of prostate is common and involves hyperplasia of glandular, fibrous and muscular tissues in varying proportions.
- ▣ Cancer of the prostate is the second most common form of cancer in males in older age group.
- ▣ Androgens are considered essential for development and maintenance of prostatic epithelium.
- ▣ Prostatic adenocarcinoma is the most common type of prostatic cancer. It may spread directly to adjacent tissues or may metastasise, especially to bones.
- ▣ Diagnosis of prostatic cancer requires DRE, PSA determination and histopathologic examination of core needle biopsy.
- ▣ Gleason's histologic grading and TNM clinical staging are followed for assessing clinical course of prostate cancer.

CLINICAL CASE 22

A 25 years old man complains of enlargement of right testis for about one month without history of antecedent trauma. In personal history, he is a non-smoker and non-alcoholic.

On local examination, there is a 5 cm firm, single, non-tender, testicular mass inside the right scrotum. The swelling is negative for transillumination. Regional lymph nodes are not palpable.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 912 (Appendix II)

22

The Female Genital Tract

VULVA

NORMAL STRUCTURE

The vulva consists of structures of ectodermal origin—labia majora, labia minora, mons pubis, clitoris, vestibule, hymen, Bartholin's glands and minor vestibular glands. The mons pubis and labia majora are covered externally by skin with hair follicles, sebaceous glands and sweat glands including apocrine glands. The inner surface of labia majora, labia minora and vestibule are covered by stratified squamous epithelium. The clitoris is made up of vascular erectile tissue. Bartholin's or vulvovaginal glands are located one on each side of the mass of tissue forming labia majora. The glands are racemose type and their secretions are released during sexual excitement.

Since vulva is of ectodermal origin, the common inflammatory conditions affecting it are similar to those found on the skin generally. A few specific conditions such as Bartholin's cyst and abscess, vulvar dystrophy and certain tumours are described below.

MISCELLANEOUS CONDITIONS

BARTHOLIN'S CYST AND ABSCESS

Inflammation of Bartholin's vulvovaginal glands (Bartholin's adenitis) may occur due to bacterial infection, notably gonorrhoeal infection. Infection may be *acute* or *chronic*.

◆ **Acute Bartholin's adenitis** occurs from obstruction and dilatation of the duct by infection resulting in formation of a Bartholin's abscess. The condition presents with intense pain, swelling and fluctuant mass which can be incised and drained.

Microscopic examination shows the usual appearance of acute suppurative inflammation with neutrophilic infiltration, hyperaemia, oedema and epithelial degeneration.

◆ **Chronic Bartholin's adenitis** results from a less virulent infection so that the process is slow and prolonged. Alternatively, the chronic process evolves from repeated attacks of less severe acute inflammation which may be short of abscess formation and resolves incompletely. In either case, the chronic inflammatory process terminates into fluid-filled Bartholin's cyst. The resulting cyst may be quite large, 3-5 cm in diameter and readily palpable in the perineum, but may remain asymptomatic for years.

Microscopic examination shows variable lining of the cyst varying from the transitional epithelium of the normal duct to a flattened lining because of increased intracystic pressure. The cyst wall may show chronic inflammatory infiltrate and a few mucus-secreting acini.

NON-NEOPLASTIC EPITHELIAL DISORDERS

The older nomenclature vulvar dystrophy has been replaced by more descriptive and clinically relevant term, non-neoplastic epithelial disorders of vulvar skin and mucosa of the vulva. The term is applied to chronic lesions of the vulva characterised clinically by white, plaque-like, pruritic mucosal thickenings and pathologically by disorders of epithelial growth. Clinicians often use the term '*leukoplakia*' for such white lesions. But white lesions may represent other depigmented conditions as well such as vitiligo, inflammatory dermatoses, carcinoma *in situ*, Paget's disease, or even invasive carcinoma, and thus use of the term leukoplakia by pathologists is not recommended.

Currently, non-neoplastic epithelial disorders of the skin of vulva includes following 2 lesions:

1. Lichen sclerosus (older term: atrophic dystrophy).
2. Squamous hyperplasia or keratosis (older term: hyperplastic dystrophy, or lichen simplex chronicus).

The two types of lesions may coexist in the same patient called *mixed vulvar dystrophy*.

Lichen Sclerosus

Lichen sclerosus may occur anywhere in the skin (page 766) but is more common and more extensive in the vulva in post-menopausal women. The lesions appear as multiple, small, coalescent, yellowish-blue macules or papules which produce thin and shiny parchment-like skin. The lesions may extend from vulva onto the perianal and perineal area. Clinically, the patient, usually a post-menopausal woman, complains of intense pruritus which may produce excoriation of the affected skin. Eventually, there is progressive shrinkage and atrophy resulting in narrowing of the introitus, clinically referred to as *kraurosis vulvae*.

MORPHOLOGIC FEATURES Microscopically, the following characteristics are seen (**Fig. 22.1,A**):

1. Hyperkeratosis of the surface layer.
2. Thinning of the epidermis with disappearance of rete ridges.
3. Amorphous homogeneous degenerative change in the dermal collagen.
4. Chronic inflammatory infiltrate in the mid-dermis.

Lichen sclerosus is *not* a premalignant lesion and responds favourably to topical treatment with androgens.

Squamous Hyperplasia

Squamous hyperplasia, or simply called keratosis, is characterised by white, thickened vulvar lesions which are usually itchy. The cause is unknown but symptomatic relief results from use of topical treatment with corticosteroids.

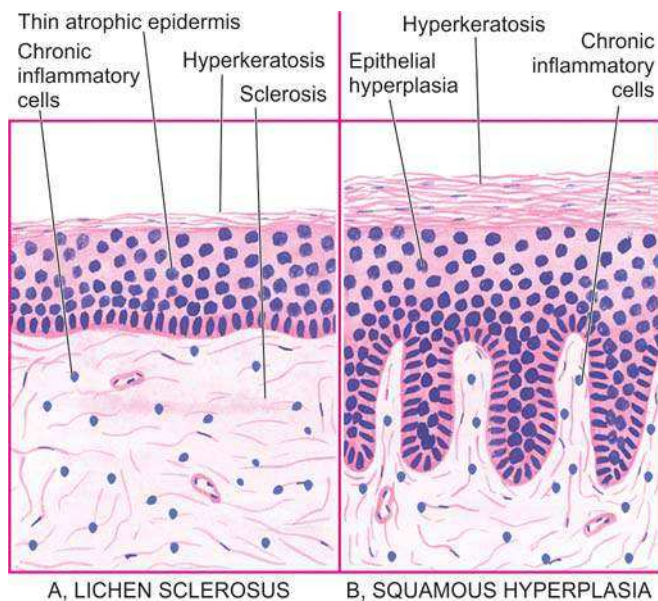

Figure 22.1 Non-neoplastic epithelial disorders of vulval skin.

MORPHOLOGIC FEATURES The histologic characteristics are as under (**Fig. 22.1,B**):

1. Hyperkeratosis.
2. Hyperplasia of squamous epithelium with elongation of rete ridges.
3. Increased mitotic activity of squamous layers but cytologically no atypia.
4. Chronic inflammatory infiltrate in the underlying dermis.

Squamous hyperplasia is not a precancerous condition. However, a variant having marked acanthosis, parakeratosis and a verruciform architecture called *vulval acanthosis with altered differentiation (VAAD)*, does not have HPV association, but may be forerunner for HPV-negative vulvar cancer.

VULVAL TUMOURS

Vulva is the site of a variety of benign and malignant neoplasms which are in common with skin neoplasms elsewhere in the body. These include papillomas, fibromas, neurofibromas, angiomas, lipomas, sweat gland tumours, squamous cell carcinoma, verrucous carcinoma, malignant melanoma and mesenchymal sarcomas. However, a few tumours peculiar to the vulva such as stromal polyps, papillary hidradenoma, condyloma acuminatum, extra-mammary Paget's disease, vulval carcinoma and intra-epithelial neoplasia are discussed below.

STROMAL POLYPS

Stromal (fibroepithelial) polyps or acrochordons may form in the vulva or vagina. There may be single or multiple polypoid masses.

Histologically, they are covered by an orderly stratified squamous epithelium. The stroma consists of loose fibrous and myxomatous connective tissue with some adipose tissue and blood vessels.

PAPILLARY HIDRADENOMA (HIDRADENOMA PAPILLIFERUM)

This is a benign tumour arising from apocrine sweat glands of the vulva. Most commonly, it is located in the labia or in the perianal region as a small sharply circumscribed nodule.

Histologically, the tumour lies in the dermis under a normal epidermis. The tumour consists of papillary structures composed of fibrovascular stalk and is covered by double layer of epithelial cells—a layer of flattened myoepithelial cells and an overlying layer of columnar cells.

CONDYLOMA ACUMINATUM

Condyloma acuminata or anogenital warts are benign papillary lesions of squamous epithelium which can be transmitted venereally to male sex partner. They may be solitary but more frequently are multiple forming soft warty masses. The common locations are the anus, perineum, vaginal wall, vulva and vagina. They are induced by human papilloma virus (HPV), particularly types 6 and 11.

Histologically, they are identical to their counterparts on male external genitalia (page 702). The features consist of a tree-like proliferation of stratified squamous epithelium, showing marked acanthosis, hyperkeratosis, parakeratosis, papillomatosis and perinuclear vacuolisation of epithelium called *koilocytosis*, indicative of HPV infection. The papillary projections consist of fibrovascular stroma.

Condylomas are benign lesions and regress spontaneously except in immunosuppressed individuals.

EXTRA-MAMMARY PAGET'S DISEASE

Paget's disease of the vulva is a rare condition which has skin manifestations like those of Paget's disease of the nipple (page 755). The affected skin, most often on the labia majora, appears as map-like, red, scaly, elevated and indurated area.

Histologically, extra-mammary Paget's disease is identified by the presence of large, pale, carcinoma cells lying singly or in small clusters within the epidermis and adnexal structures. These cells characteristically have halo which stains positively with PAS, alcian blue and mucicarmine and are thus believed to be of apocrine epithelial origin.

Unlike Paget's disease of the breast in which case there is always an underlying ductal carcinoma, extra-mammary Paget's disease is confined to the epidermis in most cases and only a small proportion of cases have an underlying adenocarcinoma. Prognosis is good if there is no invasion but occasional cases progress into invasive carcinoma.

VULVAL INTRAEPITHELIAL NEOPLASIA AND INVASIVE CARCINOMA

Vulval intraepithelial neoplasia (VIN) and invasive squamous cell carcinoma are morphologically similar to those in the cervix and vagina. The etiologic role of certain viruses in carcinogenesis, particularly high-risk HPV types 16 and 18, in these sites is well documented. VIN is often multifocal within vulva and may be multicentric as well with involvement of

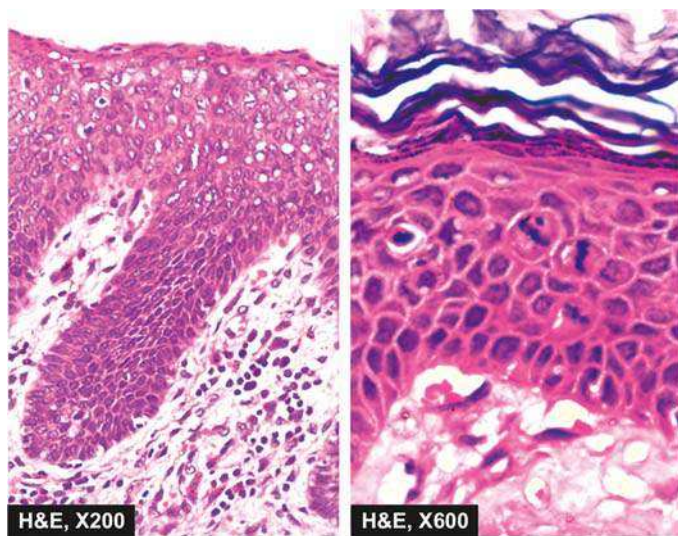

Figure 22.2 Vulval intraepithelial neoplasia (VIN) lesion (Bowen's disease). There is hyperkeratosis, parakeratosis, acanthosis, koilocytosis and presence of atypical anaplastic cells throughout the entire thickness of the epithelium. Photomicrograph on right under higher magnification shows mitotic figures in the layers of squamous epithelium.

contiguous cervix and vagina. Mention has already been made about the preceding stage of vulval epithelial disorders, particularly VAAD variant of keratosis, in the development of these lesions.

Vulval carcinoma constitutes 3% of all female genital tract cancers. While VIN occurs in reproductive age, development of vulval cancer or VIN is the 4th to 6th decade.

Grossly, VIN and vulval carcinoma in early stage is a 'white' lesion (leukoplakia) while later the area develops an exophytic or endophytic (ulcerative) growth pattern. The traditional VIN lesion, described as Bowen's disease of the vulva, is generally a slightly elevated, velvety, plaque lesion. **Microscopically**, just as in cervix, VIN may also range from VIN I to VIN III, higher grade being also called Bowen's disease (*in situ* carcinoma). Vulval cancer is squamous cell type with varying degree of anaplasia and depth of invasion depending upon the stage (**Fig. 22.2**). HPV-positive tumours are more often poorly-differentiated squamous

Table 22.1 FIGO staging of carcinoma of the vulva.

| | | |
|-------|-----|--|
| Stage | 0 | Carcinoma <i>in situ</i> . |
| Stage | I | Tumour confined to the vulva and/or perineum; 2 cm or less in diameter. |
| Stage | II | Tumour confined to the vulva and/or perineum; more than 2 cm in diameter. |
| Stage | III | Tumour of any size with (1) adjacent spread to the lower urethra and/or vagina, or the anus, and/or (2) unilateral regional lymph node metastasis. |
| Stage | IVA | Tumour invades any of the following—upper urethra, bladder mucosa, rectal mucosa, pelvic bone, and/or bilateral regional node metastasis. |
| Stage | IVB | Any distant metastasis including pelvic lymph nodes. |

cell carcinoma while HPV-negative are well-differentiated keratinising type. *Verrucous carcinoma* is a rare variant which is a fungating tumour but is locally malignant.

Clinical staging for vulval carcinoma based on tumour size (< or > 2 cm) and extent of spread has been described by International Federation of Gynaecology and Obstetrics (FIGO staging, **Table 22.1**).

GIST BOX 22.1 Diseases of Vulva

- ▣ Bartholin's adenitis is bacterial infection of Bartholin's gland and may be acute or chronic.
- ▣ Vulvar dystrophies or leukoplakias are chronic pruritic non-neoplastic epithelial disorders of vulval skin and mucosa of the vulva which may be lichen sclerosus (or atrophic dystrophy) and squamous hyperplasia (or keratosis or hyperplastic dystrophy, or lichen simplex chronicus).
- ▣ Stromal (fibroepithelial) polyps or acrochordons may form in the vulva or vagina.
- ▣ Condyloma acuminata or anogenital warts are benign papillary lesions of squamous epithelium which can be transmitted venereally to male sex partner.
- ▣ Vulval intraepithelial neoplasia (VIN) and invasive squamous cell carcinoma are morphologically similar to those in the cervix and vagina. There is etiologic role of high-risk HPV types 16 and 18 in most cases.

VAGINA

NORMAL STRUCTURE

The vagina consists of a collapsed cylinder extending between vestibule externally and the cervix internally.

Histologically, the vaginal wall consists of 3 layers: an *outer* fibrous, a *middle* muscular and an *inner* epithelial. The muscular coat has a double layer of smooth muscle. The epithelial layer consists of stratified squamous epithelium which undergoes cytologic changes under hormonal stimuli. Oestrogen increases its thickness such as during reproductive years, whereas the epithelium is thin in childhood, and atrophic after menopause when oestrogen stimulation is minimal.

Primary diseases of the vagina are uncommon. The only important clinicopathologic conditions which require to be described here are vaginitis and certain tumours.

VAGINITIS AND VULVOVAGINITIS

Since vulva and vagina are anatomically close to each other, often inflammation of one affects the other location. Certain other infections are quite common in the vulva and vagina as follows:

- i) Bacterial e.g. streptococci, staphylococci, *Escherichia coli*, *Haemophilus vaginalis*.
- ii) Fungal e.g. *Candida albicans*.
- iii) Protozoal e.g. *Trichomonas vaginalis*.
- iv) Viral e.g. Herpes simplex.

The most common causes of vaginitis are *Candida* (moniliasis) and *Trichomonas* (trichomoniasis). The hyphae of

Candida can be seen in the vaginal smears (page 892). Similarly, the protozoa, *Trichomonas*, can be identified in smears (Appendix I). These infections are particularly common in pregnant and diabetic women and may involve both vulva and vagina. However, the adult vaginal mucosa is relatively resistant to gonococcal infection because of its histology.

TUMOURS AND TUMOUR-LIKE CONDITIONS

Vaginal cysts such as Gartner's duct (Wolffian) cyst lined by glandular epithelium and vaginal inclusion cyst arising from inclusion of vaginal epithelium are more common benign vaginal tumours and tumour-like conditions. Other uncommon benign tumours are papillomas, fibromas, lipomas, angiomas and leiomyomas and resemble their counterparts elsewhere in the body. Primary malignancies of the vagina are rare and include carcinoma (squamous cell carcinoma and adenocarcinoma) and embryonal rhabdomyosarcoma (sarcoma botryoides).

CARCINOMA OF VAGINA

Primary carcinoma of the vagina is an uncommon tumour. Squamous cell dysplasia or vaginal intraepithelial neoplasia occur less frequently as compared to the cervix or vulva and can be detected by Pap smears as discussed in Appendix I. Invasive carcinoma of the vagina includes two main types:

1. Squamous cell carcinoma of vagina constitutes less than 2% of all gynaecologic malignancies and is similar in morphology as elsewhere in the female genital tract. The role of HPV types 16 and 18 in its etiology and the possibility of an extension from cervical carcinoma to the vagina have been emphasised.

2. Adenocarcinoma of the vagina is much less frequent than squamous cell carcinoma of the vagina. It may be endometrioid or mucinous type. The significance of association of diethylstilbestrol administered during pregnancy to the mother with development of adenocarcinoma of the vagina in the daughter has been discussed in neoplasia (page 200).

Clinical staging of carcinoma of vagina proposed by FIGO is given in **Table 22.2**.

EMBRYONAL RHABDOMYOSARCOMA (SARCOMA BOTRYOIDES)

This is an unusual and rare malignant tumour occurring in infants and children under 5 years of age. The common location is anterior vaginal wall. Similar tumours may occur in the urinary bladder (page 690), head and neck region (orbit, nasopharynx, middle ear, oral cavity) (page 500) and biliary tract.

MORPHOLOGIC FEATURES *Grossly*, the tumour is characterised by bulky and polypoid grape-like mass (*botryoides* = grape) that fills and projects out of the vagina.

Histologically, the features are as under:

1. Groups of round to fusiform tumour cells are characteristically lying underneath the vaginal epithelium, called *cambium layer* of tumour cells.
2. The central core of polypoid masses is composed of loose and myxoid stroma with many inflammatory cells.

The tumour invades extensively in the pelvis and metastasises to regional lymph nodes and distant sites

Table 22.2 FIGO clinical staging of carcinoma of the vagina.

| | | |
|-------|-----|---|
| Stage | 0 | Carcinoma <i>in situ</i> . |
| Stage | I | Carcinoma is limited to the vaginal wall. |
| Stage | II | Carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall. |
| Stage | III | Carcinoma has extended to the pelvic wall. |
| Stage | IV | Carcinoma has extended beyond the true pelvis or has clinically involved the mucosa of the bladder or rectum. |
| Stage | IVA | Spread of the growth to adjacent organs and/ or direct extension beyond the true pelvis. |
| Stage | IVB | Spread to distant organs. |

such as to lungs and liver. Radical surgery combined with chemotherapy offers some benefit.

GIST BOX 22.2 Diseases of Vagina

- ▣ The most common causes of vaginitis are *Candida* (moniliasis) and *Trichomonas* (trichomoniasis).
- ▣ Vaginal cysts include Gartner's duct (Wolffian) cyst lined by glandular epithelium and vaginal inclusion cyst.
- ▣ Primary cancers of the vagina are uncommon and include squamous cell carcinoma, adenocarcinoma of the vagina and embryonal rhabdomyosarcoma (sarcoma botryoides).

CERVIX

NORMAL STRUCTURE

The cervix consists of an *internal os* communicating with the endometrial cavity above, and an *external os* opening into the vagina below. *Ectocervix* (exocervix) or *portio vaginalis* is the part of the cervix exposed to the vagina and is lined by stratified squamous epithelium, whereas the endocervix is continuous with the endocervical canal and is lined by a single layer of tall columnar mucus-secreting epithelium. The endocervical mucosa is thrown into folds resulting in formation of clefts and tunnels, commonly referred to as cervical glands that secrete mucus. The junction of the ectocervix and endocervix—*junctional mucosa*, consists of gradual transition between squamous and columnar epithelia (squamo-columnar junction) and is clinically and pathologically significant landmark. The cervical mucosa undergoes changes under the influence of hormones and during pregnancy. The cervical mucus varies during the menstrual cycle, being viscus after menses, but under the influence of oestrogen becomes thin which on drying forms fern-like pattern on glass slide.

Lesions of the cervix are rather common. Of great significance are cervicitis, certain benign tumours, dysplasia, carcinoma *in situ* and invasive carcinoma.

CERVICITIS

Some degree of cervical inflammation is present in virtually all multiparous women and some nulliparous women. The normal intact ectocervical stratified epithelium is usually

more resistant to infection whereas the endocervical columnar epithelium bears the brunt of the initial inflammation.

Cervicitis may be specific or nonspecific, acute or chronic. *Specific cervicitis* may be caused by tuberculosis, syphilis, granuloma inguinale, lymphogranuloma venereum, chlamydia and chancroid. *Nonspecific cervicitis* is more frequent and is generally divided into acute and chronic forms, the latter being quite common.

ACUTE CERVICITIS

Acute cervicitis is usually associated with puerperium or gonococcal infection. Other causes are primary chancre and infection with herpes simplex.

Grossly, the cervix shows everted endocervical mucosa which is red and oedematous.

Histologically, there is infiltration of the subepithelial and periglandular tissue with neutrophils, and there is oedema and congestion. The mucosa may be ulcerated and haemorrhagic.

CHRONIC CERVICITIS

Chronic nonspecific cervicitis is encountered quite frequently and is the common cause of leucorrhoea. The most common organisms responsible for chronic cervicitis are the normal mixed vaginal flora that includes streptococci, enterococci (e.g. *E. coli*) and staphylococci. Other infecting organisms include gonococci, *Trichomonas vaginalis*, *Candida albicans* and herpes simplex. Factors predisposing to chronic cervicitis are sexual intercourse, trauma of childbirth, instrumentation and excess or deficiency of oestrogen.

Grossly, there is eversion of ectocervix with hyperaemia, oedema and granular surface. Nabothian (retention) cysts may be grossly visible from the surface as pearly grey vesicles.

Histologically, chronic cervicitis is characterised by extensive subepithelial inflammatory infiltrate of lymphocytes, plasma cells, large mononuclear cells and a few neutrophils. There may be formation of lymphoid follicles termed *follicular cervicitis*. The surface epithelium may be normal, or may show squamous metaplasia. The squamous epithelium of the ectocervix in cases of uterine prolapse may develop surface keratinisation and hyperkeratosis, so called *epidermidisation*. Areas of squamous metaplasia and hyperkeratosis may be mistaken on cursory microscopic look for a well-differentiated squamous carcinoma.

TUMOURS

Both benign and malignant tumours are common in the cervix. In addition, cervix is the site of 'shades of grey' lesions that include cervical dysplasia and carcinoma *in situ* (cervical intraepithelial neoplasia, CIN), currently termed squamous intraepithelial lesions (SIL). Benign tumours of the cervix consist most commonly of cervical polyps. Uncommon benign cervical tumours are leiomyomas, papillomas and condyloma acuminatum which resemble in morphology with similar tumours elsewhere in the genital tract. The most common malignant tumour is squamous carcinoma of the cervix.

CERVICAL POLYPS

Cervical polyps are localised benign proliferations of endocervical mucosa though they may protrude through the external os. They are found in 2-5% of adult women and produce irregular vaginal spotting.

MORPHOLOGIC FEATURES **Grossly**, cervical polyp is a small (up to 5 cm in size), bright red, fragile growth which is frequently pedunculated but may be sessile.

Microscopically, most cervical polyps are endocervical polyps and are covered with endocervical epithelium which may show squamous metaplasia. Less frequently, the covering is by squamous epithelium of the portio vaginalis. The stroma of the polyp is composed of loose and oedematous fibrous tissue with variable degree of inflammatory infiltrate and contains dilated mucus-secreting endocervical glands (**Fig. 22.3**).

MICROGLANDULAR HYPERPLASIA

Microglandular hyperplasia is a benign condition of the cervix in which there is closely packed proliferation of endocervical glands without intervening stroma. The condition is caused by progestin stimulation such as during pregnancy, postpartum period and in women taking oral contraceptives. Morphologically, condition may be mistaken for well-differentiated adenocarcinoma.

SQUAMOUS INTRAEPITHELIAL LESION (SIL) (CERVICAL INTRAEPITHELIAL NEOPLASIA, CIN)

Terminology

Presently, the terms dysplasia, CIN, carcinoma *in situ*, and SIL are used synonymously as follows:

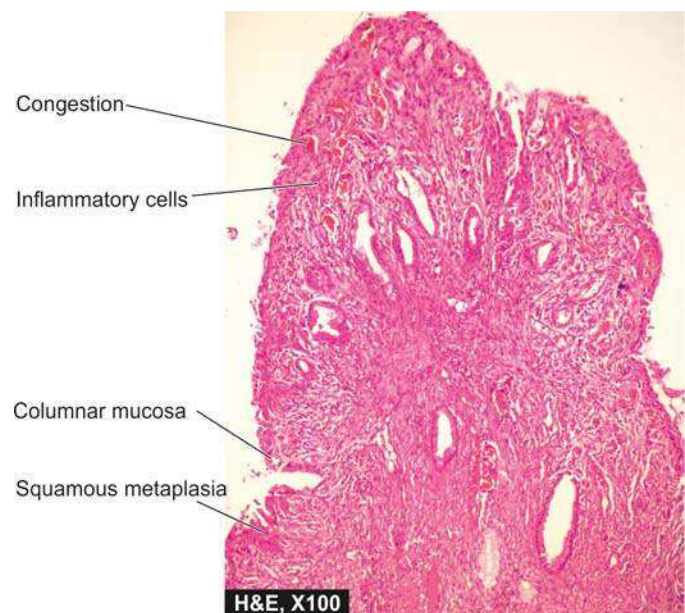

Figure 22.3 Endocervical polyp. The surface is covered by endocervical mucosa with squamous metaplasia. The stromal core is composed of dense fibrous tissue which shows nonspecific inflammation.

DYSPLASIA The term ‘dysplasia’ (meaning ‘bad moulding’) has been commonly used for atypical cytologic changes in the layers of squamous epithelium, the changes being progressive (page 41). Depending upon the thickness of squamous epithelium involved by atypical cells, dysplasia is conventionally graded as *mild*, *moderate* and *severe*. Carcinoma *in situ* is the full-thickness involvement by atypical cells, or in other words carcinoma confined to layers above the basement membrane. At times, severe dysplasia may not be clearly demarcated from carcinoma *in situ*. It is well accepted that invasive cervical cancer evolves through progressive stages of dysplasia and carcinoma *in situ*.

CIN An alternative classification is to group various grades of dysplasia and carcinoma *in situ* together into cervical intraepithelial neoplasia (CIN) which is similarly graded from grade I to III. According to this concept, the criteria are as under:

- ◆ *CIN-1* represents less than one-third involvement of the thickness of epithelium (mild dysplasia).
- ◆ *CIN-2* is one-third to two-third involvement (moderate dysplasia).
- ◆ *CIN-3* is full-thickness involvement or equivalent to carcinoma *in situ* (severe dysplasia and carcinoma *in situ*).

SIL Currently, the National Cancer Institute (NCI) of the US has proposed the *Bethesda System (TBS)* for reporting cervical and vaginal cytopathology. According to the Bethesda system, based on cytomorphologic features and HPV types implicated in their etiology, the three grades of CIN are readjusted into two grades of squamous intraepithelial lesions (SIL)—low-grade SIL (L-SIL) and high-grade SIL (H-SIL) as under:

- ◆ *L-SIL* corresponds to *CIN-1* and is a flat condyloma, having koilocytic atypia, usually related to HPV 6 and 11 infection (i.e. includes mild dysplasia and HPV infection). About 10% cases of *L-SIL* may progress to *H-SIL*.
- ◆ *H-SIL* corresponds to *CIN-2* and 3 and has abnormal pleomorphic atypical squamous cells. HPV 16 and 18 are implicated in the etiology of *H-SIL* (i.e. includes moderate dysplasia, severe dysplasia, and carcinoma *in situ*). Approximately, 10% cases of *H-SIL* may progress to invasive cervical cancer over a period of about two years.

A comparison of these classifications is shown in **Table 22.3**.

Progressive grades of dysplasia/CIN/SIL is a classical example of progression of malignancy through stepwise epithelial changes and that it can be detected early by simple Papanicolaou cytologic test (‘Pap smear’) (Appendix I). The use of Pap smear followed by colposcopy-directed biopsy confirms the diagnosis which has helped greatly in instituting early effective therapy and thus has reduced the incidence of cervical cancer in many developed countries.

CIN or SIL can develop at any age though it is rare before puberty. Low-grade reversible changes arise in young women

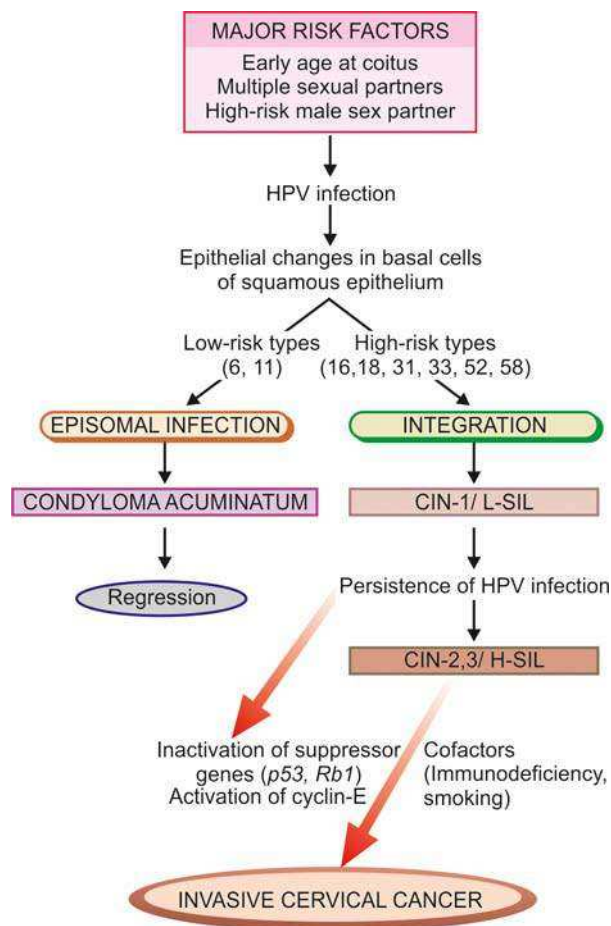

Figure 22.4 Role of human papillomavirus (HPV) in the pathogenesis of cervical neoplasia.

between 25 and 30 years of age, whereas progressively higher grades of epithelial changes develop a decade later. Hence, the desirability of periodic Pap smears on all women after they become sexually active.

Etiopathogenesis

The biology of CIN/SIL and its relationship to invasive carcinoma of the cervix is well understood by epidemiologic, virologic, molecular, immunologic and ultrastructural studies (**Fig. 22.4**):

1. Epidemiologic studies Based on epidemiology of large population of women with cervical cancer, several risk factors have been identified which include the following 4 most important factors:

- i) Women having *early age of sexual activity*.
- ii) Women having *multiple sexual partners*.

Table 22.3 Classification of cervical intraepithelial neoplasia/squamous intraepithelial lesion (CIN/SIL).

| BETHESDA SYSTEM | HPV TYPES | MORPHOLOGY | CIN | DYSPLASIA |
|-----------------|-----------|---|--------------|--|
| L-SIL | 6, 11 | Koilocytic atypia, flat condyloma | CIN-1 | Mild |
| H-SIL | 16, 18 | Progressive cellular atypia, loss of maturation | CIN-2, CIN-3 | Moderate, severe, carcinoma <i>in situ</i> |

(L-SIL = Low-grade squamous intraepithelial lesions; H-SIL = High-grade squamous intraepithelial lesion; CIN = Cervical intraepithelial neoplasia)

iii) Women with *persistent HPV infection* with high-risk types of oncogenic virus.

iv) *Potential role of high risk male sexual partner* such as promiscuous male having previous multiple sexual partners, having history of penile condyloma, or male who had previous spouse with cervical cancer.

In addition to the above factors, other epidemiologic observations reveal high incidence of cervical cancer in lower socioeconomic strata, in multiparous women, cigarette smoking women, users of oral contraceptives, HIV infection and immunosuppression, while a low incidence is noted in virgins and nuns.

2. Virologic studies Human papillomavirus (HPV) infection is strongly implicated in the etiology of cervical cancer. By recombinant DNA hybridisation techniques, following observations have been documented:

i) *High-risk type* HPV, most commonly of types 16 and 18 (in 70% cases), and less often types 31, 33, 52 and 58, are present in 70-100% cases of cervical cancer.

ii) *Low-risk type* HPV types 6 and 11 are found most frequently in condylomas.

iii) *Mixed high and low risk types* of HPV may be found in dysplasias.

Besides HPV, a few other viruses which may adversely affect the prognosis but do not have etiologic relationship are HIV, HTLV-1 and EBV infection.

3. Molecular studies Immunohistochemical, cytogenetic and molecular studies have shown that low-risk HPV types do not integrate in the host cell genome, while high-risk HPV types are integrated into the nucleus of cervical epithelial cells. Upon integration, protein product of HPV-16 and 18, E7 and E6 proteins respectively, inactivate tumour suppressor genes, *p53* and *RB-1 gene*, thus permitting uncontrolled cellular proliferation. It has been possible to document that morphologic abnormalities in cervical lesions have good correlation with underlying cellular events by use of techniques such as proliferation cell nuclear antigen (PCNA), *p16*, *p53* and *p63* expression, and nucleolar organizer region (AgNOR). However, all women who harbour HPV infection with high-risk type do not develop invasive cancer of the cervix. Women who have persistence of this infection or those who have another cofactor such as cigarette smoking or immunodeficiency, are at greater risk to develop progression of lesions.

4. Immunologic studies Circulating tumour specific antigens and antibodies are detected in patients of cervical cancer. Antibodies to virus specific antigens are identified on tumour cells and in sera of such patients.

5. Ultrastructural studies The changes observed on ultrastructural studies of cells in CIN/SIL reveal increased mitochondria and free ribosomes, and depletion of normally accumulated glycogen in the surface cells. The latter change forms the basis of *Schiller's test* in which the suspected cervix is painted with solution of iodine and potassium iodide. The cancerous focus, if present, fails to stain because of lack of glycogen in the surface cells.

MORPHOLOGIC FEATURES *Grossly*, no specific picture is associated with cellular atypia found in dysplasias or carcinoma *in situ* except that the changes begin at the squamocolumnar junction or transitional zone. The diagnosis can be suspected clinically on the basis of Schiller's test done on bedside.

Histologically, distinction between various grades of CIN is quite subjective, but, in general dysplastic cells are distributed in the layers of squamous epithelium for varying thickness, and accordingly graded as mild, moderate and severe dysplasia, and carcinoma *in situ* (Fig. 22.5,A).

◆ In *mild dysplasia (CIN-1)*, the abnormal cells extend up to one-third thickness from the basal to the surface layer;

◆ In *moderate dysplasia (CIN-2)* up to two-thirds;

◆ In *severe dysplasia (CIN-3)*, these cells extend from 75-90% thickness of epithelium; and

◆ In *carcinoma in situ* (included in *CIN-3*), the entire thickness from the basement membrane to the surface shows dysplastic cells.

The atypical cells migrate to the surface layers from where they are shed off (exfoliated) into vaginal secretions in Pap smear. The individual dysplastic or abnormal cells in these grades of atypia show various cytologic changes such as: crowding of cells, pleomorphism, high nucleocytoplasmic ratio, coarse and irregular nuclear chromatin, numerous mitoses and scattered dyskaryotic cells.

The diagnosis of dysplasia and carcinoma *in situ* or CIN/SIL is best made by *exfoliative cytologic studies* discussed in Appendix I. The degree of atypicality in the exfoliated surface epithelial cells can be objectively graded on the basis of 3 principal features (Fig. 22.5,B):

1. More severe nuclear dyskaryotic changes such as increased hyperchromasia and nuclear membrane folding.

2. Decreased cytoplasmic maturation i.e. less cytoplasm as the surface cells show less maturation.

3. In lower grades of dysplasia (CIN-1/L-SIL) predominantly superficial and intermediate cells are shed off whereas in severe dysplasia and in carcinoma *in situ* (CIN-3/H-SIL) the desquamated cells are mainly small, dark basal cells. The lesions of SIL in cytology have histologic correlation with colposcopy-directed cervical biopsy in 70-90% cases (Fig. 22.6).

Cervical Screening and the Bethesda System

Naked eye visual inspection of the uterine cervix with either 5% acetic acid (VIA) or with Lugol's iodine (VILI) under intense illumination provide simple tests for early detection of cervical precancerous lesions and invasive cervical cancer. These tests have largely superseded the earlier Schiller's test due to their ease and low cost. The basis for appearance of 'acetowhite' area as suspicion in VIA is coagulation of increased nuclear DNA in precancerous and cancerous area which assume white appearance compared to pink normal squamous mucosa and reddish normal columnar mucosa.

With introduction of effective Pap screening programme in developed countries, incidence of invasive cervical cancer has declined greatly. However, still worldwide cervical cancer remains third most common cancer in women, next to breast and lung cancer. Although accurate statistics are not available from India, but it is perhaps the leading cause of death in women. In the Pap screening programme, patients having abnormal Pap smear are appropriately followed up and, therefore, it requires understanding of the Bethesda system

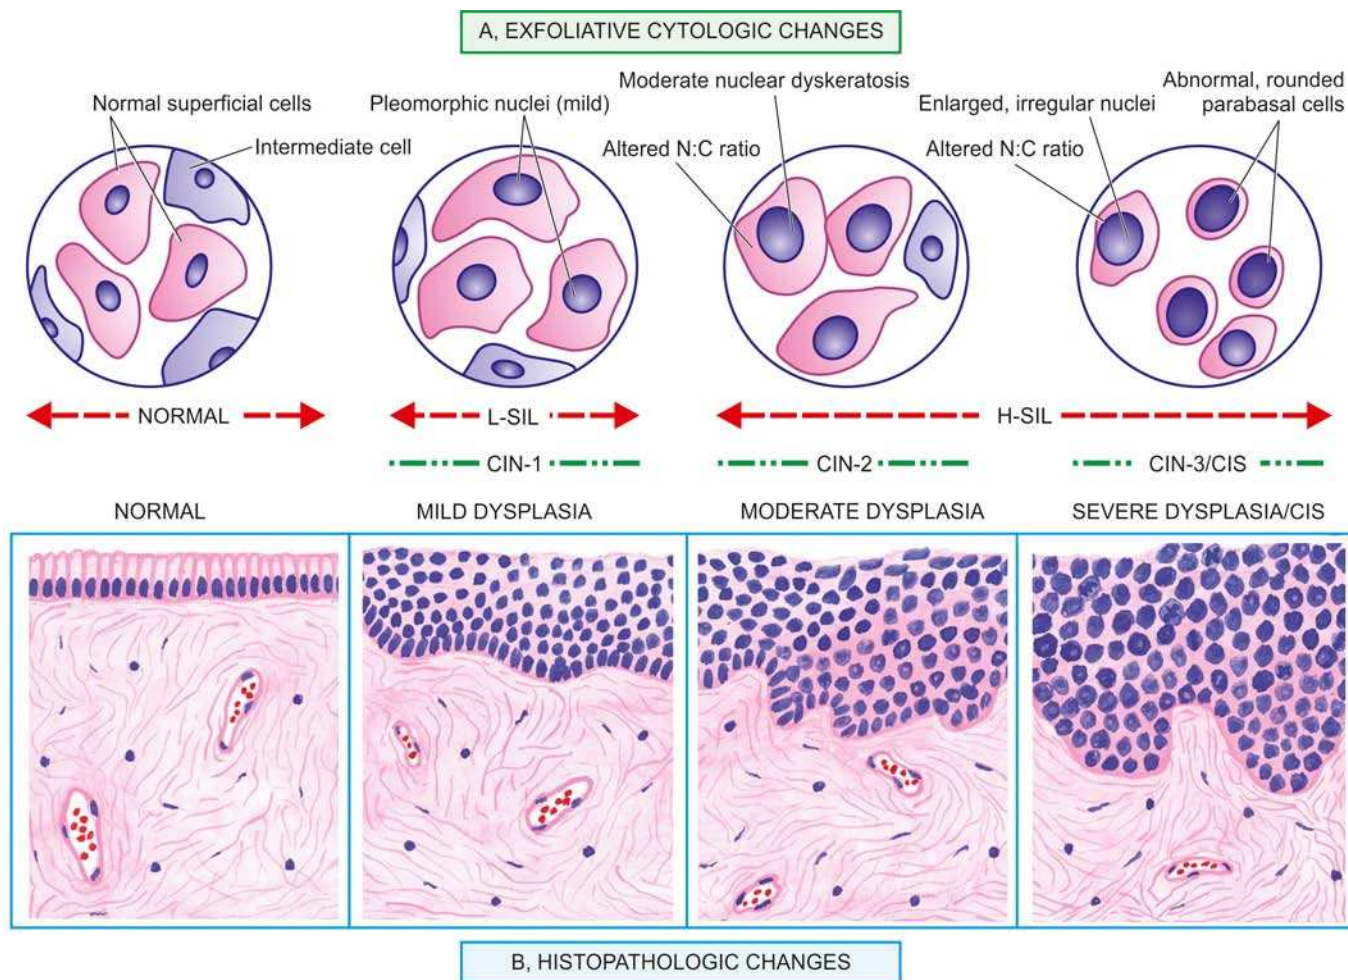

Figure 22.5 Cervical intraepithelial neoplasia (CIN) and squamous intraepithelial lesions (SIL). A, Exfoliative cytologic studies in various grades of cellular changes (upper part of figure). B, Schematic representation of histologic changes (lower part of figure). The grades of CIN-1 or mild dysplasia (L-SIL), CIN-2 (moderate dysplasia) and CIN-3 (severe dysplasia and carcinoma *in situ*) (together grouped as H-SIL) show progressive increase in the number of abnormal cells parallel to the increasing severity of grades.

by the clinician as regards value and limitations of cytology reports prepared by the cytologist/cytotechnician.

Cervical screening recommendations include annual cervical smear in all sexually active women having any risk factors listed above. However, if three consecutive Pap smears are negative in 'high-risk women' or satisfactory in 'low risk women,' frequency of Pap screening is reduced. There is no upper age limit for cervical screening.

The broad principles of the **Bethesda system** (TBS) of cytologic evaluation are as under:

1. Pap smears are evaluated as regards *adequacy of specimen* i.e. satisfactory for evaluation, satisfactory but limited, or unsatisfactory for evaluation giving reason.
2. General diagnosis is given in the form of *normal or abnormal smear*.
3. *Descriptive diagnosis* is given in abnormal smears that includes: benign cellular changes, reactive cellular changes, and abnormalities of epithelial cells.
4. Cellular abnormalities include: *ASCUS* (atypical squamous cells of undetermined significance), *L-SIL* (mentioning HPV infection and CIN-1 present or not), *H-SIL* (stating CIN-2 or CIN-3) and *squamous cell carcinoma*.

INVASIVE CERVICAL CANCER

Invasive cervical cancer in about 80% of cases is epidermoid (squamous cell) carcinoma. The incidence of invasive carcinoma of the cervix has shown a declining trend in developed countries in the last half of the century due to increased use of Pap smear technique for early detection and diagnosis but the incidence remains high in developing countries with low living standards. The risk factors and etiologic factors are the same as for CIN discussed above. The peak incidence of invasive cervical cancer is in 4th to 6th decades of life.

MORPHOLOGIC FEATURES *Grossly*, invasive cervical carcinoma may present 3 types of patterns: fungating, ulcerating and infiltrating. The fungating or exophytic pattern appearing as cauliflower-like growth infiltrating the adjacent vaginal wall is the most common type (Fig. 22.7). Characteristically, cervical carcinoma arises from the squamocolumnar junction. The advanced stage of the disease is characterised by widespread destruction and infiltration into adjacent structures including the urinary bladder, rectum, vagina and regional lymph nodes. Distant

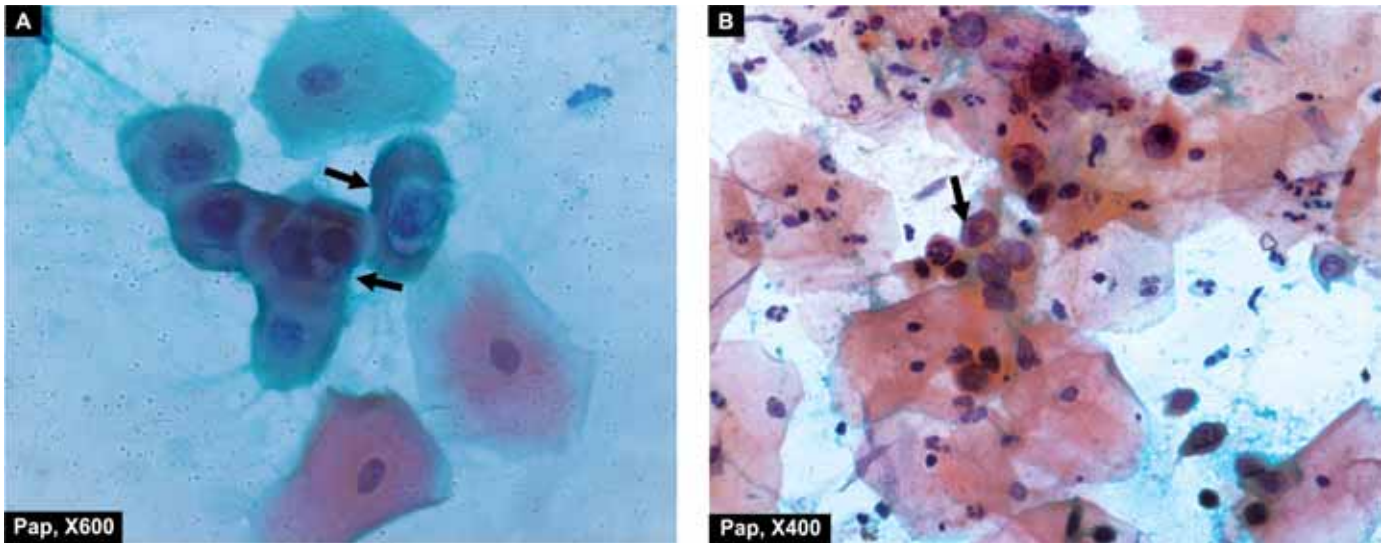

Figure 22.6 Squamous intraepithelial lesions (SIL). A, L-SIL. The smear shows koilocytes having abundant vacuolated cytoplasm and nuclear enlargement (arrow). B, H-SIL. The squamous cells have scanty cytoplasm and markedly hyperchromatic nuclei having irregular nuclear outlines. The background shows numerous PMNs.

metastases occur in the lungs, liver, bone marrow and kidneys.

Histologically, the following patterns are seen:

1. Epidermoid (Squamous cell) carcinoma This type comprises vast majority of invasive cervical carcinomas (about 70%).

◆ The most common pattern (70%) is moderately-differentiated non-keratinising large cell type and has better prognosis (**Fig. 22.8**).

◆ Next in frequency (25%) is well-differentiated keratinising epidermoid carcinoma.

◆ Small cell undifferentiated carcinoma (neuroendocrine or oat cell carcinoma) is less common (5%) and has a poor prognosis.

2. Adenocarcinoma Adenocarcinomas comprise about 20-25% of cases. These may be well-differentiated mucous-secreting adenocarcinoma, or clear cell type containing glycogen but no mucin.

3. Others The remaining 5% cases are a variety of other patterns such as adenosquamous carcinoma, verrucous carcinoma and undifferentiated carcinoma.

CLINICAL STAGING Classification of cervical cancer described by the Cancer Committee of the International Federation of Gynaecology and Obstetrics (FIGO classification) is widely adopted by the clinicians and pathologists and is given in **Table 22.4**.

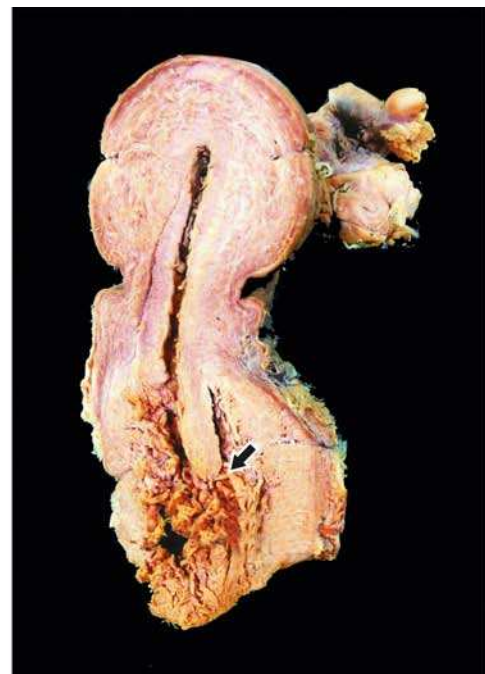

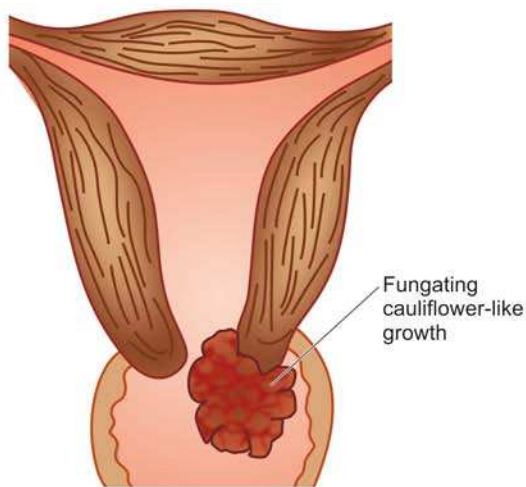

Figure 22.7 Invasive carcinoma of the cervix common gross appearance is of a fungating or exophytic, cauliflower-like tumour. Gross photograph on right shows replacement of the cervix by irregular grey-white friable growth (arrow) extending into cervical canal as well as distally into attached vaginal cuff.

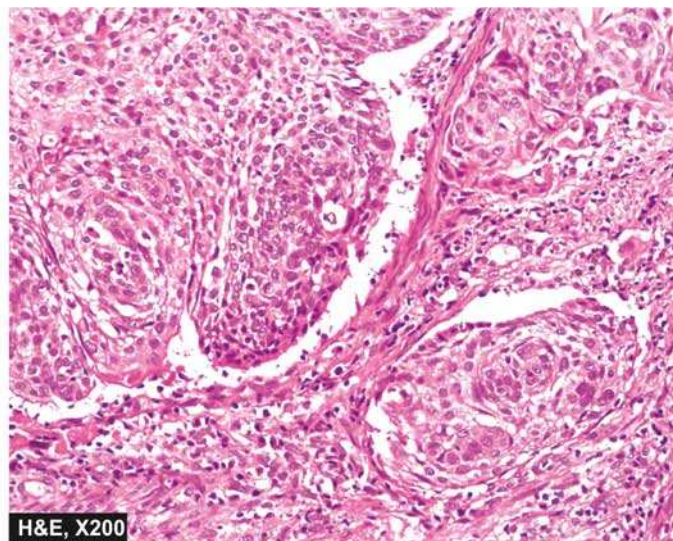

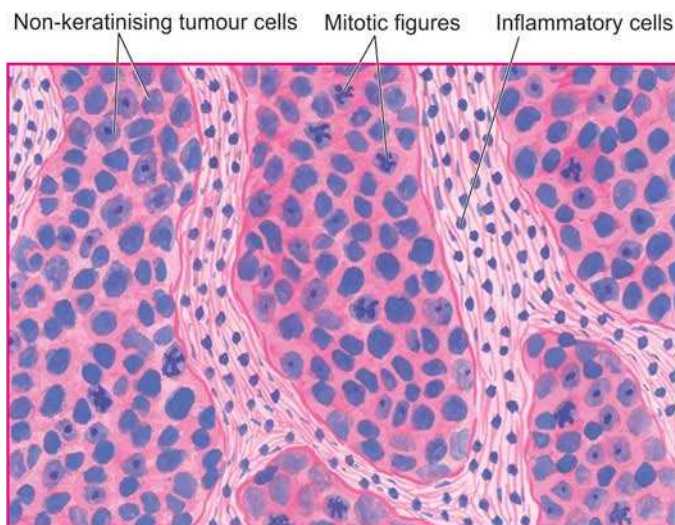

Figure 22.8 Invasive cancer cervix. Common histologic type is epidermoid (squamous cell) carcinoma showing the pattern of a moderately-differentiated non-keratinising large cell carcinoma.

Table 22.4 FIGO clinical staging of carcinoma of the cervix uteri.

| | | |
|-------|------|---|
| Stage | 0 | Carcinoma <i>in situ</i> |
| Stage | I | Carcinoma strictly confined to the cervix |
| | IA | Preclinical carcinomas diagnosed only by microscopy Maximum size 5 mm deep and 7 mm across measured from the base of epithelium. |
| | IA1 | Stromal invasion of less than 3 mm in depth and 7 mm in horizontal axis (minimally invasive). |
| | IA2 | Stromal invasion of 3 to 5 mm depth and horizontal 7 mm or less (microinvasive). |
| | IB | Clinical lesion confined to the cervix or preclinical lesions greater than stage IA. |
| | IB1 | Clinical lesions no greater than 4 cm in size. |
| | IB2 | Clinical lesions greater than 4 cm in size. |
| Stage | II | Carcinoma extends beyond the cervix but has not extended to the pelvic wall. Involvement of the vagina limited to upper two-thirds. |
| | IIA | No obvious parametrial involvement. |
| | IIB | Obvious parametrial involvement. |
| Stage | III | The carcinoma has extended to the pelvic wall. The tumour invades the lower third of vagina. |
| | IIIA | No extension to the pelvic wall. |
| | IIIB | Extension to the pelvic wall and/or hydronephrosis or nonfunctioning kidney. |
| Stage | IV | The carcinoma has extended beyond the true pelvis or has clinically involved the mucosa of the bladder or rectum. |
| | IVA | Spread of the growth to adjacent organs. |
| | IVB | Spread to distant organs. |

GIST BOX 22.3

Diseases of Cervix

- ☐ Cervicitis may be specific or nonspecific, acute or chronic.
- ☐ Cervical polyps are localised benign proliferations of endocervical mucosa.
- ☐ *L-SIL* corresponds to CIN-1 and is a flat condyloma, having koilocytic atypia, usually related to HPV 6 and 11 infection.
- ☐ *H-SIL* corresponds to CIN-2 and 3 and has abnormal pleomorphic atypical squamous cells. HPV 16 and 18 are implicated in the etiology of H-SIL.
- ☐ Introduction of effective Pap screening programme and Bethesda reporting protocol for smears in developed countries has resulted in lowered incidence of invasive cervical cancer.
- ☐ Invasive cervical cancer in about 80% of cases is epidermoid (squamous cell) carcinoma.

MYOMETRIUM AND ENDOMETRIUM

NORMAL STRUCTURE

The *myometrium* is the thick muscular wall of the uterus which is covered internally by uterine mucosa called the *endometrium*. The endometrium extends above the level of the internal os where it joins the endocervical epithelium. The myometrium is capable of marked alterations in its size, capacity and contractility during pregnancy and labour. The endometrium responds in a cyclic fashion to the ovarian hormones with resultant monthly menstruation and has remarkable regenerative capacity.

The lesions pertaining to the corpus uteri and the endometrium are numerous and constitute vast majority of gynaecologic conditions. However, some of the important pathologic entities are discussed below, but first, the cyclic changes in normal menstrual cycle are briefly reviewed.

In addition to the changes that take place during the normal menstrual cycle, the endometrium undergoes morphologic changes when hormonal preparations are administered, or during pregnancy and menopause.

NORMAL CYCLIC CHANGES

The normal endometrial cycle begins with proliferative phase lasting for about 14 days under the influence of oestrogen, followed by ovulation on or around 14th day, and consequent secretory phase under the influence of progesterone. The cycle ends with endometrial shedding and the next cycle begins anew.

The histologic changes in different phases of the menstrual cycle vary.

Histologically, the endometrium has different appearance in different phases of the menstrual cycle (Fig. 22.9). Essentially, the endometrium consists of 3 structures: the endometrial lining epithelium, endometrial glands and stroma.

◆ **Epithelial lining** undergoes increase in its thickness from cuboidal to tall columnar appearance at ovulation and subsequently regresses.

◆ **Endometrial glands** with their lining provide most of the information on phase of the menstrual cycle. In the immediate postmenstrual period, the glands are straight and tubular, having columnar lining with basal nuclei. This phase is under the predominant influence of oestrogen and lasts for about 14 days and is called *proliferative phase*. The evidence of ovulation is taken from the appearance of convolutions in the glands and subnuclear vacuolation in the cells indicative of secretions. The secretory changes remain prominent for the next 7 days after ovulation for implantation of the ovum if it has been fertilised. Otherwise,

the secretory activity wanes during the following 7 days with increased luminal secretions and a frayed and ragged luminal border of the cells lining the glands. This phase is under the predominant influence of progesterone and is called *secretory phase*. Eventually, the endometrium is sloughed away at *menstruation* followed by beginning of the fresh cycle.

◆ **Endometrial stroma** in the pre-ovulatory phase or proliferative phase is generally dense and compact, composed of oval to spindled cells. In the post-ovulatory phase or secretory phase, the stroma is loose and oedematous, composed of large, pale and polyhedral cells. The true *decidual reaction* of the stroma occurs if the pregnancy has taken place. However, decidual reaction may be suggested in the absence of pregnancy due to extreme response to progesterone. Thus, it may be impossible to distinguish an advanced progestational endometrium from early pregnancy except for the presence of trophoblastic tissue.

EFFECT OF OESTROGEN AND PROGESTERONE

Oestrogen produces the characteristic changes of proliferative phase at the time of menopause and in young women with anovulatory cycles as occurs in Stein-Leventhal syndrome. The therapeutic addition of progesterone produces secretory pattern in an oestrogen-primed endometrium. Oestrogen-progesterone combination hormonal therapy is employed for control of conception. The sequential type of oestrogen-progesterone oral contraceptives act by producing prolonged oestrogenic effect past the time of ovulation and implantation so that the secretion is delayed until about 25th day, followed by progestational effect and shedding. Repeated cyclic administration with combination therapy such as after long-term use of oral contraceptives produces inactive-looking, small and atrophic endometrial glands, and compact decidua-like stroma.

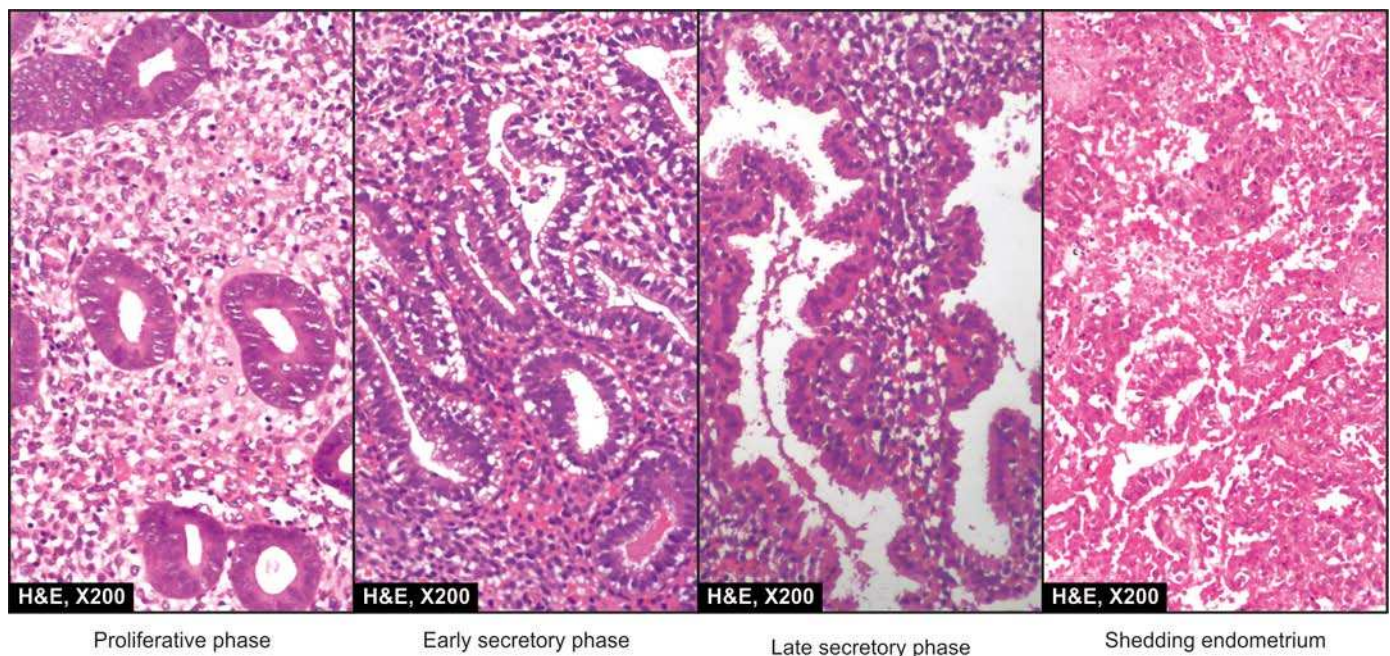

Figure 22.9 Sequential physiologic patterns of endometrium.

EFFECT OF PREGNANCY

The implantation of a fertilised ovum results in interruption of the endometrial cycle. The endometrial glands are enlarged with abundant glandular secretions and the stromal cells become more plump, polygonal with increased cytoplasm termed *decidual reaction*. About 25% cases of uterine or extrauterine pregnancy show hyperactive secretory state called *Arias-Stella reaction*. It is characterised by hyperchromatic, atypical, tall cells lining the glands and the glandular epithelium may show multilayering and budding which may be mistaken for an adenocarcinoma.

EFFECT OF MENOPAUSE

The onset of menopause is heralded with hormonal transition and consequent varying morphologic changes in the endometrium. Most commonly, the *senile endometrium*, as it is generally called, is thin and atrophic with inactive glands and fibrous stroma. However, some of the glands may show cystic dilatation. Sometimes, retrogressive hyperplasia is seen which is characterised by Swiss-cheese pattern of glands resembling endometrial hyperplasia but composed of inactive retrogressive lining epithelium. There is intermingling of cystic and dilated glands with small and atrophic glands. Postmenopausal endometrium may show actual active hyperplasia under the stimulatory influence of post-menopausal oestrogen originating from the ovary or adrenal gland.

DYSFUNCTIONAL UTERINE BLEEDING (DUB)

Dysfunctional uterine bleeding (DUB) may be defined as excessive bleeding occurring during or between menstrual periods without a causative uterine lesion such as tumour, polyp, infection, hyperplasia, trauma, blood dyscrasia or pregnancy. But it occurs most commonly in association with anovulatory cycles when the ovarian function is waning off (menopause). Anovulatory cycles are also seen at the other extreme of menstrual life when the ovarian function is first beginning i.e. menarche. Anovulation is the result of prolonged and excessive oestrogenic stimulation without the development of progestational phase. The causes for *anovulation* at different ages are as follows:

1. In *pre-puberty*: precocious puberty of hypothalamic, pituitary or ovarian origin.
2. In *adolescence*: anovulatory cycles at the onset of menstruation.
3. In *reproductive age*: complications of pregnancy, endometrial hyperplasia, carcinoma, polyps, leiomyomas and adenomyosis.
4. At *premenopause*: anovulatory cycles, irregular shedding, endometrial hyperplasia, carcinoma and polyps.
5. At *perimenopause*: endometrial hyperplasia, carcinoma, polyps and senile atrophy.

It has been observed that women who ovulate may also occasionally have anovulatory cycles. In addition to anovulatory cycles, DUB may occur in *inadequate luteal phase* that manifests clinically as infertility (*ovulatory dysfunctional bleeding*). In such cases, the premenstrual endometrial biopsy shows histologic lag of more than 2 days.

ENDOMETRITIS AND MYOMETRITIS

Inflammatory involvement of the endometrium and myometrium are uncommon clinical problems; myome-

tritis is seen less frequently than endometritis and occurs in continuation with endometrial infections. Endometritis and myometritis may be acute or chronic.

◆ **Acute form** generally results from 3 types of causes—puerperal (following full-term delivery, abortion and retained products of conception), intrauterine contraceptive device (IUCD), and extension of gonorrhoeal infection from the cervix and vagina.

◆ **Chronic form** is more common and occurs by the same causes which result in acute phase. In addition, *tuberculous endometritis* is an example of specific chronic inflammation, uncommon in the Western countries but not so uncommon in developing countries. Its incidence in India is reported to be approximately in 5% of women.

MORPHOLOGIC FEATURES In *acute endometritis and myometritis*, there is progressive infiltration of the endometrium, myometrium and parametrium by polymorphs and marked oedema. *Chronic nonspecific endometritis and myometritis* are characterised by infiltration of plasma cells alongwith lymphocytes and macrophages. *Tuberculous endometritis* is almost always associated with tuberculous salpingitis and shows small caseating granulomas (Fig. 22.10).

ADENOMYOSIS

Adenomyosis is defined as abnormal distribution of histologically benign endometrial tissue within the myometrium alongwith myometrial hypertrophy. The term *adenomyoma* is used for actually circumscribed mass made up of endometrium and smooth muscle tissue. Adenomyosis is found in 15-20% of all hysterectomies. Pathogenesis of the condition remains unexplained. The possible underlying cause of the invasiveness and increased proliferation of the endometrium into the myometrium appears to be either a metaplasia or oestrogenic

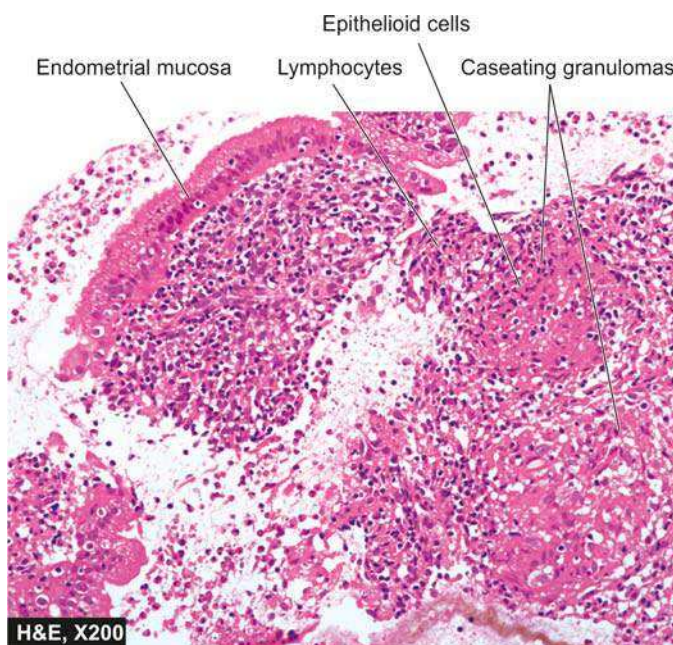

Figure 22.10 Tuberculous endometritis. The stroma has caseating epithelioid cell granulomas having Langhans' giant cells and peripheral layer of lymphocytes.

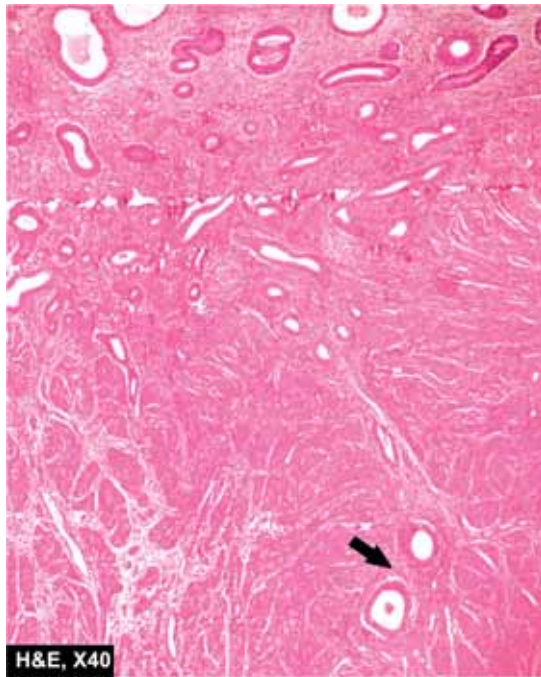

Figure 22.11 Adenomyosis. The endometrial glands are present deep inside the myometrium (arrow).

stimulation due to endocrine dysfunction of the ovary. Clinically, the patients of adenomyosis generally complain of menorrhagia, colicky dysmenorrhoea and menstrual pain in the sacral or sacrococcygeal regions.

MORPHOLOGIC FEATURES *Grossly*, the uterus may be slightly or markedly enlarged. On cut section, there is diffuse thickness of the uterine wall with presence of coarsely trabecular, ill-defined areas of haemorrhages.

Microscopically, the diagnosis is based on the finding of normal, benign endometrial islands composed of glands as well as stroma deep within the muscular layer. The minimum distance between the endometrial islands within the myometrium and the basal endometrium should be one low-power microscopic field (2-3 mm) for making the diagnosis (**Fig. 22.11**). Associated muscle hypertrophy is generally present.

ENDOMETRIOSIS

Endometriosis refers to the presence of endometrial glands and stroma in abnormal locations outside the uterus. Endometriosis and adenomyosis are closely interlinked, so much so that some gynaecologists have termed adenomyosis as *endometriosis interna* and the other category termed as *endometriosis externa* for similar appearance at the extrauterine sites. However, the two differ as regards age, fertility and histogenesis and thus endometriosis should be regarded as a distinct clinicopathologic entity.

The chief locations where the abnormal endometrial development may occur are as follows (in descending order of frequency): ovaries, uterine ligaments, rectovaginal septum,

pelvic peritoneum, laparotomy scars, and infrequently in the umbilicus, vagina, vulva, appendix and hernial sacs.

The **histogenesis** of endometriosis has been a debatable matter for years. Currently, however, the following 3 theories of its histogenesis are described:

1. *Transplantation or regurgitation theory* is based on the assumption that ectopic endometrial tissue is transplanted from the uterus to an abnormal location by way of fallopian tubes due to regurgitation of menstrual blood.
2. *Metaplastic theory* suggests that ectopic endometrium develops *in situ* from local tissues by metaplasia of the coelomic epithelium.
3. *Vascular or lymphatic dissemination* explains the development of endometrial tissue at extrapelvic sites by these routes.

Endometriosis is characteristically a disease of reproductive years of life. Clinical signs and symptoms include intrapelvic bleeding from implants, severe dysmenorrhoea, pelvic pain, dyspareunia and infertility.

MORPHOLOGIC FEATURES *Grossly*, the appearance of endometriosis varies widely depending upon the location and extent of the disease. Typically, the foci of endometriosis appear as blue or brownish-black underneath the surface of the sites mentioned. Often, these foci are surrounded by fibrous tissue resulting in adherence to adjacent structures. The ovary is the most common site of endometriosis and shows numerous cysts varying in diameter from 0.1 to 2.5 cm. Ovarian involvement is often bilateral. Larger cysts, 3-5 cm in diameter, filled with old dark brown blood form 'chocolate cysts' of the ovary.

Histologically, the diagnosis is simple and rests on identification of foci of endometrial glands and stroma, old or new haemorrhages, haemosiderin-laden macrophages and surrounding zone of inflammation and fibrosis (**Fig. 22.12**).

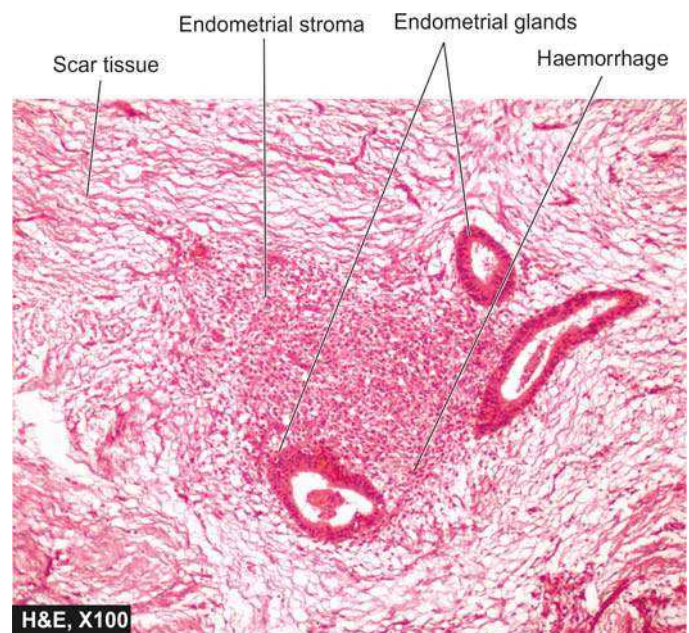

Figure 22.12 Endometriosis in abdominal scar following caesarean section in the past. Dense fibrocollagenic tissue contains endometrial glands, stroma and evidence of preceding old haemorrhage.

ENDOMETRIAL HYPERPLASIAS

Endometrial hyperplasia is characterised by exaggerated proliferation of glandular and stromal tissues. It is commonly associated with prolonged, profuse and irregular uterine bleeding in a menopausal or postmenopausal woman. It may be emphasised here that the syndrome of DUB with which endometrial hyperplasia is commonly associated is a clinical entity, while hyperplasia is a pathologic term. Hyperplasia results from prolonged oestrogenic stimulation unopposed with any progestational activity. Such conditions include Stein-Leventhal syndrome, functioning granulosa-theca cell tumours, adrenocortical hyperfunction and prolonged administration of oestrogen. Endometrial hyperplasia is clinically significant due to the presence of cellular atypia which is closely linked to endometrial carcinoma.

The following classification of endometrial hyperplasias is widely employed by most gynaecologic pathologists:

1. Simple hyperplasia without atypia (Cystic glandular hyperplasia).
2. Complex hyperplasia without atypia (Complex non-atypical hyperplasia).
3. Complex hyperplasia with atypia (Complex atypical hyperplasia).

SIMPLE HYPERPLASIA WITHOUT ATYPIA (CYSTIC GLANDULAR HYPERPLASIA) Commonly termed cystic glandular hyperplasia (CGH), this form of endometrial hyperplasia is characterised by the presence of varying-sized glands, many of which are large and cystically dilated and are lined by atrophic epithelium. Mitoses are scanty and there is no atypia. The stroma between the glands is sparsely cellular and oedematous (Fig. 22.13,A).

There is minimal risk (<1%) of adenocarcinoma developing in cystic hyperplasia.

COMPLEX HYPERPLASIA WITHOUT ATYPIA (COMPLEX NON-ATYPICAL HYPERPLASIA) This type of hyperplasia shows distinct proliferative pattern. The glands are increased in number, exhibit variation in size and are irregular in shape. The glands are lined by multiple layers of tall columnar epithelial cells with large nuclei which have not lost basal polarity and there is no significant atypia. The glandular epithelium at places is thrown into papillary infolds or out-pouchings into adjacent stroma i.e. there is crowding and complexity of glands without cellular atypia. The stroma is generally dense, cellular and compact (Fig. 22.13,B).

The malignant potential of complex hyperplasia in the absence of cytologic atypia is 3%.

COMPLEX HYPERPLASIA WITH ATYPIA (COMPLEX ATYPICAL HYPERPLASIA) Some authors have suggested the terms such as endometrial intraepithelial neoplasia (EIN) or carcinoma *in situ* for this form of endometrial hyperplasia. Complex hyperplasia with atypia is distinguished from complex non-atypical hyperplasia by the presence of 'atypical cells' in the hyperplastic epithelium. The extent of cellular atypia may be mild, moderate or

severe. The cytologic features present in these cells include loss of polarity, large size, irregular and hyperchromatic nuclei, prominent nucleoli, and altered nucleocytoplasmic ratio (Fig. 22.13,C).

Complex atypical hyperplasia is a precancerous condition and its malignant transformation is related to the degree of cytologic atypia. About 20-25% cases of untreated atypical hyperplasia progress to carcinoma.

TUMOURS OF ENDOMETRIUM AND MYOMETRIUM

Tumours arising from endometrium and myometrium may be benign or malignant. They may originate from different tissues as under:

- ◆ *Endometrial glands*—endometrial polyps, endometrial carcinoma.
- ◆ *Endometrial stroma*—stromal nodules, stromal sarcoma.
- ◆ *Smooth muscle of the myometrium*—leiomyoma, leiomyosarcoma.
- ◆ *Mullerian mesoderm*—mixed mesodermal or mullerian tumours.

Out of these, endometrial polyps, endometrial carcinoma, leiomyomas and leiomyosarcomas are relatively more common and are described below.

ENDOMETRIAL POLYPS

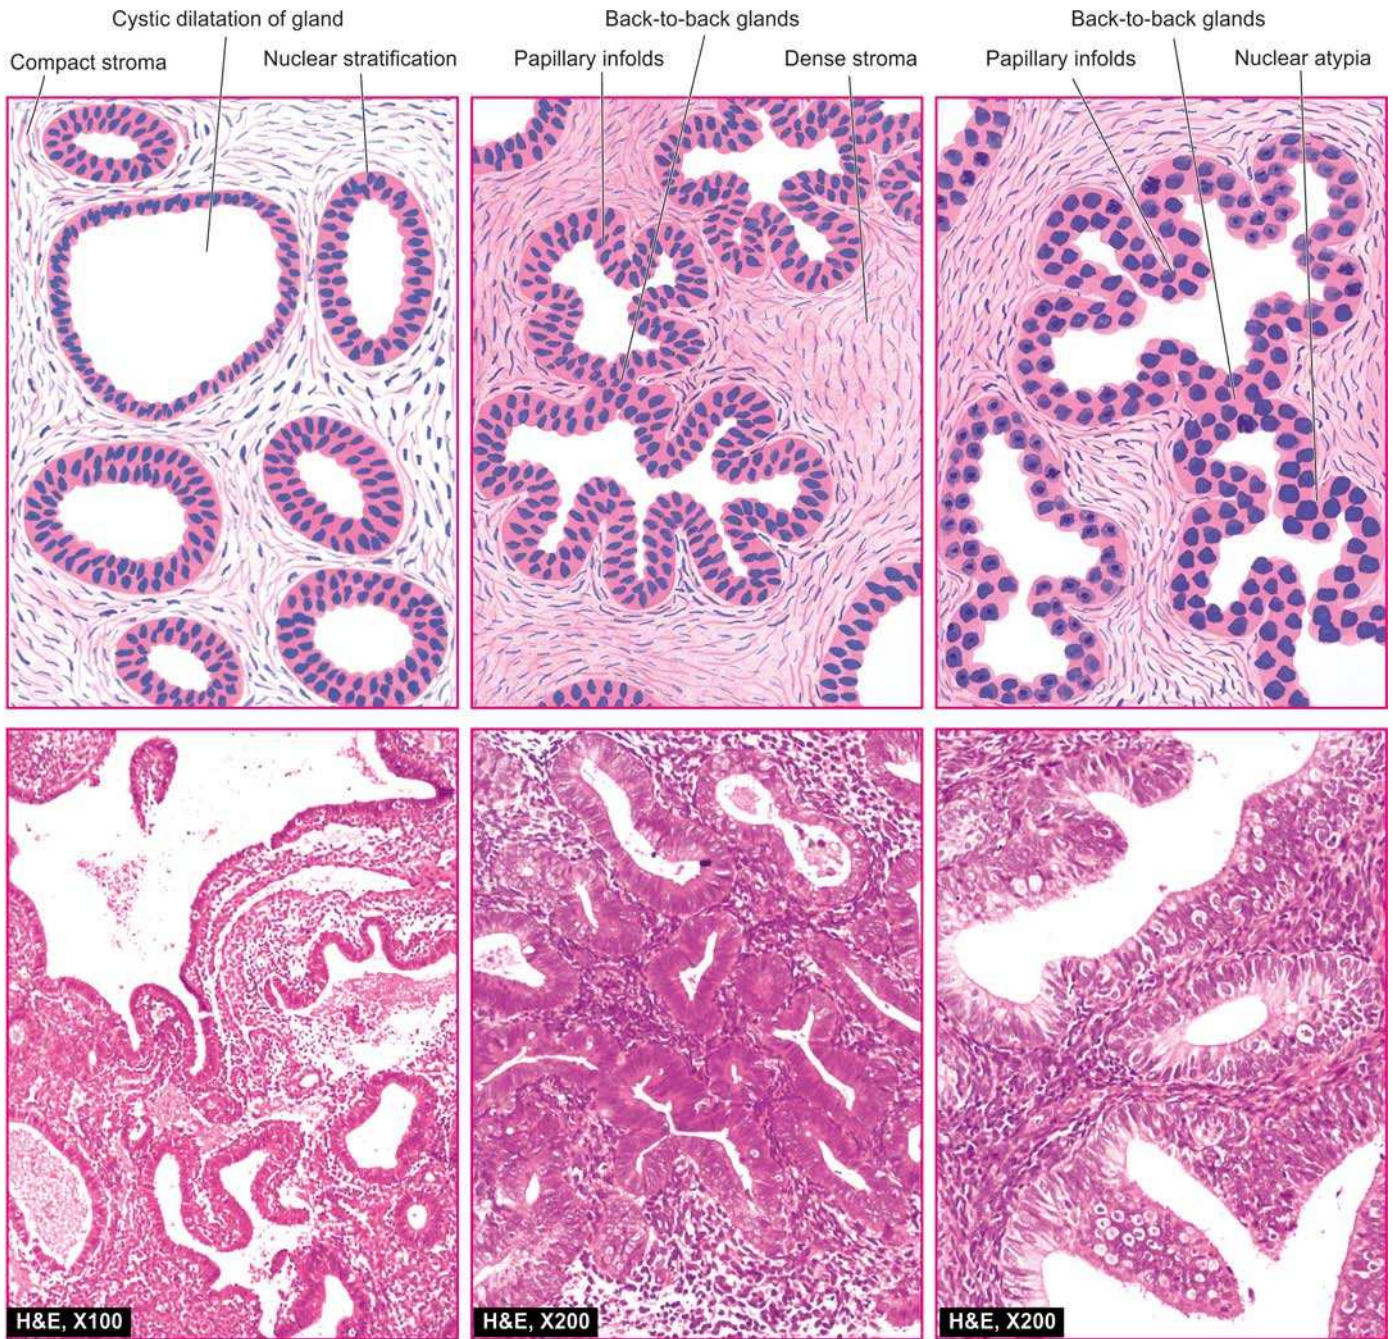

'Uterine polyp' is clinical term used for a polypoid growth projecting into the uterine lumen and may be composed of benign lesions (e.g. endometrial or mucous polyp, leiomyomatous polyp and placental polyp), or malignant polypoid tumours (e.g. endometrial carcinoma, choriocarcinoma and sarcoma). The most common variety, however, is the one having the structure like that of endometrium and is termed *endometrial or mucus polyp*. They are more common in the perimenopausal age group. Small endometrial polyps generally remain asymptomatic and are detected incidentally. The larger ones may ulcerate, degenerate and result in clinical bleeding.

MORPHOLOGIC FEATURES *Grossly*, endometrial polyps may be single or multiple, usually sessile and small (0.5 to 3 cm in diameter) but occasionally they are large and pedunculated.

Histologically, they are essentially made up of mixture of endometrial glands and stroma. The histologic pattern of the endometrial tissue in the polyp may resemble either functioning endometrium or hyperplastic endometrium of cystic hyperplasia type, the latter being more common. Rarely, a large endometrial polyp may undergo malignant change.

ENDOMETRIAL CARCINOMA

Carcinoma of the endometrium, commonly called uterine cancer, is the most common pelvic malignancy in females in the United States and Eastern Europe but is uncommon in Asia where cervical cancer continues to be the leading cancer in women. Whereas the decline in the incidence of cervical cancer in the developed countries is due to aggressive cervical

A, SIMPLE HYPERPLASIA WITHOUT ATYPIA (CYSTIC GLANDULAR HYPERPLASIA) B, COMPLEX HYPERPLASIA WITHOUT ATYPIA (COMPLEX NON-ATYPICAL HYPERPLASIA) C, COMPLEX HYPERPLASIA WITH ATYPIA (COMPLEX ATYPICAL HYPERPLASIA)

Figure 22.13 Three forms of endometrial hyperplasias.

screening programme leading to early detection and cure of *in situ* stage, increased frequency of endometrial carcinoma in these countries may be due to longevity of women's life to develop this cancer of older females. It is primarily a disease of postmenopausal women, the peak incidence at onset being 6th to 7th decades of life and is uncommon below the age of 40 years. The most important presenting complaint is abnormal bleeding in postmenopausal woman or excessive flow in the premenopausal years.

ETIOLOGY A few factors associated with increased frequency of its development are as follows:

1. Chronic unopposed oestrogen excess
2. Obesity

3. Diabetes mellitus
4. Hypertension
5. Nulliparous state
6. Heredity.

There are irrefutable evidences of *relationship of endometrial carcinoma with prolonged oestrogenic stimulation* as under:

- i) Endometrial carcinoma has association with endometrial hyperplasia (discussed earlier) in which there is unopposed chronic hyperoestrogenism and frequent anovulatory cycles.
- ii) In postmenopausal years when endometrial carcinoma occurs characteristically, there is excessive synthesis of oestrogen in the body from adrenal as well as from ovarian sources.

- iii) Women having oestrogen-secreting tumours (e.g. granulosa cell tumour) have increased risk of developing synchronous endometrial cancer.
- iv) Patients receiving prolonged exogenous oestrogen therapy are at higher risk of developing this cancer.
- v) Women of breast cancer receiving tamoxifen for prolonged period have 2-fold increased risk of developing uterine cancer.
- vi) Prolonged administration of oestrogen to laboratory animals can produce endometrial hyperplasia and carcinoma.
- vii) Women with gonadal agenesis rarely develop endometrial carcinoma.

PATHOGENESIS At molecular level, pathogenesis of endometrial cancer can be explained as under:

- ◆ Endometrial hyperplasia is a forerunner of endometrioid cancer is supported by mutated *PTEN* gene (located on chromosome 10) seen in 20% cases of complex hyperplasia while it is seen in 40-80% cases of endometrioid carcinoma. Other gene mutations in these cases are *hMLH*, *KRAS* and β -*catenin* oncogenes.
- ◆ Papillary serous endometrial carcinoma is seen in a background of atrophic endometrium and is associated with mutation in *p53* tumour suppressor gene.
- ◆ The role of heredity in pathogenesis of endometrial cancer is supported by higher incidence in hereditary non-polyposis colon cancer (HNPCC) syndrome (having simultaneous cancers of the colon and endometrioid adenocarcinoma) and in Cowden syndrome (having simultaneous cancers of the breast, thyroid, and endometrium).

MORPHOLOGIC FEATURES *Grossly*, endometrial carcinoma may have 2 patterns—localised *polypoid tumour*, or a *diffuse tumour*; the latter being more common (Fig. 22.14). The tumour protrudes into the endometrial cavity as irregular, friable and grey-tan mass. Extension of the growth into the myometrium may be identified by the presence of soft, friable and granular tissue in cut section. In advanced disease, the involvement may extend beyond the physiologic limits—into the cervical canal, into the peritoneum, besides lymphatic metastases and

haematogenous metastases to distant sites such as lungs, liver, bones and other organs.

Histologically, most endometrial carcinomas are adenocarcinomas, commonly termed *endometrioid adenocarcinomas* due to their resemblance with normal endometrium. Depending upon the pattern of glands and individual cell changes, these may be well-differentiated, moderately-differentiated or poorly-differentiated.

◆ *Well-differentiated adenocarcinoma* is characterised by increase in the number of glands which are closely packed sometimes showing 'back-to-back crowding' due to obliterated intervening stroma. The glandular epithelium shows stratification, formation of tufting and papillae and atypical changes. Most growths are well-differentiated (Fig. 22.15).

◆ *Moderately-differentiated adenocarcinoma* shows all the above features alongwith presence of some solid sheets of malignant cells.

◆ *Poorly-differentiated adenocarcinoma* is characterised by presence of solid sheets and ribbons of malignant epithelial cells which show marked cytologic atypia and frequent mitoses. Glandular pattern is hard to find.

Cases can also be categorised as regards histologic grade as follows:

G1: Well-differentiated (predominantly glandular).

G2: Moderately-differentiated (glandular and partly solid areas).

G3: Poorly-differentiated (predominantly solid).

◆ **Papillary serous carcinoma** of the endometrium resembling its ovarian counterpart is distinct since it occurs in the background of atrophic endometrium and is more aggressive.

◆ **Uncommon histologic variants** of endometrial carcinoma are: adenocarcinoma with squamous metaplasia (adenocanthoma), adenosquamous carcinoma (when both components are frankly malignant), clear cell carcinoma, mucinous adenocarcinoma and papillary serous carcinoma.

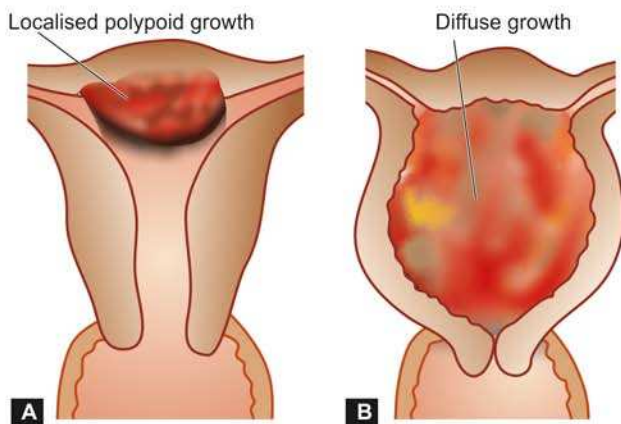

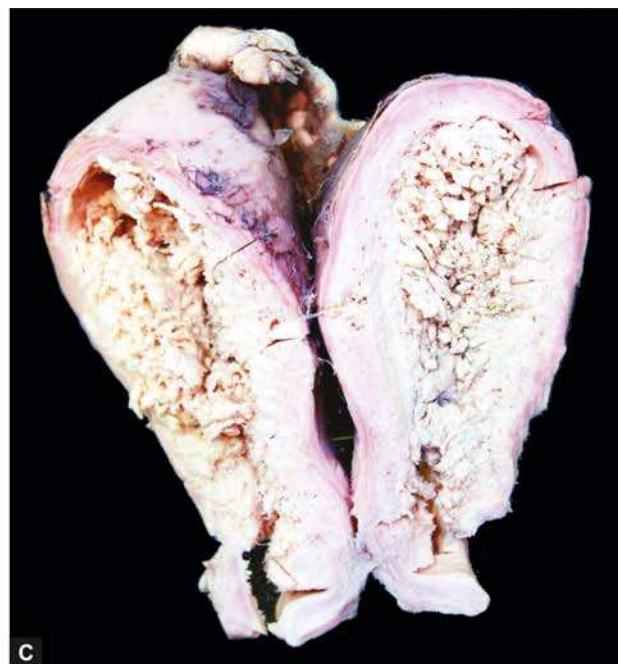

Figure 22.14 Endometrial carcinoma. A, B, Diagrammatic representation of the common gross patterns—localised polypoid growth and diffuse growth. C, The specimen of the uterus and cervix shows enlarged uterus and dilated uterine cavity containing irregular, grey-white, friable growth arising from endometrial mucosa and invading the underlying myometrium superficially.

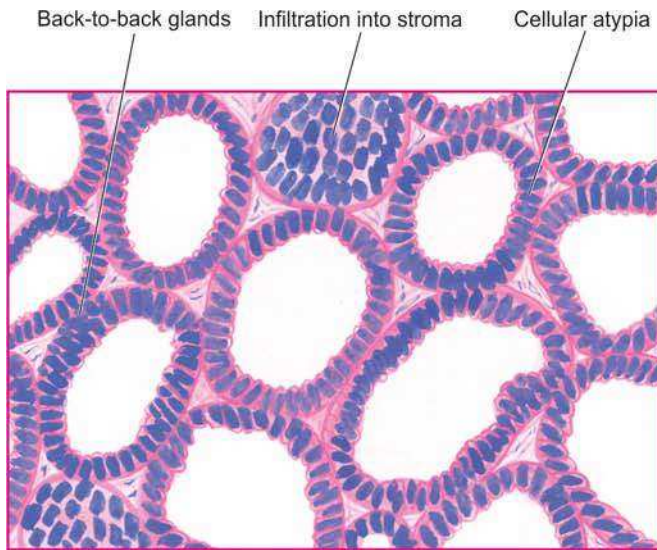

Figure 22.15 Endometrial carcinoma. The most common histologic pattern is well-differentiated adenocarcinoma showing closely packed (back-to-back) glands with cytologic atypia.

Carcinoma of the endometrium is categorised into four stages as per FIGO classification given in [Table 22.5](#).

LEIOMYOMA

Leiomyomas or fibromyomas, commonly called *fibroids* by the gynaecologists, are the most common uterine tumours of smooth muscle origin, often admixed with variable amount of fibrous tissue component. About 20% of women above the age of 30 years harbour uterine myomas of varying size. Vast majority of them are benign and cause no symptoms. Malignant transformation occurs in less than 0.5% of leiomyomas. Symptomatic cases may produce abnormal uterine bleeding, pain, symptoms due to compression of surrounding structures and infertility.

The cause of leiomyomas is unknown but the possible stimulus to their proliferation is oestrogen. This is evidenced by increase in their size in pregnancy ([Fig. 22.16,C](#)) and high dose oestrogen-therapy and their regression following menopause and castration. Other possible factors implicated in its etiology are human growth hormone and sterility.

Table 22.5 FIGO clinical staging of carcinoma of the endometrium.

| | | |
|-------|------|---|
| Stage | IA | Tumour limited to endometrium. |
| | IB | Invasion to less than one-half the myometrium. |
| | IC | Invasion to more than one-half the myometrium. |
| Stage | IIA | Endocervical glandular involvement only. |
| | IIB | Cervical stromal invasion. |
| Stage | IIIA | Tumour invades serosa and/or adnexa and/or positive peritoneal cytology. |
| | IIIB | Metastases to pelvic and/or para-aortic lymph nodes. |
| Stage | IVA | Tumour invasion of bladder and/or bowel mucosa. |
| | IVB | Distant metastases including intra-abdominal and/or inguinal lymph nodes. |

MORPHOLOGIC FEATURES Leiomyomas are most frequently located in the uterus where they may occur within the myometrium (*intramural or interstitial*), the serosa (*subserosal*), or just underneath the endometrium (*submucosal*). Subserosal and submucosal leiomyomas may develop pedicles and protrude as pedunculated myomas. Leiomyomas may involve the cervix or broad ligament.

Grossly, irrespective of their location, leiomyomas are often multiple, circumscribed, firm, nodular, grey-white masses of variable size. On cut section, they exhibit characteristic whorled pattern ([Fig. 22.16, A,B](#)).

Histologically, they are essentially composed of 2 tissue elements—whorled bundles of smooth muscle cells admixed with variable amount of connective tissue. The smooth muscle cells are uniform in size and shape with abundant cytoplasm and central oval nuclei ([Fig. 22.17](#)).

Cellular leiomyoma has preponderance of smooth muscle elements and may superficially resemble leiomyosarcoma but is distinguished from it by the absence of mitoses (see below).

The pathologic appearance may be altered by secondary changes in the leiomyomas; these include: hyaline degeneration, cystic degeneration, infarction, calcification, infection and suppuration, necrosis, fatty change, and rarely, sarcomatous change.

LEIOMYOSARCOMA

Leiomyosarcoma is an uncommon malignant tumour as compared to its rather common benign counterpart. The incidence of malignancy in pre-existing leiomyoma is less than 0.5% but primary uterine sarcoma is less common than that which arises in the leiomyoma. The peak age incidence is seen in 4th to 6th decades of life. The symptoms produced are nonspecific such as uterine enlargement and abnormal uterine bleeding.

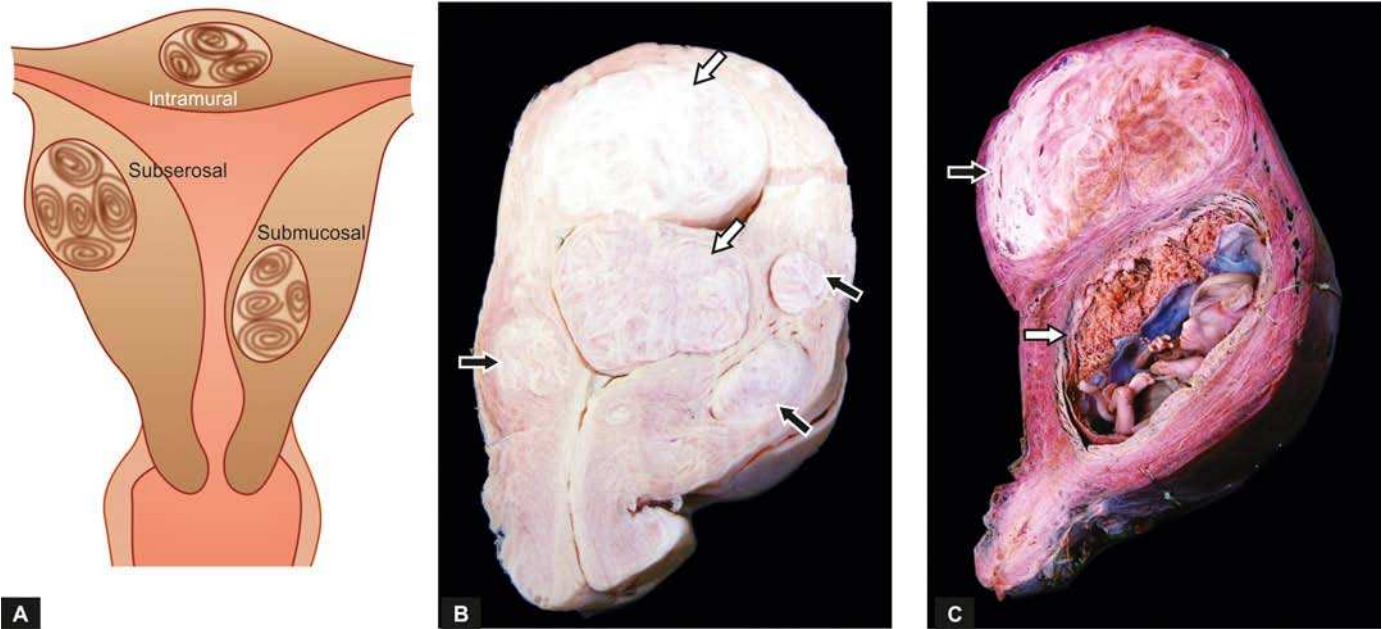

Figure 22.16 Leiomyomas. A, Diagrammatic appearance of common locations and characteristic whorled appearance on cut section. B, Sectioned surface of the uterus shows multiple circumscribed, firm nodular masses of variable sizes—submucosal (white arrows) and intramural (black arrows) in location having characteristic whorling. C, The opened up uterine cavity shows an intrauterine gestation sac with placenta (white arrow) and a single circumscribed, enlarged, firm nodular mass in intramural location (black arrow) having grey-white whorled pattern.

MORPHOLOGIC FEATURES *Grossly*, the tumour may form a diffuse, bulky, soft and fleshy mass, or a polypoid mass projecting into lumen.

Histologically, though there are usually some areas showing whorled arrangement of spindle-shaped smooth muscle cells having large and hyperchromatic nuclei, the hallmark of diagnosis and prognosis is the number of mitoses per high power field (HPF). The essential diagnostic criteria are:

more than 10 mitoses per 10 HPF with or without cellular atypia, or 5-10 mitoses per 10 HPF with cellular atypia. More the number of mitoses per 10 HPF, worse is the prognosis.

Leiomyosarcoma is liable to recur after removal and eventually metastasises to distant sites such as lungs, liver, bone and brain.

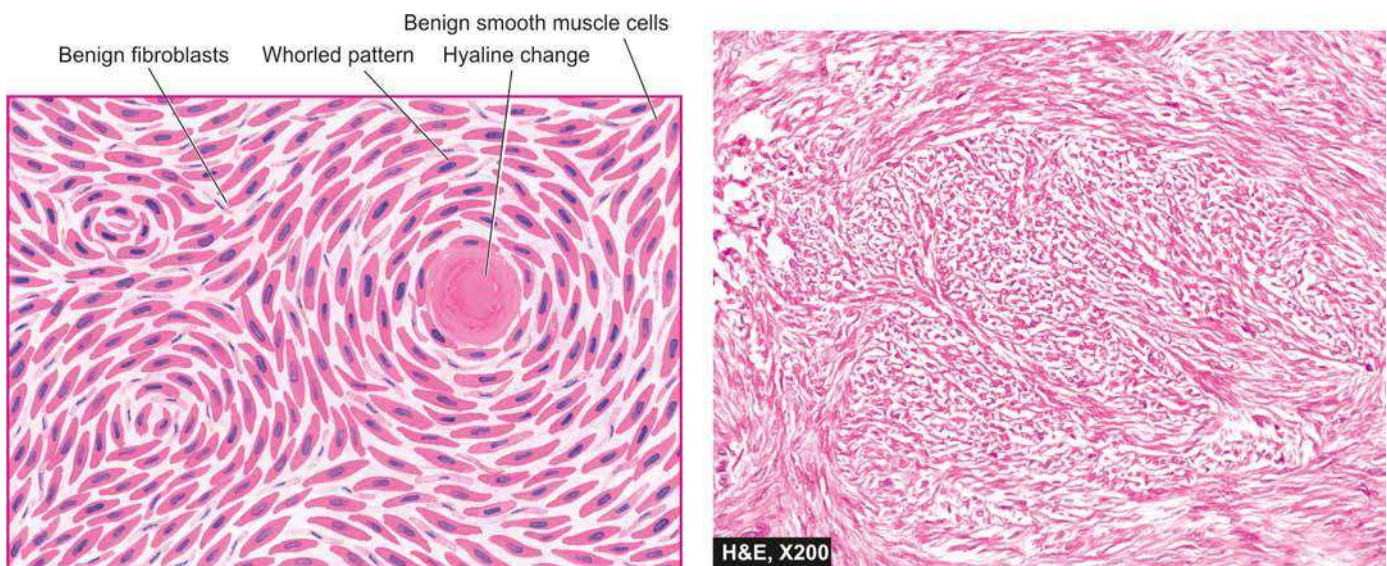

Figure 22.17 Leiomyoma uterus. Microscopy shows whorls of smooth muscle cells which are spindle-shaped, having abundant cytoplasm and oval nuclei.

GIST BOX 22.4

Diseases of Endometrium and Myometrium

- ▣ Endometrium undergoes morphologic changes when hormonal preparations are administered, or during pregnancy and menopause.
- ▣ Adenomyosis is abnormal distribution of histologically benign endometrial tissue within the myometrium.
- ▣ Endometriosis refers to the presence of endometrial glands and stroma in abnormal locations outside the uterus.
- ▣ Endometrial hyperplasia is characterised by exaggerated proliferation of glandular and stromal tissues due to prolonged oestrogenic stimulation. Endometrial hyperplasia may be simple or complex; the latter may be without atypia or with atypia.
- ▣ Endometrial cancer occurs frequently in a background of complex hyperplasia and hence related to prolonged oestrogenic stimulation.
- ▣ Leiomyomas or fibroids are the most common benign uterine tumours of smooth muscle origin while leiomyosarcoma is an uncommon malignant tumour.

FALLOPIAN TUBES

NORMAL STRUCTURE

The fallopian tube or oviducts are paired structures, each extending from superior angle of the uterus laterally to the region of the ovaries and running in the superior border of the broad ligaments forming mesosalpinx. Each tube is 7-14 cm long and is divided into 4 parts—*interstitial portion* in the uterine cornual wall; narrow *isthmic portion*; wider *ampullary region*; and funnel-like distal *infundibulum*. The infundibulum is fringed by fimbriae, the longest of which called fimbria ovarica is attached to the ovary.

Histologically, the wall of tube has 4 coats—*serous* forming the peritoneal covering, *subserous* consisting of fibrovascular tissue, *muscular* composed of longitudinal and circular smooth muscle layers, and *tubal mucosa* having 3 types of cells namely: ciliated, columnar and dark intercalated cells. The tubal serosal covering may contain tiny nodular masses of mesothelial cells forming *Walther's cell rests*.

The major conditions involving the fallopian tubes are inflammations, ectopic tubal gestation, and endometriosis.

INFLAMMATIONS

SALPINGITIS AND PELVIC INFLAMMATORY DISEASE

Pelvic inflammatory disease (PID) by definition is a clinical syndrome characterised by signs and symptoms of ascending infection beginning in the vulva or vagina and spreading through the entire genital tract. Although ascending route of infection is the most common mode of spread, PID may occur following abortion and puerperium, with use of intrauterine contraceptive devices, or from local intra-abdominal infections such as appendicitis with peritonitis. In addition, haematogenous spread may occur, though this route is more important in the pathogenesis of tuberculosis.

Most commonly, PID occurs as a venereally-transmitted infection, chiefly caused by *Chlamydia trachomatis* and

Neisseria gonorrhoeae. Post-abortion and postpartum infections are mainly caused by staphylococci, streptococci, coliform bacteria, clostridia and pneumococci.

Patients generally complain of lower abdominal and pelvic pain which is often bilateral, dysmenorrhoea, menstrual abnormalities and fever with tachycardia. Long-standing chronic PID may lead to infertility and adhesions between small intestine and pelvic organs.

MORPHOLOGIC FEATURES *Grossly*, the fallopian tubes are invariably involved bilaterally. The distal end is blocked by inflammatory exudate and the lumina are dilated. There may be formation of loculated tubo-ovarian abscess involving the tube, ovary, broad ligament and adjacent part of uterus.

Microscopically, the appearance varies with the duration of inflammatory process.

1. The process begins with *acute salpingitis* characterised by oedema and intense acute inflammatory infiltrate of neutrophils involving the tubal mucosa as well as wall. The lumen is filled with purulent exudate consisting of leucocytes and sloughed off epithelial cells.

2. The purulent process may extend to involve tube as well as ovary causing salpingo-oophoritis and forming *tubo-ovarian abscess*.

3. The escape of purulent exudate into the peritoneal cavity produces *pelvic peritonitis* and *pelvic abscess*.

4. *Pyosalpinx* is distension of the fallopian tube with pus due to occluded fimbrial end.

5. End-result of pyosalpinx after resorption of the purulent exudate is *hydrosalpinx* in which the tube is thin-walled, dilated and filled with clear watery fluid.

6. Acute salpingitis may resolve with treatment but some cases pass into *chronic salpingitis* with infiltrate of polymorphs, lymphocytes and plasma cells and fibrosis.

7. *Salpingitis isthmica nodosa* used to be considered another manifestation of chronic salpingitis but currently accepted pathogenesis of this lesion appears to be similar to that of adenomyosis. Nevertheless, the appearance is characterised by multiple nodules containing spaces which are lined by benign tubal epithelium. Inflammatory changes are scanty or absent.

TUBERCULOUS SALPINGITIS

Tuberculous salpingitis is almost always secondary to focus elsewhere in the body. The tubercle bacilli reach the tube, most commonly by haematogenous route, generally from the lungs, but occasionally from the urinary tract or abdominal cavity. Tubal tuberculosis is always present when there is tuberculosis of other female genital organs such as of endometrium, cervix and lower genital tract. Though infrequent in developed countries of the world, the incidence of tubal tuberculosis in developing countries like India is estimated to be about 5%; concomitant involvement of endometrium is present in about 80% cases. It affects more commonly young women in their active reproductive life and the most common complaint is infertility.

MORPHOLOGIC FEATURES *Grossly*, the tube is dilated and contains purulent exudate though the fimbrial end

Figure 22.18 Ectopic tubal gestation. The lumen of the fallopian tube is dilated in the middle and contains dark tan, haemorrhagic and friable gestational tissue (sac, foetus and placenta).

is generally patent. The tubal peritoneum as well as the peritoneum in general is studded with yellowish tubercles.

Microscopically, typical caseating granulomas and chronic inflammation are identified in the tubal serosa, muscularis and mucosa.

ECTOPIC TUBAL PREGNANCY

The term ectopic tubal pregnancy is used for implantation of a fertilised ovum in the tube. Though ectopic pregnancy may rarely occur in the uterine horn, cornu, ovary and abdominal cavity, tubal pregnancy is by far the most common form of ectopic gestation (**Fig. 22.18**). Several factors which predispose to ectopic tubal pregnancy are: PID, previous tubal surgery, use of IUCD and congenital anomalies of the female genital tract. The most frequent site of tubal pregnancy is the ampullary portion and the least common is interstitial pregnancy. Ectopic tubal pregnancy is a potentially hazardous problem because of rupture which is followed by intraperitoneal haemorrhage.

TUMOURS AND TUMOUR-LIKE LESIONS

Tumours in the fallopian tubes are rare. Relatively more common are tumour-like conditions such as hydatids of Morgagni or parovarian cysts which are unilocular, thin-walled cysts hanging from the tubal fimbriae. Rare tumours include adenomatoid tumours, leiomyomas, teratomas, adenocarcinomas and choriocarcinoma all of which are similar in morphology to such tumours elsewhere in the body.

GIST BOX 22.5 Diseases of Fallopian Tube

- ▣ Pelvic inflammatory disease (PID) is a clinical syndrome characterised by signs and symptoms of ascending infection beginning in the vulva or vagina and spreading through the entire genital tract.
- ▣ Tuberculous salpingitis is almost always secondary to focus elsewhere in the body.
- ▣ Ectopic tubal pregnancy is implantation of a fertilised ovum in the tube.

OVARIES

NORMAL STRUCTURE

The ovaries are paired bean-shaped organs hanging from either tube by a mesentery called the mesovarium, the lateral suspensory ligament and the ovarian ligament. The lateral suspensory ligament of the ovary contains blood vessels, lymphatics and plexuses of nerves. Each ovary measures 2.5-5 cm in length, 1.5-3 cm in breadth and 0.7-1.5 cm in width and weighs 4-8 gm.

Histologically, the ovarian structure consists of covering by coelomic epithelium, outer cortex and inner medulla (**Fig. 22.19**).

Coelomic epithelium The surface of the ovary is covered by a single layer of cuboidal epithelial cells.

Cortex During active reproductive life, the cortex is broad and constitutes the predominant component of the ovary. The cortex contains numerous ovarian follicles and their derivative structures. Each follicle consists of a central *germ cell ovum* surrounded by specialised gonadal stroma. This stroma consists of *granulosa cells* encircling the ovum, and concentrically-arranged plump spindle-shaped *theca cells*. In infancy, the granulosa cells form a single layer of cuboidal cells around the ovum but later form several layers. Granulosa cells may form *Call-Exner bodies* normally as well as in certain neoplastic conditions. Call-Exner bodies have a central small round mass of dense pink material surrounded by a rosette of granulosa cells. The granulosa component is avascular and draws its nutrition from the highly vascular theca component. The theca component has 2 parts—luteinised theca layer called *theca interna*, and outer condensed ovarian stroma called *theca externa*. Granulosa cells and follicle-associated (luteinised) theca cells produce oestrogen. Fully mature ovarian follicle called *graafian follicle* bursts releasing the ovum and becomes transformed into corpus luteum which is the principal source of progesterone that brings about secretory endometrial pattern. The corpus luteum is later replaced by corpus albicans. In addition to specialised gonadal stroma and follicles, the cortex contains unspecialised ovarian stroma consisting of spindle-shaped connective tissue cells and smooth muscle fibres.

Medulla The ovarian medulla is primarily made up of connective tissue fibres, smooth muscle cells and numerous blood vessels, lymphatics and nerves. In addition, the medulla may also contain clusters of hilus cell (or hilar-Leydig cells) which may have androgenic role in contrast to oestrogenic role of the ovarian cortex.

The major pathologic lesions of the ovary are the non-neoplastic cysts and ovarian tumours.

NON-NEOPLASTIC CYSTS

The most common of the non-neoplastic cysts of the ovary are tubo-ovarian inflammatory mass (discussed already) and follicular and luteal cysts. Polycystic ovarian disease of Stein-Leventhal syndrome is another cause of cystic ovary.

FOLLICULAR AND LUTEAL CYSTS

Normally follicles and corpus luteum do not exceed a diameter of 2 cm. When their diameter is greater than 3 cm, they are termed as cysts.

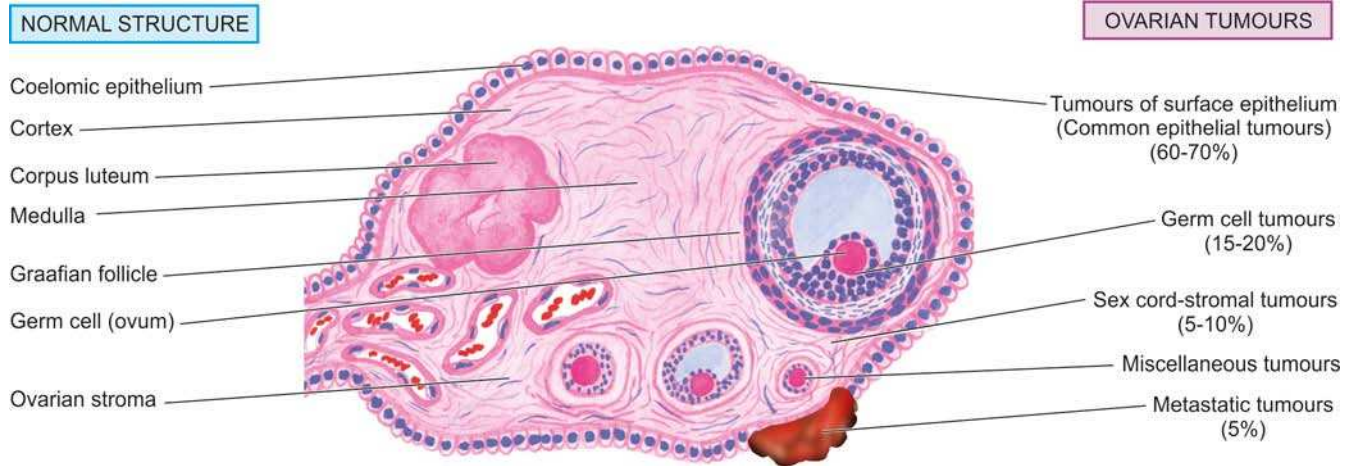

Figure 22.19 Structure of the ovary to illustrate origin of ovarian tumours.

◆ **Follicular cysts** are frequently multiple, filled with clear serous fluid and may attain a diameter upto 8 cm. When large, they produce clinical symptoms.

Histologically, they are lined by granulosa cells. Occasionally, however, there may be difficulty in distinguishing between a large cyst of coelomic epithelial origin (*serous cyst*) lined by flattened epithelial cells and a cyst of follicular origin. Such cases are appropriately designated as 'simple cysts.'

◆ **Luteal cysts** are formed by rupture and sealing of corpus haemorrhagicum. The wall of these cysts is composed of yellowish luteal tissue (*lutein* = yellow pigment).

Histologically, luteal cysts are commonly lined by luteinised granulosa cells. Lining by predominantly luteinised theca cells may also be seen in cystic ovaries in association with hydatidiform mole and choriocarcinoma, and rarely, in normal pregnancy. *Corpus albicans cyst* is a variant of corpus luteum cyst in which there is hyalinisation in the wall and distension of the cavity with fluid.

POLYCYSTIC OVARY DISEASE (STEIN-LEVENTHAL SYNDROME)

Polycystic ovary syndrome (PCOS) is a syndrome characterised by oligomenorrhoea, anovulation, infertility, hirsutism and obesity in young women having bilaterally enlarged and cystic ovaries. The principal biochemical abnormalities in most patients are excessive production of androgens, and low levels of pituitary follicle stimulating hormone (FSH). These endocrinologic abnormalities were previously attributed to primary ovarian dysfunction as evidenced by excellent results from wedge resection of the ovary. Current concept of pathogenesis of PCOS is the unbalanced release of FSH and LH by the pituitary. FSH is inhibited to low levels by testosterone but the level of LH is sufficient to cause luteinisation of ovarian theca and granulosa cells which then secrete androgen inappropriately and produce an abnormal state of anovulation. A hereditary basis for the syndrome has been suggested in some cases.

MORPHOLOGIC FEATURES Grossly, the ovaries are usually involved bilaterally and are at least twice the size of the normal ovary. They are grey-white in colour and studded with multiple small (0.5-1.5 cm in diameter) bluish cysts just beneath the cortex. The medullary stroma is abundant, solid and grey.

Histologically, the outer cortex is thick and fibrous. The subcortical cysts are lined by prominent luteinised theca cells and represent follicles in various stages of maturation but there is no evidence of corpus luteum.

OVARIAN TUMOURS

The ovary is third most common site of primary malignancy in the female genital tract, preceded only by endometrial and cervical cancer. Both benign and malignant tumours occur in the ovaries.

ETIOPATHOGENESIS

Unlike the two other female genital cancers (cervix and endometrium), not much is known about the etiology of ovarian tumours. However, a few risk factors have been identified as under:

1. **Nulliparity** There is higher incidence of ovarian cancer in unmarried women and married women with low or no parity.
2. **Heredity** About 10% cases of ovarian cancer occur in women with family history of ovarian or breast cancer. Women with hereditary breast-ovarian cancer susceptibility have mutation in tumour suppressor *BRCA* genes—*BRCA-1* (located on chromosome 17q) and *BRCA-2* (located on chromosome 13q). The risk in *BRCA-1* carriers is higher compared to that in *BRCA-2* carriers. Interestingly, men in such families have an increased risk of prostate cancer. In addition to *BRCA* mutation, other molecular abnormalities in ovarian cancers include mutation of *p53* tumour suppressor gene and overexpression of *ERBB-2* and *K-RAS* genes.
3. **Complex genetic syndromes** Besides the above two main factors, several complex genetic syndromes are associated with ovarian tumours:
 - i) *Lynch syndrome* associated with increased risk of ovarian cancer.

iv) *Nevoid basal cell carcinoma* with ovarian fibromas.

CLINICAL FEATURES AND CLASSIFICATION

In general, benign ovarian tumours are more common, particularly in young women between the age of 20 and 40 years, and account for 80% of all ovarian neoplasms. Malignant tumours may be primary or metastatic, ovary being a common site for receiving metastases from various other cancers. Primary malignant ovarian tumours are more common in older women between the age of 40 and 60 years.

Although certain specific tumours have distinctive features such as elaboration of hormones, most benign and malignant ovarian tumours are discovered when they grow sufficiently to cause abdominal discomfort and distension. Urinary tract and gastrointestinal tract symptoms are frequently associated due to compression by the tumour. Ascites is common in both benign and malignant ovarian tumours. Menstrual irregularities may or may not be present. Some ovarian tumours are bilateral. Malignant tumours usually spread beyond the ovary to other sites before the diagnosis is made.

A simplified classification proposed by the WHO with minor modifications has been widely adopted (**Table 22.6**). According to this classification, ovarian tumours arise from normally-occurring cellular components of the ovary (**Fig. 22.19**). Five major groups have been described:

- I. Tumours of surface epithelium (common epithelial tumours)
- II. Germ cell tumours
- III. Sex cord-stromal tumours
- IV. Miscellaneous tumours
- V. Metastatic tumours

I. TUMOURS OF SURFACE EPITHELIUM (COMMON EPITHELIAL TUMOURS)

Tumours derived from the surface (coelomic) epithelium called common epithelial tumours form the largest group of ovarian tumours. This group constitutes about 60-70% of all ovarian neoplasms and 90% of malignant ovarian tumours. The common epithelial tumours are of 3 major types—*serous*, *mucinous* and *endometrioid*, though mixtures of these epithelia may occur in the same tumour. These tumours frequently have prominent cystic component which may have a single or multiple loculations and hence the descriptive prefix *cystadeno-* in these tumours. In addition, surface epithelial tumours may differentiate along urothelium to form *Brenner tumour*, and along mesonephroid pattern forming *clear cell (mesonephroid) adenocarcinoma*.

Depending upon the aggressiveness, the surface epithelial tumours are divided into 3 groups: *clearly benign*, *clearly malignant*, and *borderline* (or *atypical proliferating* or *low-grade malignant tumours*). In general, the criteria for diagnosis of these 3 grades of aggressiveness are as follows (**Fig. 22.20**):

1. Clearly benign tumours are lined by a single layer of well-oriented columnar epithelium. Papillary projections, if present, are covered by the same type of epithelium without any invasion into fibrovascular stromal stalk.

2. Clearly malignant tumours have anaplastic epithelial component, multilayering, loss of basal polarity and unquestionable stromal invasion. The prognosis of these tumours is very poor.

3. Borderline (atypical proliferating) tumours or tumours with low malignant potential have some morphological features of malignancy, apparent detachment of cellular clusters from their site of origin and essential absence of stromal invasion. Morphological features of malignancy which may be present in varying combinations include: stratification (2-3 layers) of the epithelial cells but generally maintained basal polarity of nuclei, moderate nuclear abnormalities, and some mitotic activity. This group has a much better prognosis than frankly malignant tumours of the ovary.

Based on this categorisation of biologic behaviour, groups of surface epithelial ovarian tumours are described here.

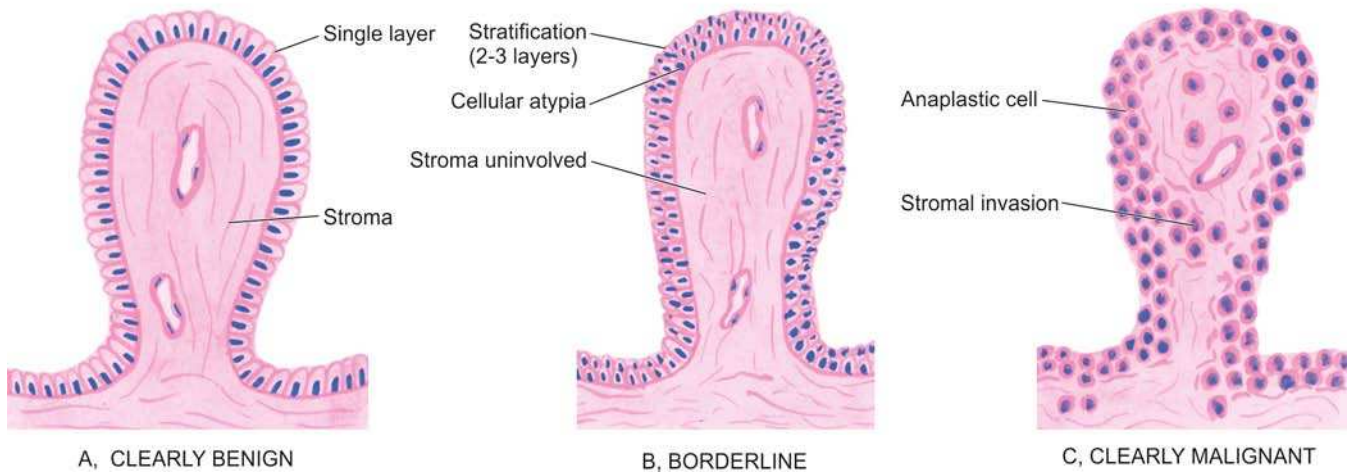

Figure 22.20 Diagrammatic representation of general histologic criteria to distinguish benign, borderline (atypical proliferating) and malignant surface epithelial tumours of the ovary.

Serous Tumours

Serous tumours comprise the largest group constituting about 50% of all surface ovarian tumours and 40% of malignant ovarian tumours. They are called serous tumours because of the presence of clear, watery, serous fluid in these predominantly cystic tumours. About 60% of serous tumours are benign, 15% borderline and 25% malignant. Only 20% of benign tumours occur bilaterally, whereas 65% of both borderline and malignant serous tumours have bilateral ovarian involvement. Serous tumours occur most commonly in 2nd to 5th decades of life, the malignant forms being more frequent in later life.

Histogenesis of the serous tumours is by metaplasia from the surface (coelomic) epithelium or mesothelium which differentiates along tubal-type of epithelium.

MORPHOLOGIC FEATURES *Grossly*, benign, borderline and malignant serous tumours are large (above 5 cm in diameter) and spherical masses. Small masses are generally unilocular while the larger serous cysts are multiloculated similar to the mucinous variety, or may have one large loculus and many daughter loculi in its wall. These serous variants contain serous fluid rather than the viscid fluid of mucinous tumours. *Malignant serous tumours* may have

solid areas in the cystic mass. Exophytic as well as intracystic papillary projections may be present in all grades of serous tumours but are more frequent in malignant tumours termed papillary serous cystadenocarcinomas (**Fig. 22.21**).

Histologically, the features are as follows:

1. Serous cystadenoma is characteristically lined by properly-oriented low columnar epithelium which is sometimes ciliated resembling tubal epithelium. Microscopic papillae may be found. Tumour having prominent stromal tissue are called serous cystadenofibroma.

2. Borderline (atypical proliferating) serous tumour usually has stratification (2-3 layers) of benign serous type of epithelium. There is detachment of cell clusters from their site of origin and moderate features of malignancy but there is absence of stromal invasion.

3. Serous cystadenocarcinoma has multilayered malignant cells which show loss of polarity, presence of solid sheets of anaplastic epithelial cells and definite evidence of stromal invasion. Papillae formations are more frequent in malignant variety and may be associated with psammoma bodies but mere presence of psammoma bodies is not indicative of malignancy (**Fig. 22.22**).

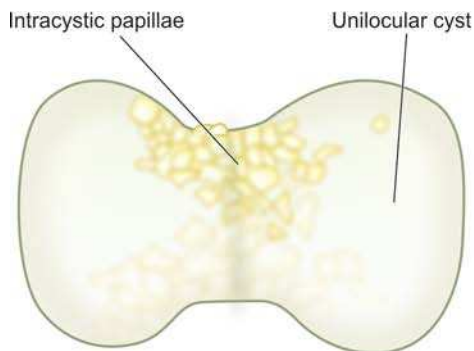

Figure 22.21 Papillary serous cystadenocarcinoma of the ovary. It shows an enlarged ovary replaced with a large unilocular cyst with intracystic papillae (arrow).

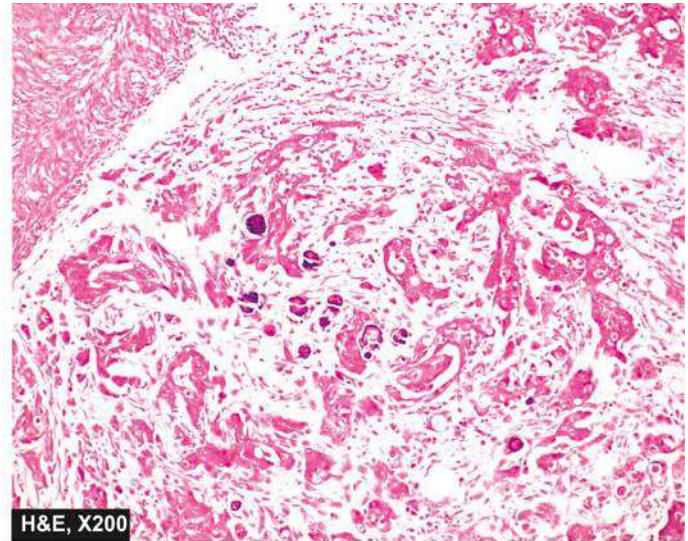

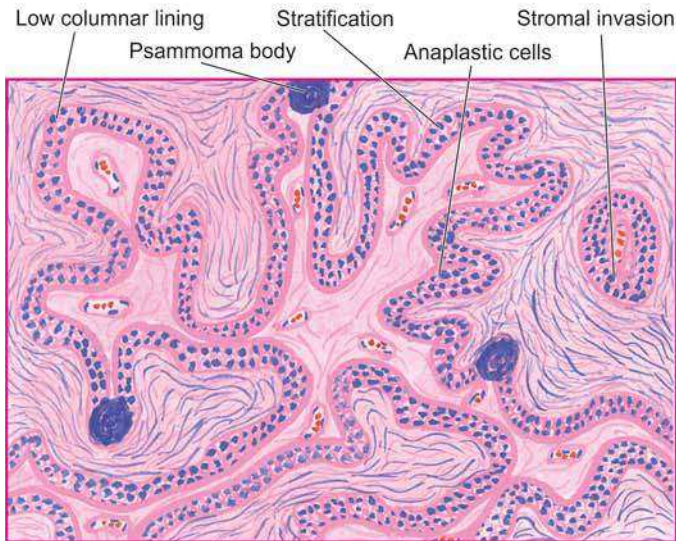

Figure 22.22 Papillary serous cystadenocarcinoma of the ovary. Microscopic features include stratification of low columnar epithelium lining the inner surface of the cyst and a few psammoma bodies. The stroma shows invasion by clusters of anaplastic tumour cells.

Mucinous Tumours

Mucinous tumours are somewhat less common than serous tumours and constitute about 30% of all ovarian tumours. Over 80% are benign, 10-15% are borderline (atypical proliferating) and 5% are malignant. These predominantly cystic tumours contain mucin which was previously described as pseudomucin. In mucinous tumours associated with mucinous ascites (i.e. *pseudomyxoma peritonei*), it is important to assess the state of appendix because mucinous tumours of ovary and appendix are clearly linked (page 562). As compared with serous tumours, mucinous tumours are more commonly unilateral. Benign mucinous tumours occur bilaterally in 5% of cases while vast majority of bilateral borderline and malignant mucinous tumours are metastatic to the ovaries. Thus, in general, the diagnosis of primary ovarian mucinous adenocarcinoma should be generally made after excluding metastatic tumours

to the ovary, while bilateral mucinous adenocarcinoma of the ovary is invariably metastatic deposits to the ovary. Another variant of mucinous carcinoma metastatic to the ovary having peculiar features, Krukenberg tumour, is discussed on page 740. Mucinous tumours occur principally between 2nd and 5th decades of life. Mucinous cystadenocarcinoma usually develops in women above the age of 40 years.

Histogenesis of mucinous tumours, in line with that of serous tumours, is by metaplasia from the coelomic epithelium that differentiates along endocervical type or intestinal type of mucosa.

MORPHOLOGIC FEATURES *Grossly*, mucinous tumours are much larger than serous tumours. They are smooth-surfaced cysts with characteristic multiloculations containing thick and viscid gelatinous fluid (**Fig. 22.23**).

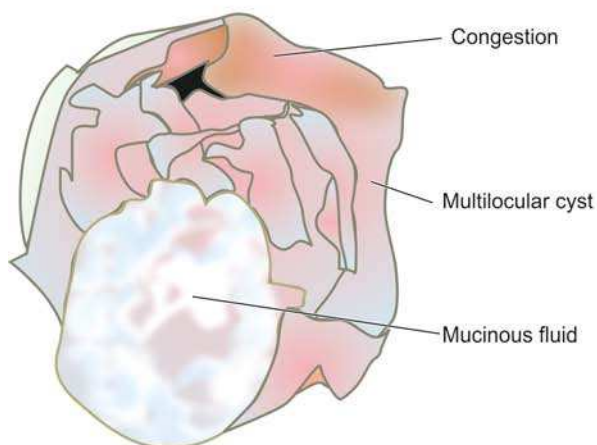

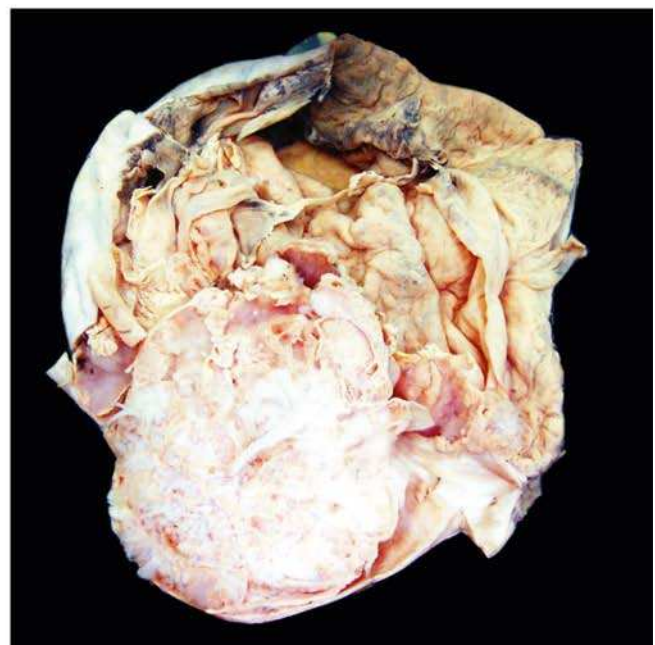

Figure 22.23 Mucinous cystadenoma of the ovary. Cut surface shows a very large multilocular cyst without papillae. The cyst wall shows presence of loculi containing gelatinous mucoid material.

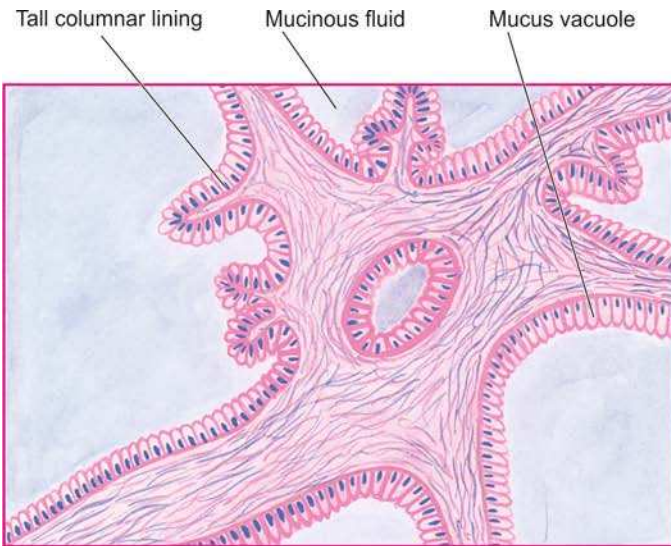

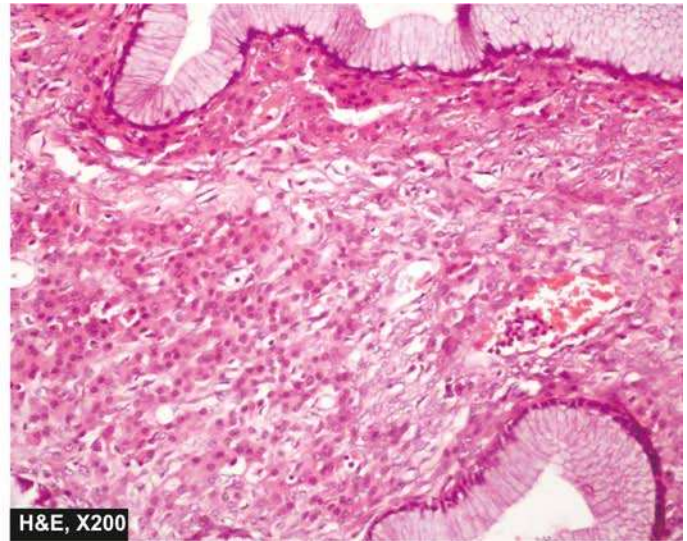

Figure 22.24 Mucinous cystadenoma of the ovary. The cyst wall and the septa are lined by a single layer of tall columnar mucin-secreting epithelium with basally-placed nuclei and large apical mucinous vacuoles.

Benign tumours generally have thin wall and septa dividing the loculi are also thin and often translucent, but malignant varieties usually have thickened areas. In younger patients, an element of teratoma may be recognised in the firm areas of the tumour.

Histologically, the most distinctive feature is the characteristic tall columnar nonciliated epithelium similar to intestinal type or endocervical (Mullerian) type, lining the loculi (Fig. 22.24). Other features are as under:

1. Mucinous cystadenoma is lined by a single layer of these cells having basal nuclei and apical mucinous vacuoles. There is very little tendency to papillary proliferation of the epithelium. Tumours with more abundant stroma are called mucinous cystadenofibromas.

2. Borderline (atypical proliferating) mucinous tumour is identified by the same histologic criteria as for borderline serous tumour i.e. stratification (usually 2-3 cell thick) of typical epithelium without stromal invasion.

3. Mucinous cystadenocarcinoma likewise is characterised by piling up of malignant epithelium, at places forming solid sheets, papillary formation, adenomatous pattern and infiltration into stroma with or without pools of mucin.

Salient contrasting features of serous and mucinous ovarian tumours are presented in Table 22.7.

Endometrioid Tumours

Endometrioid tumours comprise about 5% of all ovarian tumours. Most of them are malignant accounting for about 20% of all ovarian cancers. Benign and borderline forms are very rare. They are called endometrioid carcinomas because of the close resemblance of histologic pattern to that of uterine endometrioid adenocarcinoma. About 40% of ovarian endometrioid carcinomas have bilateral involvement. About 15-30% of cases have coexistent endometrial adenocarcinoma.

Histogenesis of these tumours in majority of cases is believed to be from ovarian coelomic epithelium differentiating towards endometrial type of epithelium. In view of presence of endometriosis in a few cases of endometrioid tumours, some authors have suggested malignant transformation of endometriosis.

MORPHOLOGIC FEATURES Grossly, these tumours are partly solid and partly cystic and may have foci of haemorrhages, especially in benign variety.

Histologically, the endometrioid adenocarcinoma is distinguished from serous and mucinous carcinomas by typical glandular pattern that closely resembles that of uterine endometrioid adenocarcinoma. There may be foci of squamous metaplasia justifying the diagnosis of adenoacanthoma. Papillary pattern and foci of serous and mucinous carcinoma may also be found. Benign variety closely resembles endometriosis with cystic change. There are no clearly defined criteria for borderline endometrioid tumours.

Clear Cell (Mesonephroid) Tumours

Clear cell (mesonephroid) tumours are almost always malignant and comprise about 5% of all ovarian cancers; rare benign variety is called *clear cell adenofibroma*. They are termed clear cell or mesonephroid carcinomas because of the close histologic resemblance to renal adenocarcinoma. They have also been called as mesonephroma or mesonephric carcinoma because of the questionable relationship to the mesonephric structures.

MORPHOLOGIC FEATURES Grossly, these tumours are large, usually unilateral, partly solid and partly cystic. Less than 10% are bilateral.

Histologically, clear cell or mesonephroid carcinoma is characterised by tubules, glands, papillae, cysts and solid sheets of tumour cells resembling cells of renal adenocarcinoma i.e. clear cells having abundant eosinophilic cytoplasm rich in glycogen.

Brenner Tumour

Brenner tumours are uncommon and comprise about 2% of all ovarian tumours. They are characteristically solid ovarian tumours. Less than 10% of Brenner tumours are bilateral. Most Brenner tumours are benign. Rarely, borderline form is encountered called *proliferating Brenner tumour* while the

Table 22.7 Contrasting features of serous and mucinous ovarian tumours.

| FEATURE | SEROUS TUMOURS | MUCINOUS TUMOURS |
|--------------------------|---|--|
| 1. Incidence | | |
| i) Overall | More common (50% of all ovarian tumours) | Less common (30% of all ovarian tumours) |
| ii) Benign-borderline | 75% | 95% |
| iii) Malignant | 25% | 5% |
| 2. Laterality | | |
| i) Unilateral | Less often | More frequent |
| ii) Benign-bilateral | 20% | 5% |
| iii) Malignant-bilateral | 65% (primary) | 95% (usually metastatic) |
| 3. Age | | |
| | 20-50 years | 40-60 years |
| 4. Mutation | | |
| | BRCA1, BRCA2, K-RAS | K-RAS |
| 5. Gross | | |
| i) Size | Moderate, >5 cm diameter | Much larger, heavier |
| ii) External projections | May be seen in all types | Infrequent |
| iii) Loculation | Generally unilocular, may contain daughter loculi in wall | Invariably multiloculated |
| iv) Luminal content | Serous or viscid fluid | Gelatinous fluid |
| 6. Microscopy | | |
| i) Lining cells | Tubal type (low columnar, ciliated), may contain foci of mucinos epithelium | Intestinal, or endocervical type (tall columnar, mucinous) |
| ii) Papillae | Frequent in all types, external or intacystic | In borderline or malignant tumours only |

one with carcinomatous change is termed *malignant Brenner tumour*.

Histogenesis of the tumour is from coelomic epithelium by metaplastic transformation into transitional epithelium (urothelium).

MORPHOLOGIC FEATURES *Grossly*, Brenner tumour is typically solid, yellow-grey, firm mass of variable size. Occasionally, a few scattered tiny cysts may be present on cut section.

Histologically, Brenner tumour consists of nests, masses and columns of epithelial cells, scattered in fibrous stroma of the ovary. These epithelial cells resemble urothelial cells which are ovoid in shape, having clear cytoplasm, vesicular nuclei with characteristic nuclear groove called 'coffee-bean' nuclei.

II. GERM CELL TUMOURS

Ovarian germ cell tumours arising from germ cells which produce the female gametes (i.e. ova) account for about 15-20% of all ovarian neoplasms. The neoplastic germ cells may follow one of the several lines of differentiation as shown in **Fig. 22.25**. Nearly 95% of them are benign and occur chiefly in young females, vast majority of them being benign cystic teratomas (dermoid cysts). The remainder are malignant germ cell tumours comprising a variety of morphologic forms occurring chiefly in children and young adults and are highly aggressive tumours. Most germ cell tumours of the ovaries have their counterparts in the testis (page 697) and sometimes in the mediastinum but their frequency differs from one site to the other. For instance, benign cystic teratoma or dermoid cyst so common in ovaries is extremely rare in the testis.

Teratomas

Teratomas are tumours composed of different types of tissues derived from the three germ cell layers—ectoderm, mesoderm

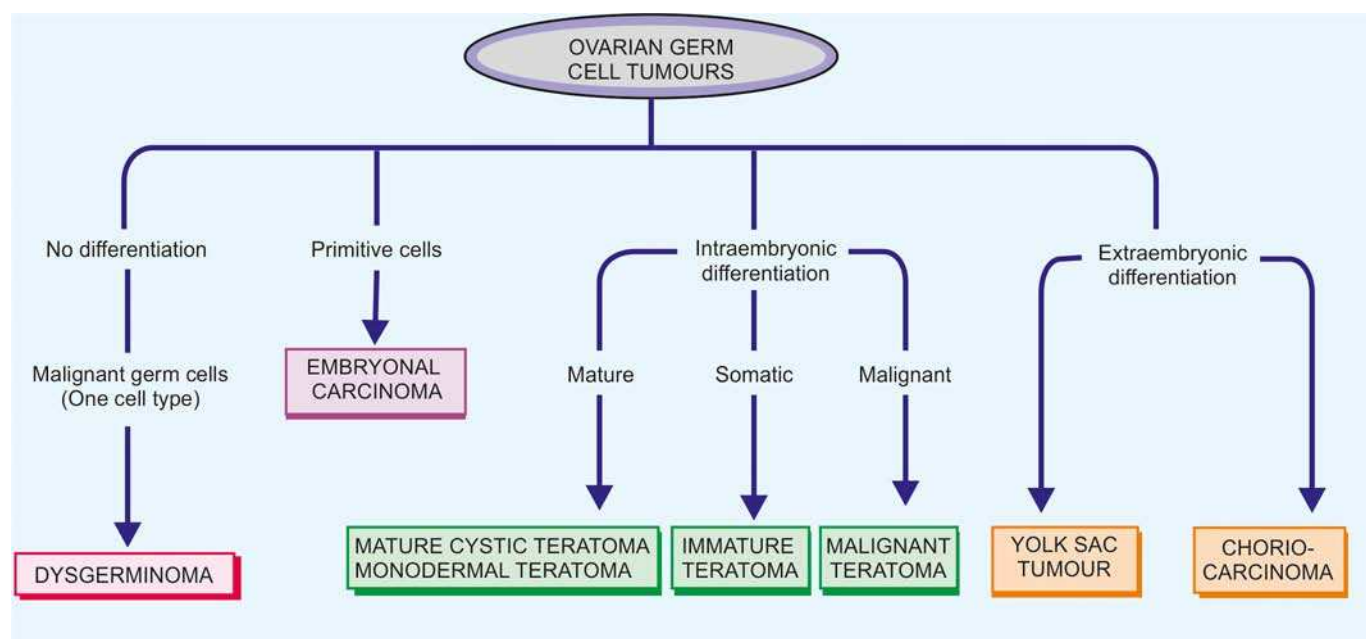

Figure 22.25 Histogenetic classification of germ cell tumours of the ovary.

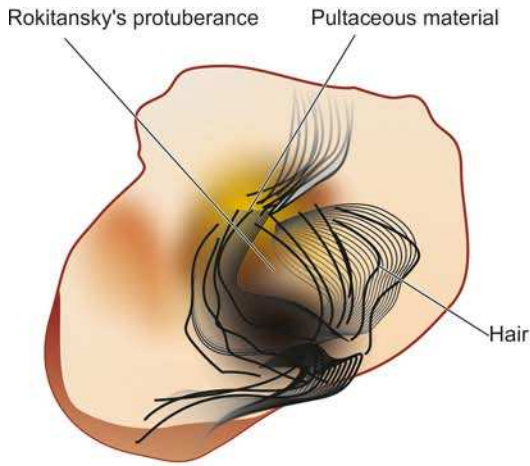

Figure 22.26 Dermoid cyst of the ovary. The ovary is enlarged and shows a large unilocular cyst containing hair, pultaceous material and bony tissue.

and endoderm, in varying combinations. In view of wide spectrum of tissue elements found in these teratomas, their *histogenesis* has been a matter of speculation for a long time. Cytogenetic studies have revealed that these tumours arise from a single germ cell (ovum) after its first meiotic division.

Teratomas are divided into 3 types: mature (benign), immature (malignant), and monodermal or highly specialised teratomas.

MATURE (BENIGN) TERATOMA Vast majority of ovarian teratomas are benign and cystic and have the predominant ectodermal elements, often termed clinically as *dermoid cyst*. Infrequently, mature teratoma may be solid and benign and has to be distinguished from immature or malignant teratoma. Benign cystic teratomas are more frequent in young women during their active reproductive life. The tumour is bilateral in 10% of cases.

Grossly, benign cystic teratoma or dermoid cyst is characteristically a unilocular cyst, 10-15 cm in diameter, usually lined by the skin and hence its name. On sectioning, the cyst is filled with paste-like sebaceous secretions and desquamated keratin admixed with masses of hair. The cyst wall is thin and opaque grey-white. Generally, in one area of the cyst wall, a solid prominence is seen (Rokitansky's protuberance) where tissue elements such as tooth, bone, cartilage and various other odd tissues are present (**Fig. 22.26**). Less often, the cyst may contain mucoid material.

Microscopically, the most prominent feature is the lining of the cyst wall by stratified squamous epithelium and its adnexal structures such as sebaceous glands, sweat glands and hair follicles (**Fig. 22.27**). Though ectodermal derivatives are most prominent features, tissues of

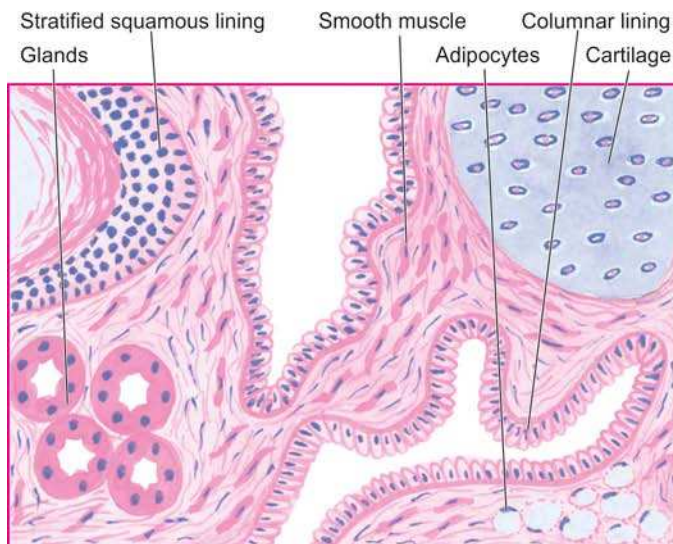

Figure 22.27 Benign cystic teratoma. Microscopy shows characteristic lining of the cyst wall by epidermis and its appendages. Islands of mature cartilage are also seen.

mesodermal and endodermal origin are also commonly present. Various other tissue components frequently found in teratomas are bronchus, intestinal epithelium, cartilage, bone, tooth, smooth muscle, neural tissue, salivary gland, retina, pancreas and thyroid tissue. Thus, viewing a benign cystic teratoma in different microscopic fields reveals a variety of mature differentiated tissue elements, producing *kaleidoscopic patterns*.

Less than 1% of patients with a dermoid cyst develop malignant transformation of one of the tissue components, most commonly squamous cell carcinoma.

IMMATURE (MALIGNANT) TERATOMA Immature or malignant teratomas of the ovary are rare and account for approximately 0.2% of all ovarian tumours. They are predominantly solid tumours that contain immature or embryonal structures in contrast to the mature or adult structures of the benign teratomas. They are more common in prepubertal adolescents and young women under 20 years of age.

Grossly, malignant teratoma is a unilateral solid mass which on cut section shows characteristic variegated appearance revealing areas of haemorrhages, necrosis, tiny cysts and heterogeneous admixture of various tissue elements.

Microscopically, parts of the tumour may show mature tissues, while most of it is composed of immature tissues having an embryonic appearance. Immature tissue elements may differentiate towards cartilage, bone, glandular structures, neural tissue etc, and are distributed in spindle-shaped myxoid or undifferentiated sarcoma cells. An important factor in grading and determining the prognosis of immature teratoma is the relative amount of immature neural tissue. Immature neural tissue can undergo maturation even at the site of metastases over a period of years. Immature teratoma may contain areas of other germ cell tumours such as endodermal sinus tumour, embryonal carcinoma and choriocarcinoma.

Grade I tumours having relatively mature elements and confined to the ovary have a good prognosis, whereas grade III immature teratomas with metastases have an extremely poor prognosis.

MONODERMAL (SPECIALISED) TERATOMA Monodermal or highly specialised teratomas are rare and include 2 important examples—struma ovarii and carcinoid tumour.

◆ **Struma ovarii** It is a teratoma composed exclusively of thyroid tissue, recognisable grossly as well as microscopically. Most often, the tumour has the appearance of a follicular adenoma of the thyroid. Rarely, struma ovarii may be hyperfunctioning and produce hyperthyroidism.

◆ **Carcinoid tumour** This is an ovarian teratoma arising from argentaffin cells of intestinal epithelium in the teratoma. Ovarian carcinoid may also hyperfunction and produce 5-HT and consequent carcinoid syndrome.

◆ **Struma-carcinoid** This is a rare combination of struma ovarii and ovarian carcinoid.

Dysgerminoma

Dysgerminoma is an ovarian counterpart of seminoma of the testes (page 697). Dysgerminomas comprise about 2% of all ovarian cancers. They occur most commonly in 2nd to 3rd decades. About 10% of them are bilateral. About 10% of patients with dysgerminoma have elevated hCG level in the plasma. All dysgerminomas are malignant and are extremely radiosensitive.

MORPHOLOGIC FEATURES **Grossly**, dysgerminoma is a solid mass of variable size. Cut section of the tumour is grey-white to pink, lobulated, soft and fleshy with foci of haemorrhages and necrosis.

Histologically, their structure is similar to that of seminoma of the testis (**Fig. 22.28**). The tumour cells are arranged in diffuse sheets, islands and cords separated by scanty fibrous stroma. The tumour cells are uniform in appearance and large, with vesicular nuclei and clear cytoplasm rich in glycogen. The fibrous stroma generally contains lymphocytic infiltrate and sometimes may have sarcoid granulomas.

Endodermal Sinus (Yolk Sac) Tumour

Endodermal sinus tumour or yolk sac tumour is the second most common germ cell tumour occurring most frequently in children and young women. More often, endodermal sinus tumour is found in combination with other germ cell tumours rather than in pure form. The tumour is rich in alphafetoprotein (AFP) and α -1-antitrypsin. The tumour is usually unilateral but may metastasise to the other ovary. It is a highly aggressive and rapidly growing tumour.

MORPHOLOGIC FEATURES **Grossly**, the tumour is generally solid with areas of cystic degeneration.

Histologically, like its testicular counterpart, the endodermal sinus tumour is characterised by the presence of

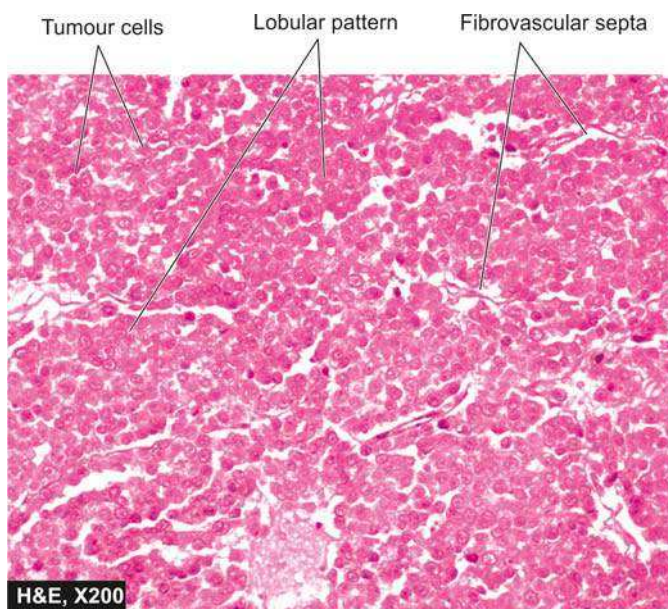

Figure 22.28 Dysgerminoma. The histologic appearance is identical to that of seminoma of the testis. Masses of large uniform tumour cells are separated by scanty fibrous stroma that is infiltrated by lymphocytes.

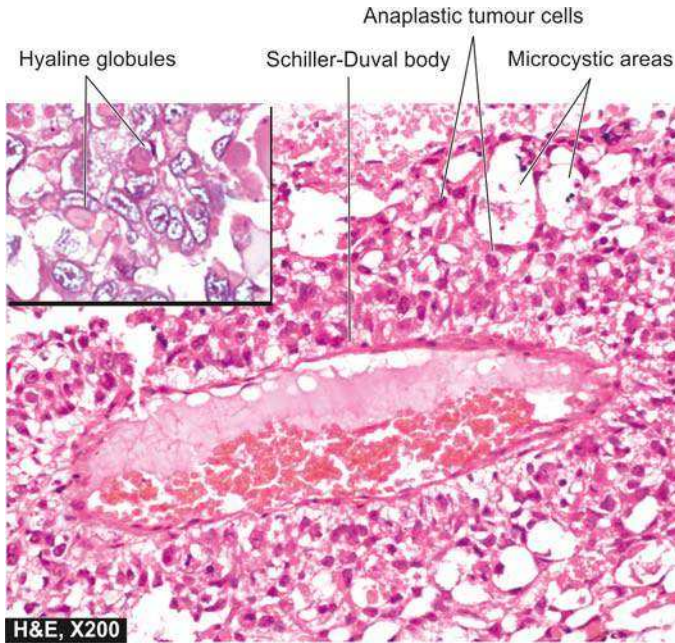

Figure 22.29 Endodermal sinus (yolk sac) tumour ovary. The tumour has microcystic pattern and has highly anaplastic tumour cells. Several characteristic Schiller-Duval bodies are present. Inset shows intra- and extracellular hyaline globules.

papillary projections having a central blood vessel with perivascular layer of anaplastic embryonal germ cells. Such structures resemble the endodermal sinuses of the rat placenta (Schiller-Duval body) from which the tumour derives its name. It is common to find intracellular and extracellular PAS-positive hyaline globules which are composed of AFP (**Fig. 22.29**).

Choriocarcinoma

Choriocarcinoma in females is of 2 types—*gestational and non-gestational*. Gestational choriocarcinoma of placental origin is more common and considered separately later (page 742). Pure primary non-gestational choriocarcinoma of ovarian origin is rare while its combination with other germ cell tumours is seen more often. The patients are usually young girls under the age of 20 years.

Morphologically, ovarian choriocarcinoma is identical to gestational choriocarcinoma. Ovarian choriocarcinoma is more malignant than that of placental origin and disseminates widely via bloodstream to the lungs, liver, bone, brain and kidneys. The marker for both types of choriocarcinoma is hCG.

Other Germ Cell Tumours

Certain other germ cell tumours occasionally encountered in the ovaries are embryonal carcinoma, polyembryoma and mixed germ cell tumours. All these tumours are morphologically identical to similar tumours occurring in the testes (page 697).

III. SEX CORD-STROMAL TUMOURS

Sex cord-stromal tumours of the ovaries comprise 5-10% of all ovarian neoplasms. They arise from specialised ovarian stromal cells of the developing gonads. Thus, these include tumours

originating from granulosa cells, theca cells and Sertoli-Leydig cells. Since sex cord-stromal cells have functional activity, most of these tumours elaborate steroid hormones which may have feminising effects or masculinising effects.

Granulosa-Theca Cell Tumours

Granulosa-theca cell tumours comprise about 5% of all ovarian tumours. The group includes: pure granulosa cell tumours, pure thecomas, combination of granulosa-theca cell tumours and fibromas.

GRANULOSA CELL TUMOUR Pure granulosa cell tumours may occur at all ages. These tumours invade locally but occasionally may have more aggressive and malignant behaviour. Recurrences after surgical removal are common. Most granulosa cell tumours secrete oestrogen which may be responsible for precocious puberty in young girls, or in older patients may produce endometrial hyperplasia, endometrial adenocarcinoma and cystic disease of the breast. Rarely, granulosa cell tumour may elaborate androgen which may have masculinising effect on the patient.

Grossly, granulosa cell tumour is a small, solid, partly cystic and usually unilateral tumour. Cut section of solid areas is yellowish-brown (**Fig. 22.30**).

Microscopically, the granulosa cells are arranged in a variety of patterns including micro- and macrofollicular, trabecular, bands and diffuse sheets. The microfollicular pattern is characterised by the presence of characteristic rosette-like structures, Call-Exner bodies, having central rounded pink mass surrounded by a circular row of granulosa cells (**Fig. 22.31**).

Morphologic appearance alone is a poor indicator of clinical malignancy but presence of metastases and invasion outside the ovary are considered better indicators of aggressive behaviour.

THECOMA Pure thecomas are almost always benign. They occur more frequently in postmenopausal women. Thecomas are typically oestrogenic. Endometrial hyperplasia, endometrial carcinoma and cystic disease of the breast are some of its adverse effects. Occasionally a thecoma may secrete androgen and cause virilisation.

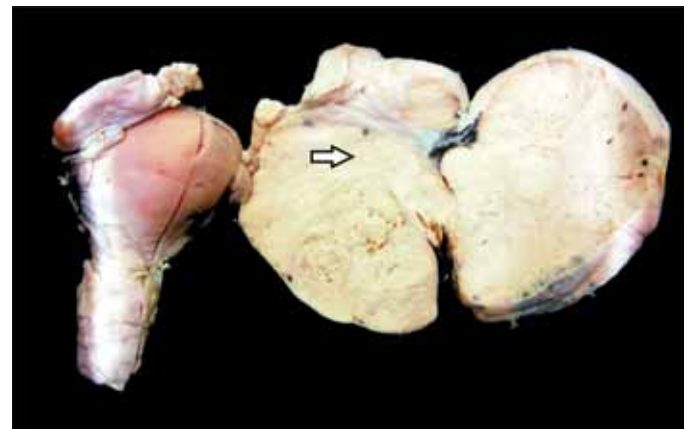

Figure 22.30 Solid ovarian tumour. Specimen of the uterus, cervix and adnexa shows enlarged ovarian mass (arrow) on one side which on cut section is solid, grey-white and firm.

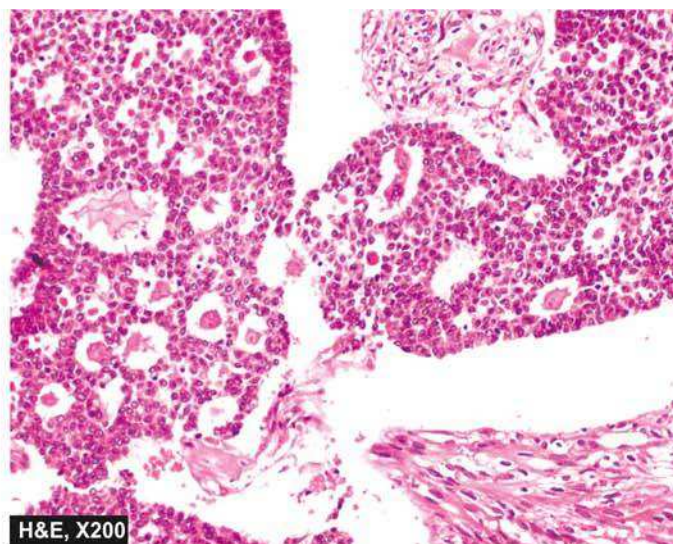

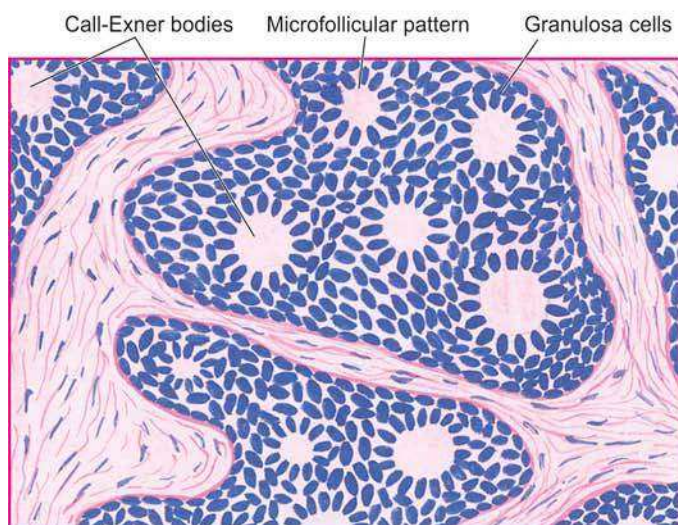

Figure 22.31 Granulosa cell tumour showing uniform granulosa cells and numerous rosette-like Call-Exner bodies containing central amorphous pink material surrounded by granulosa cells.

Grossly, thecoma is a solid and firm mass, 5-10 cm in diameter. Cut section is yellowish.

Microscopically, thecoma consists of spindle-shaped theca cells of the ovary admixed with variable amount of hyalinised collagen. The cytoplasm of theca cells is lipid-rich and vacuolated which reacts with lipid stains.

GRANULOSA-THECA CELL TUMOUR Mixture of both granulosa and theca cell elements in the same ovarian tumour is seen in some cases with elaboration of oestrogen.

FIBROMA Fibromas of the ovary are more common and account for about 5% of all ovarian tumours. These tumours are hormonally inert but some of them are associated with pleural effusion and benign ascites termed Meig's syndrome.

Grossly, these tumours are large, firm and fibrous, usually unilateral masses.

Histologically, they are composed of spindle-shaped well-differentiated fibroblasts and collagen. Sometimes, combination of fibroma and thecoma is present called fibrothecoma.

Sertoli-Leydig Cell Tumours (Androblastoma, Arrhenoblastoma)

Tumours containing Sertoli and Leydig cells in varying degree of maturation comprise Sertoli-Leydig cell tumours, also called androblastomas or arrhenoblastomas. Characteristically, they produce androgens and masculinise the patient. Less often, they may elaborate oestrogen. Their peak incidence is in 2nd to 3rd decades of life.

Grossly, Sertoli-Leydig cell tumour resembles a granulosa-theca cell tumour.

Histologically, these tumours recapitulate to some extent the structure of the testis. Three histologic types are distinguished:

1. *Well-differentiated* androblastoma composed almost entirely of Sertoli cells or Leydig cells forming well-defined tubules.

2. *Tumours with intermediate differentiation* have a biphasic pattern with formation of solid sheets in which abortive tubules are present.

3. *Poorly-differentiated or sarcomatoid variety* is composed of spindle cells resembling sarcoma with interspersed scanty Leydig cells.

Gynandroblastoma

Gynandroblastoma is an extremely rare tumour in which there is combination of patterns of both granulosa-theca cell tumour and Sertoli-Leydig cell tumour. The term gynandroblastoma stands for combination of female (*gyn*) and male (*andro*).

IV. MISCELLANEOUS TUMOURS

LIPID CELL TUMOURS There is a small group of ovarian tumours that appears as soft yellow or yellow-brown nodules which on histologic examination are composed of large lipid-laden cells. These cells resemble Leydig, lutein and adrenal cortical cells. The examples of these tumours are: hilus cell tumours, adrenal rest tumours and luteomas. These tumours elaborate steroid hormones and are responsible for various endocrine dysfunctions such as Cushing's syndrome and virilisation.

GONADOBLASTOMA This is a rare tumour occurring exclusively in dysgenetic gonads, more often in phenotypic females and in hermaphrodites. Dysfunctions include virilism, amenorrhoea and abnormal external genitalia.

Microscopically, gonadoblastoma is composed of mixture of germ cell and sex cord components.

V. METASTATIC TUMOURS

About 10% of ovarian cancers are secondary carcinomas. Metastasis may occur by lymphatic or haematogenous route but direct extension from adjacent organs (e.g. uterus, fallopian tube and sigmoid colon) too occurs frequently. Bilaterality of the tumour is the most helpful clue to diagnosis

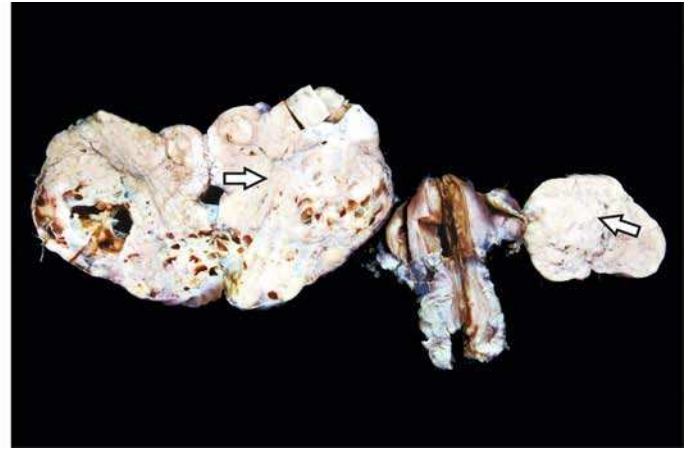

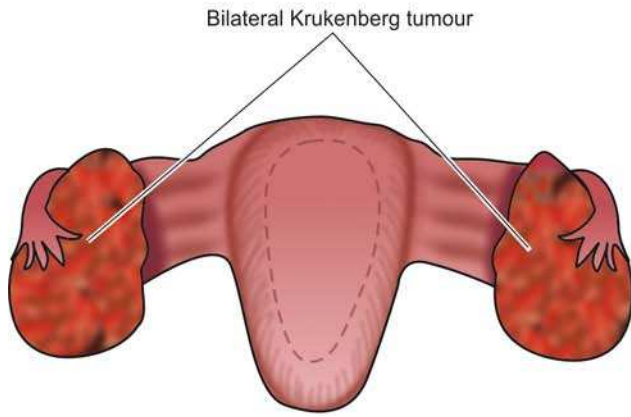

Figure 22.32 Krukenberg tumour showing characteristic bilateral metastatic ovarian cancer (arrow) having firm white appearance.

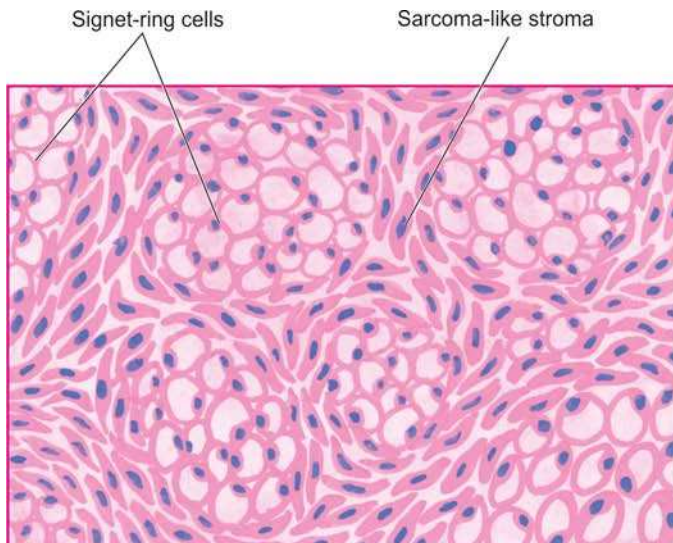

of metastatic tumour. Most common primary sites from where metastases to the ovaries are encountered are: carcinomas of the breast, genital tract, gastrointestinal tract (e.g. stomach, colon appendix, pancreas, biliary tract) and haematopoietic malignancies.

Krukenberg Tumour

Krukenberg tumour is a distinctive bilateral tumour metastatic to the ovaries by transcoelomic spread. The tumour is generally secondary to a gastric carcinoma (page 541) but other primary sites where signet ring carcinomas occur (e.g. colon, appendix and breast) may also produce Krukenberg tumour in the ovary.

Grossly, Krukenberg tumour forms moderately large, rounded or kidney-shaped, firm, multinodular masses in both ovaries. Cut section shows grey-white to yellow, firm, fleshy tumour and may have areas of haemorrhage and necrosis (**Fig. 22.32**).

Microscopically, it is characterised by the presence of mucin-filled signet ring cells which may lie singly or in clusters. It is accompanied by cellular proliferation of ovarian stroma in a storiform pattern (**Fig. 22.33**).

GIST BOX 22.6

Diseases of Ovaries

- ▣ Non-neoplastic lesions of the ovary are tubo-ovarian inflammatory mass, follicular and luteal cysts, and polycystic ovarian disease of Stein-Leventhal syndrome.
- ▣ Tumours derived from the surface (coelomic) epithelium called common epithelial tumours form the largest group of ovarian tumours and include serous and mucinous tumours which may be benign, borderline or malignant. Other types are endometrioid, clear cell type and Brenner.
- ▣ Germ cell tumours of the ovary are similar to testicular germ cell tumours but nearly 95% of them are benign and occur chiefly in young females, vast majority of them being benign cystic teratomas (dermoid cysts).
- ▣ Sex cord-stromal tumours of the ovaries are less frequent and include tumours originating from granulosa cells, theca cells and Sertoli-Leydig cells.
- ▣ About 10% of ovarian cancers are secondary carcinomas, an important example of bilateral signet ring carcinoma metastatic to ovary from bowel called Krukenberg's tumour.

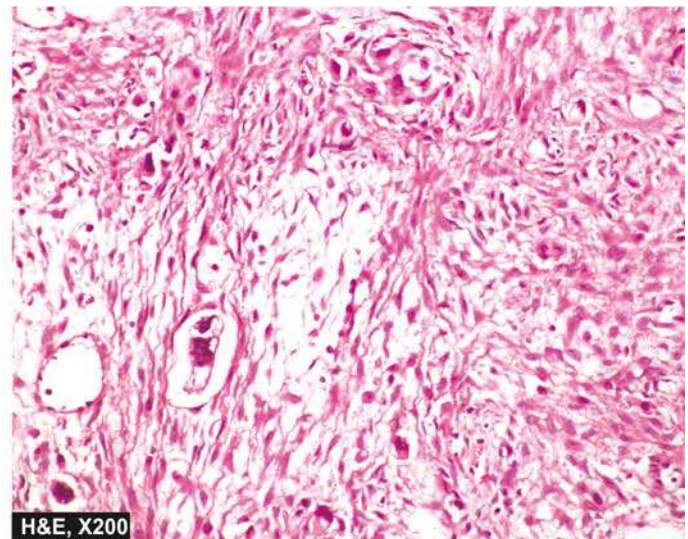

Figure 22.33 Krukenberg tumour. Histologic features include mucin-filled signet-ring cells and richly cellular proliferation of the ovarian stroma.

Table 22.8 FIGO clinical staging of carcinoma of the ovary.

| | | |
|-----------|------|---|
| Stage I | I | Growth limited to ovaries. |
| | IA | Growth limited to one ovary; no ascites; capsule intact. |
| | IB | Growth limited to both ovaries; no ascites; capsule intact. |
| | IC | Tumour classified as either stage IA or IB but with tumour in the surface of one or both ovaries, or with ascites containing malignant cells. |
| Stage II | II | Growth involving one or both ovaries, with pelvic extension. |
| | IIA | Extension and/or metastases to the uterus and/or tubes. |
| | IIB | Extension to other pelvic tissues. |
| | IIC | Tumour either stage IIA or IIB but with tumour on the surface of one or both ovaries, or with capsule ruptured, or with ascites containing malignant cells. |
| Stage III | III | Tumour invading one or both ovaries with peritoneal implants outside the pelvis. |
| | IIIA | Tumour grossly limited to the true pelvis with negative nodes but with microscopic seeding of abdominal peritoneal surfaces. |
| | IIIB | Tumour of one or both ovaries with histologically confirmed implants of abdominal peritoneal surfaces, not exceeding 2 cm in diameter; nodes are negative. |
| | IIIC | Abdominal implants greater than 2 cm in diameter and/or positive retroperitoneal or inguinal nodes. |
| | IV | Growth involving one or both ovaries, with distant metastases. |

PLACENTA

NORMAL STRUCTURE

At term, the normal placenta is blue red, rounded, flattened and discoid organ 15-20 cm in diameter and 2-4 cm thick. It weighs 400-600 gm or about one-sixth the weight of the newborn. The umbilical cord is about 50 cm long and contains two umbilical arteries and one umbilical vein attached at the foetal surface. The placenta is derived from both maternal and foetal tissues. The *maternal portion* of the placenta has irregular grooves dividing it into cotyledons which are composed of sheets of decidua basalis and remnants of blood vessels. The *foetal portion* of the placenta is composed of numerous functional units called chorionic villi and comprise the major part of placenta at term. The villi consist of a loose fibrovascular stromal core and a few phagocytic (Höffbauer's) cells. The villous core is covered by an inner layer of cytotrophoblast and outer layer of syncytiotrophoblast. The basement membrane separating the foetal capillaries in the villous core and the trophoblast forms zones where nutrients and metabolites are transported between the mother and the foetus. Such zones are called vasculosyncytial membranes. The placenta secretes a number of hormones and enzymes into the maternal blood. These include: human chorionic gonadotropin (hCG), human placental lactogen (HPL), chorionic thyrotropin and adreno-

corticotropin hormone which partake in oestrogen and progesterone metabolism.

Diseases related to pregnancy and placenta are numerous and form the subject matter of discussion in obstetrics. Certain conditions such as inflammation of the placenta and chorionic membranes (placentitis and chorioamnionitis), placental gross abnormalities (e.g. placenta accreta, placenta praevia and twin placenta etc), toxæmia of pregnancy (eclampsia and pre-eclampsia) and products of gestation seen in abortions need mere mention only here. However, gestational trophoblastic diseases resulting from benign and malignant overgrowth of trophoblast—hydatidiform mole (complete and partial mole) and choriocarcinoma respectively, are significant morphologic lesions and are discussed below and their features contrasted in **Table 22.9**.

HYDATIDIFORM MOLE

The word 'hydatidiform' means *drop of water* and 'mole' for a *shapeless mass*. Hydatidiform mole is defined as an abnormal placenta characterised by 2 features:

- i) Enlarged, oedematous and hydropic change of the chorionic villi which become vesicular.
- ii) Variable amount of circumferential trophoblastic proliferation.

Most workers consider hydatidiform mole as a benign tumour of placental tissue with potential for developing into choriocarcinoma, while some authors have described mole as a degenerative lesion though capable of neoplastic change. The incidence of molar pregnancy is high in teenagers and in older women. For unknown reasons, frequency of hydatidiform mole varies in different regions of the world; the incidence in Asia and Central America is about 10 times higher than in the United States. The incidence is higher in poorer socioeconomic class of people.

Hydatidiform mole may be non-invasive or invasive. Two types of non-invasive moles are distinguished—complete (classic) and partial. *Pathogenesis* of these 2 forms is different:

- ◆ **Complete (classic) mole** by cytogenetic studies has been shown to be derived from the father (androgenesis) and has 46, XX or rarely 46, XY chromosomal pattern. Complete mole bears relationship to choriocarcinoma.
- ◆ **Partial mole** is mostly triploid (i.e. 69,XXY or 69,XXX) and rarely tetraploid. Partial mole rarely develops into choriocarcinoma.

Clinically, the condition appears in 4th-5th month of gestation and is characterised by increase in uterine size, vaginal bleeding and often with symptoms of toxæmia. Frequently, there is history of passage of grape-like masses per vaginam. About 1% of women with molar pregnancy develop it again in a subsequent pregnancy.

The single most significant *investigation* forming the mainstay of management is the serial determination of β -hCG which is elevated more in both blood and urine as compared with the levels in normal pregnancy. Removal of the mole is accompanied by fall in β -hCG levels. A more ominous behaviour is associated with no fall in β -hCG levels after expulsion of the mole. About 10% of patients with complete mole develop into invasive moles and 2.5% into choriocarcinoma.

MORPHOLOGIC FEATURES The pathologic findings in non-invasive (complete and partial) and invasive mole are different:

Table 22.9 Comparative features of major forms of gestational trophoblastic disease.

| FEATURE | COMPLETE MOLE | PARTIAL MOLE | CHORIOCARCINOMA |
|---|--|---------------------------------------|---|
| 1. <i>Karyotype</i> | 46,XX or rarely 46,XY | Triploid i.e. 69,XXY or 69,XXX | 46,XY or variable |
| 2. <i>Clinical findings</i> | | | |
| i) <i>Diagnosis</i> | Mole | Missed abortion | Abortion; molar, ectopic or normal pregnancy |
| ii) <i>Vaginal bleeding</i> | Marked | Mild | Marked, abnormal |
| iii) <i>Uterus size</i> | Large | Small | Generally not bulky |
| 3. <i>hCG levels</i> | | | |
| i) <i>Serum hCG</i> | High | Low | Persistently high |
| ii) <i>hCG in tissues</i> | Marked | Mild | Localised in syncytiotrophoblast only |
| 4. <i>Embryo</i> | Not present | May be present | Not present |
| 5. <i>Gross appearance</i> | | | |
| i) <i>Vesicles</i> | Large and regular | Smaller and irregular | No vesicles |
| ii) <i>Villi</i> | Present | Present | Always absent |
| 6. <i>Microscopy</i> | | | |
| i) <i>Villous size</i> | Uniform | Variable | None present |
| ii) <i>Hydropic villi</i> | All | Some | None |
| iii) <i>Trophoblastic proliferation</i> | Circumferential, all three (cytotrophoblast, intermediate trophoblast and syncytiotrophoblast) | Focal, syncytiotrophoblast only | Both cytotrophoblast and syncytiotrophoblast, bizarre forms |
| iv) <i>Atypia</i> | Minimal | Minimal | Marked |
| v) <i>Blood vessels</i> | Generally absent | Present | Present and abnormal |
| vi) <i>Necrosis</i> | Absent | Generally absent | Present |
| 7. <i>Persistence after initial therapy</i> | 20% | 7% | May metastasise rapidly if not treated |
| 8. <i>Behaviour</i> | 2% may develop choriocarcinoma | Choriocarcinoma almost never develops | Survival rate with chemotherapy 70% |

COMPLETE (CLASSIC) MOLE *Grossly*, the uterus is enlarged and characteristically filled with grape-like vesicles up to 3 cm in diameter (Fig. 22.34). The vesicles contain clear watery fluid. Rarely, a macerated foetus may be found. *Microscopically*, the features are quite typical. These are as under (Fig. 22.35):

- i) Large, round, oedematous and acellular villi due to hydropic degeneration forming central cisterns.
- ii) Decreased vascularity of villous stroma.
- iii) Trophoblastic proliferation in the form of masses and sheets of both cytotrophoblast and syncytiotrophoblast, generally circumferential around the villi.

PARTIAL MOLE *Grossly*, the uterus is generally smaller than expected and contains some cystic villi, while part of the placenta appears normal. A foetus with multiple malformations is often present.

Microscopically, some of the villi show oedematous change while others are normal or even fibrotic. Trophoblastic proliferation is usually slight and focal.

INVASIVE (DESTRUCTIVE) MOLE (CHORIOADENOMA DESTRUENS) *Grossly*, invasive mole shows invasion of the molar tissue into the uterine wall which may be a source

of haemorrhage. Rarely, molar tissue may invade the blood vessels and reach the lungs.

Microscopically, the lesion is benign and identical to classic mole but has potential for haemorrhage. It is always associated with persistent elevation of β -hCG levels.

CHORIOCARCINOMA

Gestational choriocarcinoma is a highly malignant and widely metastasising tumour of trophoblast (non-gestational choriocarcinoma is described on page 738). Approximately 50% of cases occur following hydatidiform mole, 25% following spontaneous abortion, 20% after an otherwise normal pregnancy, and 5% develop in an ectopic pregnancy. Choriocarcinoma follows the geographic pattern of hydatidiform mole, being more common in Asia and Africa than in the United States and Europe.

Clinically, the most common complaint is vaginal bleeding following a normal or abnormal pregnancy. Occasionally, the patients present with metastases in the brain or lungs. The diagnosis is confirmed by demonstration of persistently high levels of β -hCG in the plasma and urine. Widespread

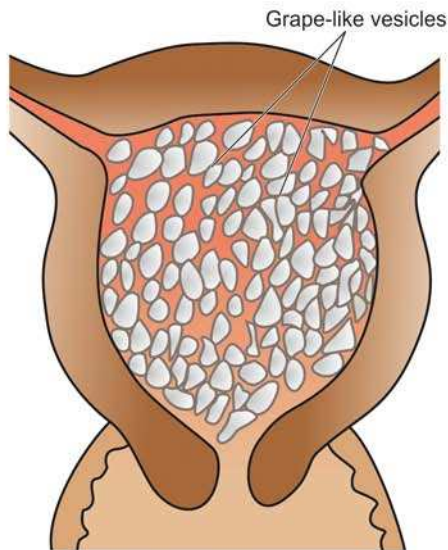

Figure 22.34 Uterus containing hydatidiform mole. The specimen shows numerous, variable-sized, grape-like translucent vesicles containing clear fluid. Tan areas of haemorrhage are also seen.

haematogenous metastases are early and frequent in choriocarcinoma if not treated; these are found chiefly in the lungs, vagina, brain, liver and kidneys.

MORPHOLOGIC FEATURES *Grossly*, the tumour appears as haemorrhagic, soft and fleshy mass. Sometimes, the tumour may be small, often like a blood clot, in the uterus.

Microscopically, the characteristic features are as under:

- i) Absence of identifiable villi.
- ii) Masses and columns of highly anaplastic and bizarre cytotrophoblast and syncytiotrophoblast cells which are intermixed.
- iii) Invariable presence of haemorrhages and necrosis.

- iv) Invasion of the underlying myometrium and other structures, blood vessels and lymphatics.

Gestational choriocarcinoma and its metastases respond very well to chemotherapy while non-gestational choriocarcinoma is quite resistant to therapy and has worse prognosis. With hysterectomy and chemotherapy, the cure rate of choriocarcinoma has remarkably improved from dismal 20 to 70% 5-year survival rate and almost total cure in localised tumours. The effectiveness of treatment is also monitored by serial β -hCG determinations. Death from choriocarcinoma is generally due to fatal haemorrhage in the CNS or lungs or from pulmonary insufficiency.

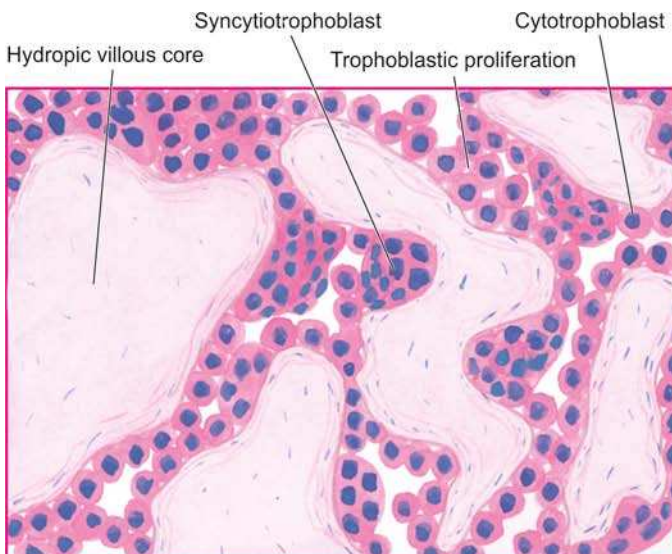

Figure 22.35 Hydatidiform mole characterised by hydropic and avascular enlarged villi with trophoblastic proliferation in the form of masses and sheets.

GIST BOX 22.7

Diseases of Placenta

- ▣ Hydatidiform mole is a benign or degenerative condition of placenta characterised by hydropic change in the villi and circumferential trophoblastic proliferation. It may be non-invasive or invasive, the former being complete (classic) or partial mole.
- ▣ Gestational choriocarcinoma is a highly malignant and widely metastasising tumour of trophoblast but responds better to chemotherapy compared from gonadal choriocarcinoma.

CLINICAL CASE 23

A 50 years old woman gives history of progressive vaginal discharge with a foul odour for 6 months. There is also history of post-coital spotting. She had menopause 5 years back. She also has right back pain and swelling in right leg.

On per vaginum and speculum examination, the cervix is ulcerated and bleeds on touch.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 912 (Appendix II)

23

The Breast

NORMAL STRUCTURE

The breast is a modified skin appendage which is functional in the females during lactation but is rudimentary in the males. Microanatomy of the breast reveals 2 types of tissue components: *epithelial* and *stromal* (Fig. 23.1). In a fully-developed non-lactating female breast, the epithelial component comprises less than 10% of the total volume but is more significant pathologically since majority of lesions pertain to this portion of the breast.

EPITHELIAL COMPONENT The epithelial component of the breast consists of 2 major parts: terminal duct-lobular unit (TDLU) which performs the main secretory function during lactation, and large duct system which performs the function of collection and drainage of secretions; both are interconnected to each other.

The breast is divided into about 20 lobes. Each lobe consists of *breast lobules* which drain their secretions through its *collecting duct system* and opens into the nipple through its own main excretory duct, *lactiferous duct*. The segment

of lactiferous duct subjacent to the nipple shows a small dilatation called *lactiferous sinus*. Each lactiferous duct has its own collecting duct system which has branches of smaller diameter, ultimately terminating peripherally as *terminal ducts* (or TDLU) in the breast lobules.

The entire ductal-lobular epithelial system has bilayered lining: the inner epithelium with secretory and absorptive function, and an outer supporting myoepithelial lining, both having characteristic ultrastructure and immunoreactivity. The inner epithelium stains positive for epithelial membrane antigen (EMA) and lactalbumin while the myoepithelium is positive for smooth muscle actin (SMA) and S-100.

STROMAL COMPONENT The supportive stroma of the breast consists of variable amount of loose connective tissue and adipose tissue during different stages of reproductive life. The stromal tissue of the breast is present at 2 locations: intralobular and interlobular stroma. *Intralobular stroma* encloses each lobule, and its acini and ducts, and is chiefly made of loose connective tissue, myxomatous stroma and a few scattered lymphocytes. *Interlobular stroma* separates one

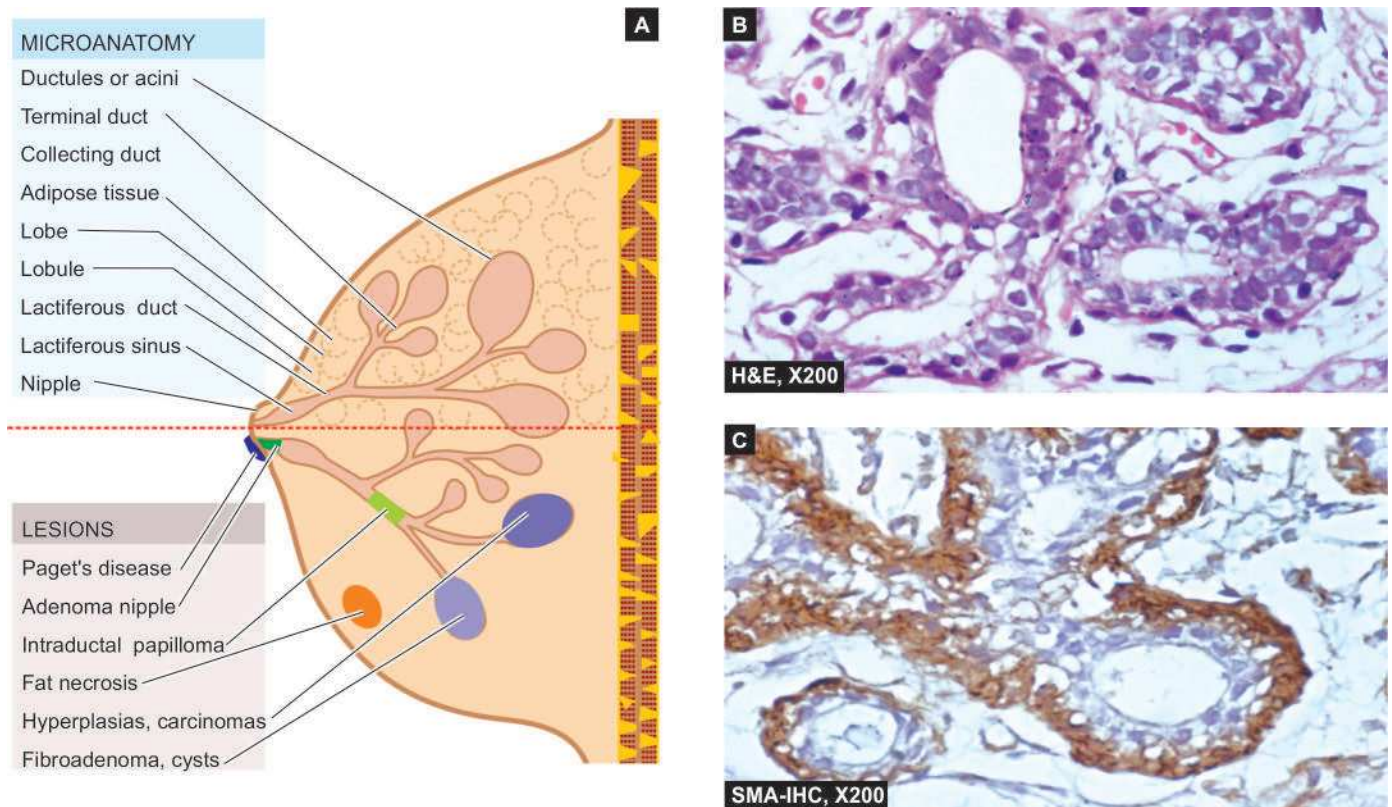

Figure 23.1 A, Microanatomy of the breast and major lesions at various sites. B, Normal terminal duct-lobular unit (TDLU). C, SMA-100 immunostain for myoepithelium.

lobule from the other and is composed mainly of adipose tissue and some loose connective tissue.

The most important disease of the breast is cancer. However, there are a few inflammatory lesions, benign tumours and tumour-like lesions which may be confused clinically with breast cancer. These pathologic lesions are described first, followed by an account of breast cancer.

NON-NEOPLASTIC CONDITIONS

These conditions in the breast include inflammations, fibrocystic change and gynaecomastia.

INFLAMMATIONS

Inflammation of the breast is called mastitis. Important types of mastitis are acute mastitis and breast abscess, chronic mastitis, mammary duct ectasia (or plasma cell mastitis), traumatic fat necrosis and galactocele.

ACUTE MASTITIS AND BREAST ABSCESS

Acute pyogenic infection of the breast occurs chiefly during the first few weeks of lactation and sometimes by eczema of the nipples. Bacteria such as staphylococci and streptococci gain entry into the breast by development of cracks and fissures in the nipple. Initially a localised area of acute inflammation is produced which, if not effectively treated, may cause single or multiple breast abscesses. Extensive necrosis and replacement by fibrous scarring of the breast with retraction of the nipple may result.

GRANULOMATOUS MASTITIS

Although chronic non-specific mastitis is uncommon, chronic granulomatous inflammation in the breast may occur as a result of the following:

1. *Systemic non-infectious granulomatous disease* e.g. as part of systemic sarcoidosis, Wegener's granulomatosis.
2. *Infections* e.g. tuberculosis which is not so uncommon in developing countries like India and may be misdiagnosed clinically as breast cancer owing to axillary nodal involvement. Tubercle bacilli reach the breast by haematogenous, lymphatic or direct spread, usually from the lungs or pleura. Pathologically, typical caseating tubercles with discharging sinuses through the surface of the breast are found. ZN staining may demonstrate acid-fast bacilli. Fungal infection of the breast may occur in immunocompromised patients.
3. *Silicone breast implants* implanted on breast cancer patients after mastectomy or as breast augmentation cosmetic surgery may rupture or silicone may slowly leak into surrounding breast tissue. This incites chronic inflammatory reaction of lymphocytes, macrophages and foreign body giant cells. Eventually, a surrounding fibrous capsule forms and after a long period it may even be calcified.
4. *Idiopathic granulomatous mastitis* is an uncommon form of reaction around lobules and ducts in the absence of any known etiology. Exact pathogenesis is not known but probably it is a form of hypersensitivity reaction to luminal secretion of the breast epithelium during lactation.

MAMMARY DUCT ECTASIA (PLASMA CELL MASTITIS)

Mammary duct ectasia is a condition in which one or more of the larger ducts of the breast are dilated and filled with

inspissated secretions. These are associated with periductal and interstitial chronic inflammatory changes. Duct ectasia affects women in their 4th to 7th decades of life. The patients may remain asymptomatic or there may be nipple discharge, retraction of the nipple due to fibrous scarring and clinically palpable dilated ducts in the subareolar area. The lesion may be mistaken for carcinoma of the breast. The etiology of the condition remains unknown but it appears to begin with periductal inflammation followed by destruction of the elastic tissue to cause ectasia and periductal fibrosis.

MORPHOLOGIC FEATURES *Grossly*, the condition appears as a single, poorly-defined indurated area in the breast with ropiness on the surface. Cut section shows dilated ducts containing cheesy inspissated secretions.

Histologically, the features are as under:

1. Dilated ducts with either necrotic or atrophic lining by flattened epithelium and lumen containing granular, amorphous, pink debris and foam cells.
2. Periductal and interstitial chronic inflammation, chiefly lymphocytes, histiocytes with multinucleate histiocytic giant cells. Sometimes, plasma cells are present in impressive numbers and the condition is then termed *plasma cell mastitis*.
3. Occasionally, there may be obliteration of the ducts by fibrous tissue and varying amount of inflammation and is termed *obliterative mastitis*.

FAT NECROSIS

Focal fat necrosis of an obese and pendulous breast followed by an inflammatory reaction is generally initiated by trauma (page 27). The condition presents as a well-defined mass with indurated appearance.

Grossly, the excised lump has central pale cystic area of necrosis.

Histologically, there is disruption of the regular pattern of lipocytes with formation of lipid-filled spaces surrounded by neutrophils, lymphocytes, plasma cells and histiocytes having foamy cytoplasm and frequent foreign body giant cell formation. In late stage, there is replacement fibrosis and even calcification.

GALACTOCELE

A galactocele is cystic dilatation of one or more ducts occurring during lactation. The mammary duct is obstructed and dilated to form a thin-walled cyst filled with milky fluid. Rarely, the wall of galactocele may get secondarily infected.

FIBROCYSTIC CHANGE

Fibrocystic change is the most common benign breast condition producing vague 'lumpy' breast rather than palpable lump in the breast. Its incidence has been reported to range from 10-20% in adult women, most often between 3rd and 5th decades of life, with dramatic decline in its incidence after menopause suggesting the role of oestrogen in its pathogenesis. It was previously termed *fibrocystic disease* but is currently considered as an exaggerated physiologic phenomena and not a disease. The entity was formerly also known as *benign*

mammary dysplasia under the mistaken belief that all forms are dysplastic or precancerous conditions, and hence has attracted considerable interest.

As such, fibrocystic change of the female breast is a histologic entity characterised by following features:

- i) Cystic dilatation of terminal ducts.
- ii) Relative increase in inter- and intralobular fibrous tissue.
- iii) Variable degree of epithelial proliferation in the terminal ducts.

It is important to identify the spectrum of histologic features by core needle biopsy or cytologic findings by FNAC in fibrocystic changes since only some subset of changes has an increased risk of development of breast cancer. Presently, the spectrum of histologic changes is divided into two clinicopathologically relevant groups:

- A. Nonproliferative changes: Simple fibrocystic change.
- B. Proliferative changes: Proliferative fibrocystic change.

A. NONPROLIFERATIVE FIBROCYSTIC CHANGES: SIMPLE FIBROCYSTIC CHANGE

Simple fibrocystic change most commonly includes 2 features—formation of cysts of varying size, and increase in fibrous stroma. Cysts are formed by dilatation of obstructed collecting ducts, obstruction being caused by periductal fibrosis following inflammation or fibrous overgrowth from oestrogen stimulation.

MORPHOLOGIC FEATURES *Grossly*, the cysts are rarely solitary but are usually multifocal and bilateral. They vary from microcysts to 5-6 cm in diameter. The usual large cyst is rounded, translucent with bluish colour prior to opening (blue-dome cyst). On opening, the cyst contains thin serous to haemorrhagic fluid.

Microscopically, simple fibrocystic change includes following 2 features (**Fig. 23.2**):

1. Cyst formation The cyst lining shows a variety of appearances. Often, the epithelium is flattened or atrophic. Frequently, there is apocrine change or apocrine metaplasia

in the lining of the cyst resembling the cells of apocrine sweat glands. Occasionally, there is simultaneous epithelial hyperplasia (discussed below) forming tiny intracystic papillary projections of piled up epithelium.

2. Fibrosis There is increased fibrous stroma surrounding the cysts and variable degree of stromal lymphocytic infiltrate.

B. PROLIFERATIVE FIBROCYSTIC CHANGES: EPITHELIAL HYPERPLASIA AND SCLEROSING ADENOSIS

Proliferative fibrocystic change in the breasts includes 2 entities: epithelial hyperplasia and sclerosing adenosis.

EPITHELIAL HYPERPLASIA Epithelial hyperplasia or epitheliosis is defined as increase in the layers of epithelial cells over the basement membrane to three or more layers in the ducts (*ductal hyperplasia*) or lobules (*lobular hyperplasia*). The latter condition, lobular hyperplasia, must be distinguished from adenosis (discussed separately) in which there is increase in the number of ductules or acini without any change in the number or type of cells lining them. Epithelial hyperplasia may be totally benign or may have atypical features. It is the latter type of hyperplasia which is precancerous and is associated with increased risk of developing breast cancer.

Microscopically, epithelial hyperplasia is characterised by epithelial proliferation to more than its normal double layer. In general, ductal hyperplasia is termed as *epithelial hyperplasia of usual type* and may show various grades of epithelial proliferations (mild, moderate and atypical) as under, while *lobular hyperplasia* involving the ductules or acini is always atypical:

1. Mild hyperplasia of ductal epithelium consists of at least three layers of cells above the basement membrane, present focally or evenly throughout the duct.

2. Moderate and florid hyperplasia of ductal type is associated with tendency to fill the ductal lumen with proliferated epithelium. Such epithelial proliferations

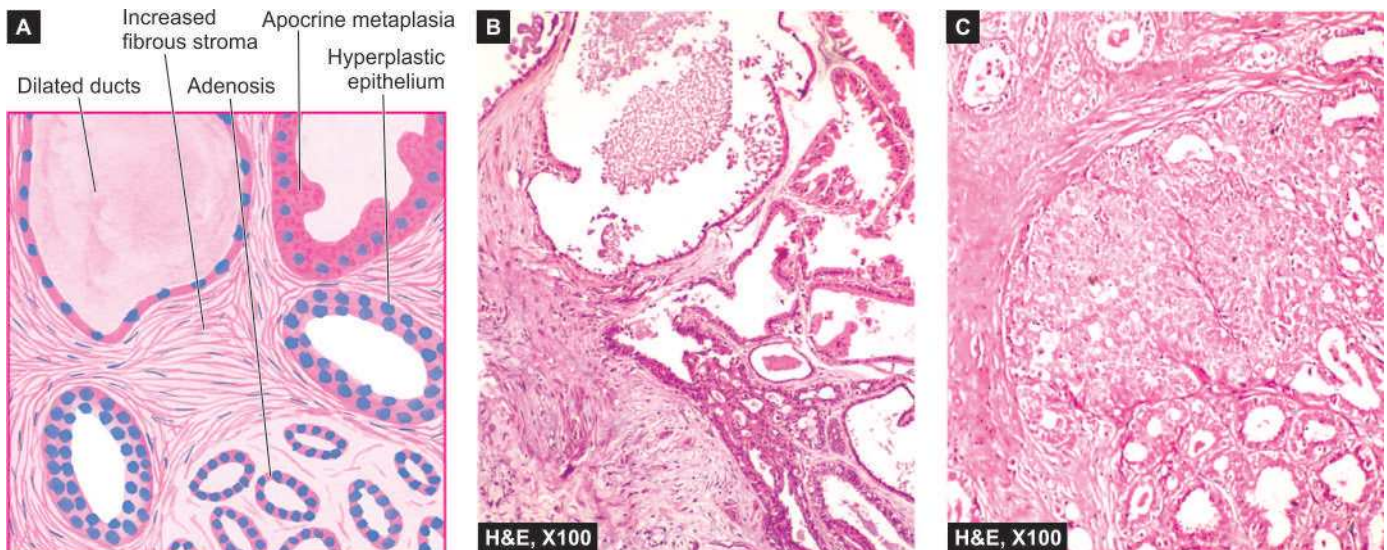

Figure 23.2 Simple fibrocystic change. A, Diagrammatic view. It shows cystic dilatation of ducts and increase in fibrous stroma. There is mild epithelial hyperplasia in terminal ducts. B, Non-proliferative fibrocystic changes—fibrosis, cyst formation, adenosis and apocrine metaplasia. C, Proliferative fibrocystic changes showing moderate epithelial hyperplasia.

into the lumina of ducts may be focal, forming papillary epithelial projections called *ductal papillomatosis*, or may be more extensive, termed *florid papillomatosis*, or may fill the ductal lumen leaving only small fenestrations in it.

3. Of all the ductal hyperplasias, **atypical ductal hyperplasia** is more ominous and has to be distinguished from intraductal carcinoma (page 752). The proliferated epithelial cells in the atypical ductal hyperplasia partially fill the duct lumen and produce irregular microglandular spaces or *cribriform pattern*. The individual cells are uniform in shape but show loss of polarity with indistinct cytoplasmic margin and slightly elongated nuclei.

4. **Atypical lobular hyperplasia** is closely related to lobular carcinoma *in situ* (page 752) but differs from the latter in having cytologically atypical cells only in half of the ductules or acini.

SCLEROSING ADENOSIS Sclerosing adenosis is benign proliferation of small ductules or acini and intralobular fibrosis. The lesion may be present as diffusely scattered microscopic foci in the breast parenchyma, or may form an isolated palpable mass which may simulate an infiltrating carcinoma, both clinically and pathologically.

Grossly, the lesion may be coexistent with other components of fibrocystic disease, or may form an isolated mass which has hard cartilage-like consistency, resembling an infiltrating carcinoma.

Microscopically, there is proliferation of ductules or acini and fibrous stromal overgrowth. The histologic appearance may superficially resemble infiltrating carcinoma but differs from the latter in having maintained lobular pattern and lack of infiltration into the surrounding fat.

Prognostic Significance

Since there is a variable degree of involvement of epithelial and mesenchymal elements in fibrocystic change, following prognostic implications may occur:

1. *Simple fibrocystic change* or *nonproliferative fibrocystic changes* of fibrosis and cyst formation do not carry any increased risk of developing invasive breast cancer.
2. Identification of *general proliferative fibrocystic changes* are associated with 1.5 to 2 times increased risk for development of invasive breast cancer.
3. *Multifocal and bilateral proliferative changes* in the breast pose increased risk to both the breasts equally.
4. Within the group of proliferative fibrocystic changes, *atypical hyperplasia* in particular, carries 4 to 5 times increased risk to develop invasive breast cancer later. This risk is further more if there is a history of breast cancer in the family.

GYNAECOMASTIA (HYPERTROPHY OF MALE BREAST)

Unilateral or bilateral enlargement of the male breast is known as gynaecomastia. Since the male breast does not contain secretory lobules, the enlargement is mainly due to proliferation of ducts and increased periductal stroma. Gynaecomastia occurs in response to hormonal stimulation, mainly oestrogen.

Such excessive oestrogenic activity in males is seen in young boys between 13 and 17 years of age (*pubertal gynaecomastia*), in men over 50 years (*senescent gynaecomastia*), in endocrine diseases associated with increased oestrogenic or decreased androgenic activity e.g. in hepatic cirrhosis, testicular tumours, pituitary tumours, carcinoma of the lung, exogenous oestrogen therapy as in carcinoma of the prostate and testicular atrophy in Klinefelter's syndrome (*secondary gynaecomastia*), and lastly, enlargement without any obvious cause (*idiopathic gynaecomastia*).

MORPHOLOGIC FEATURES **Grossly**, one or both the male breasts are enlarged having smooth glistening white tissue.

Microscopically, there are 2 main features:

1. Proliferation of branching ducts which display epithelial hyperplasia with formation of papillary projections at places.
2. Increased fibrous stroma with, myxoid appearance.

GIST BOX 23.1

Non-neoplastic Diseases of Breast

- ▣ The epithelial component of the breast consists of terminal duct-lobular unit (TDLU) with secretory function during lactation, and large duct system which performs the function of collection and drainage of secretion.
- ▣ Acute pyogenic infection of the breast (mastitis) during lactation or eczema of nipple, if not treated timely, may be followed by chronic mastitis or abscess.
- ▣ Mammary duct ectasia or plasma cell mastitis involves one or more of the larger ducts of the breast which are dilated and filled with inspissated secretions.
- ▣ Fibrocystic change of the breast is characterised by cystic dilatation of terminal ducts, relative increase in inter- and intralobular fibrous tissue and variable degree of epithelial proliferation in the terminal ducts.
- ▣ Proliferative fibrocystic changes (atypical hyperplasia) carries 4 to 5 times increased risk to develop invasive breast cancer later.
- ▣ Unilateral or bilateral enlargement of the male breast is known as gynaecomastia, which is mainly due to proliferation of ducts and increased periductal stroma.

BREAST TUMOURS

Tumours of the female breast are common and clinically significant but are rare in men. Among the important benign breast tumours are fibroadenoma, phyllodes tumour (cystosarcoma phyllodes) and intraductal papilloma. Carcinoma of the breast is an important malignant tumour which occurs as non-invasive (carcinoma *in situ*) and invasive cancer with its various morphologic varieties.

FIBROADENOMA

Fibroadenoma or adenofibroma is a benign tumour of fibrous and epithelial elements. It is the most common benign tumour of the female breast. Though it can occur at any age during reproductive life, most patients are between 15 to 30 years of age. Clinically, fibroadenoma generally appears as a solitary,

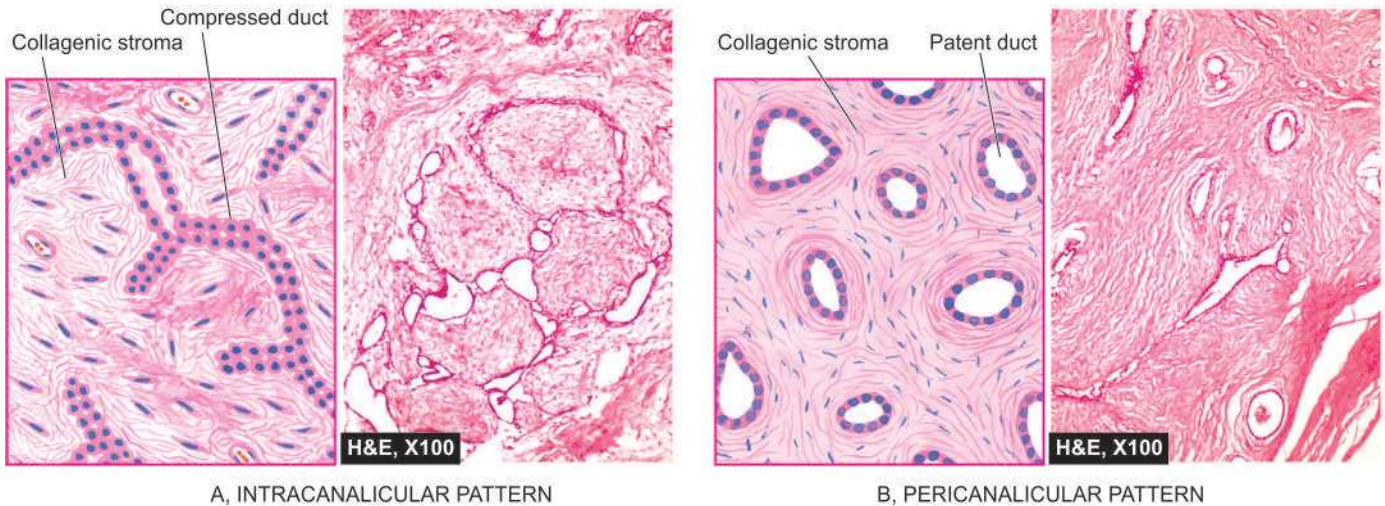

Figure 23.3 Fibroadenoma of the breast, microscopic patterns.

discrete, freely mobile nodule within the breast. Rarely, fibroadenoma may contain *in situ* or invasive lobular or ductal carcinoma, or the carcinoma may invade the fibroadenoma from the adjacent primary breast cancer.

MORPHOLOGIC FEATURES *Grossly*, typical fibroadenoma is a small (2-4 cm diameter), solitary, well-encapsulated, spherical or discoid mass. The cut surface is firm, grey-white, slightly myxoid and may show slit-like spaces formed by compressed ducts. Occasionally, multiple fibroadenomas may form part of fibrocystic disease and is termed *fibroadenomatosis*. Less commonly, a fibroadenoma may be fairly large in size, up to 15 cm in diameter, and is called *giant fibroadenoma* but lacks the histologic features of cystosarcoma phyllodes (discussed later).

Microscopically, fibrous tissue comprises most of a fibroadenoma. The arrangements between fibrous overgrowth and ducts may produce two types of patterns which may coexist in the same tumour. These are intracanalicular and pericanalicular patterns (**Fig. 23.3**):

◆ **Intracanalicular pattern** is one in which the stroma compresses the ducts so that they are reduced to slit-like clefts lined by ductal epithelium or may appear as cords of epithelial elements surrounding masses of fibrous stroma.

◆ **Pericanalicular pattern** is characterised by encircling masses of fibrous stroma around the patent or dilated ducts.

The fibrous stroma may be quite cellular, or there may be areas of hyalinised collagen. Sometimes, the stroma is loose and myxomatous.

VARIANTS A few morphologic variants of fibroadenomas have been described:

1. Occasionally, the fibrous tissue element in the tumour is scanty, and the tumour is instead predominantly composed of closely-packed ductular or acinar proliferation and is termed *tubular adenoma*.
2. If an adenoma is composed of acini with secretory activity, it is called *lactating adenoma* seen during pregnancy or lactation.
3. *Juvenile fibroadenoma* is an uncommon variant of fibroadenoma which is larger and rapidly growing mass seen in adolescent girls but fortunately does not recur after excision.

PHYLLODES TUMOUR (CYSTOSARCOMA PHYLLODES)

Cystosarcoma phyllodes was the nomenclature given by Müller in 1838 to an uncommon bulky breast tumour with leaf-like gross appearance (*phyllodes*=leaf-like) having an aggressive clinical behaviour. Most patients are between 30 to 70 years of age. Grossly, the tumour resembles a giant fibroadenoma but is distinguished histologically from the latter by more cellular connective tissue. Later, the WHO classification of breast tumours has proposed the term 'phyllodes tumour' in place of misleading term of 'cystosarcoma phyllodes.' Phyllodes tumour can be classified into *benign*, *borderline* and *malignant* on the basis of histologic features of stromal cells. Local recurrences are much more frequent than metastases.

MORPHOLOGIC FEATURES *Grossly*, the tumour is generally large, 10-15 cm in diameter, round to oval, bosselated, and less fully encapsulated than a fibroadenoma. The cut surface is grey-white with cystic cavities, areas of haemorrhages, necrosis and degenerative changes (**Fig. 23.4**).

Histologically, the phyllodes tumour is composed of an extremely hypercellular stroma, accompanied by benign ductal structures. Thus, phyllodes tumour resembles fibroadenoma except for marked stromal overgrowth. The histologic criteria considered to distinguish benign, borderline and malignant categories of phyllodes tumour are based on following cellular features of stroma:

- i) frequency of mitoses;
- ii) cellular atypia;
- iii) cellularity; and
- iv) infiltrative margins.

About 20% of phyllodes tumours are histologically malignant and less than half of them may metastasise.

INTRADUCTAL PAPILLOMA

Intraductal papilloma is a benign papillary tumour occurring most commonly in a lactiferous duct or lactiferous sinus near the nipple. Clinically, it produces serous or serosanguineous

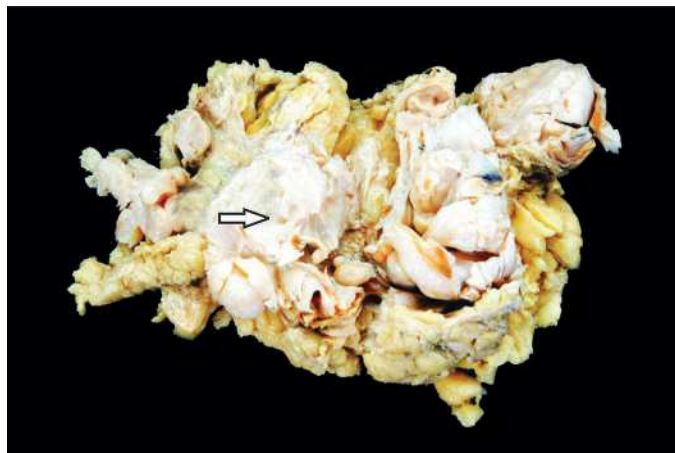

Figure 23.4 Phyllodes tumour. Simple mastectomy specimen shows replacement of almost whole breast with a large circumscribed, grey-white, firm, nodular mass having slit-like, compressed cystic areas (arrow) and areas of haemorrhage.

nipple discharge. It is most common in 3rd and 4th decades of life.

MORPHOLOGIC FEATURES *Grossly*, intraductal papilloma is usually solitary, small, less than 1 cm in diameter, commonly located in the major mammary ducts close to the nipple. Less commonly, there are multiple papillomatosis which are more frequently related to a papillary carcinoma.

Histologically, an intraductal papilloma is characterised by multiple papillae having well-developed fibrovascular stalks attached to the ductal wall and covered by benign cuboidal epithelial cells supported by myoepithelial cells. An intraductal papillary carcinoma is distinguished from intraductal papilloma in having severe cellular atypia, pleomorphism, absence of myoepithelial cells, multi-layering and presence of mitotic figures.

CARCINOMA OF THE BREAST

Cancer of the female breast is among the commonest of human cancers throughout the world. Its incidence varies in different countries (see under 'geography' below). In the United States, carcinoma of the breast constitutes about 25% of all cancers in females and causes approximately 20% of cancer deaths among females. However, there has been some decline in mortality from the breast cancer in recent years in developed countries due to both early diagnosis and modern therapy. Cancer of the male breast, on the other hand, is quite rare and comprises 0.2% of malignant tumours (ratio between male-female breast cancer is 1:150). The incidence of breast cancer is highest in the perimenopausal age group and is uncommon before the age of 25 years.

Clinically, the breast cancer usually presents as a solitary, painless, palpable lump which is detected quite often by self-examination. Higher the age, more are the chances of breast lump turning out to be malignant. Thus, all breast lumps, irrespective of the age of the patient must be removed surgically. Currently, emphasis is on early diagnosis by *triple technique*: palpation, mammography, and fine needle aspiration cytology (FNAC). Additional techniques such as stereotactic biopsy and frozen section are immensely valuable to the surgeon for immediate pathological diagnosis in doubtful cases.

RISK (EPIDEMIOLOGIC) FACTORS

Many risk factors have been identified for development of breast cancer in women:

1. Geographic and racial factors The incidence of breast cancer is about 4-6 times higher in developed countries (North America, North Europe, Australia), intermediate in Southern European and Latin American countries, and low in developing countries of Asia and Africa, with the notable exception of Japan. Breast cancer in Hispanic and African-American women tends to occur at an earlier age and the disease is more advanced at presentation.

These geographic and racial differences are considered to be related to modifiable risk factors such as diet and environment because immigrants to US or their daughters have incidence at par with local population.

2. Family history First-degree relatives (mother, sister, daughter) of women with breast cancer have 2 to 6-fold higher risk of development of breast cancer. The risk is proportionate to a few factors:

- Number of blood relatives with breast cancer.
- Younger age at the time of development of breast cancer.
- Bilateral cancers.
- High risk cancer families having breast and ovarian carcinomas.

3. Menstrual and obstetric history Total length of menstrual life is directly related to increased risk. Thus, there is increased risk of breast cancer development in women who had early menarche, nulliparity, late age of first childbirth and delayed menopause.

4. Fibrocystic change Fibrocystic change, particularly when associated with atypical epithelial hyperplasia, has about 5-fold higher risk of developing breast cancer subsequently.

5. Miscellaneous factors These include a host of following environmental influences and dietary factors associated with increased risk of breast cancer:

- Consumption of large amounts of animal fats, high calorie foods.
- Cigarette smoking.
- Alcohol consumption.
- Breast augmentation surgery.
- High breast density.
- Exposure to ionising radiation during breast development.

Identification of a transmissible retrovirus in early 20th century, mouse mammary tumour virus (MMTV), also called *Bittner milk factor* transmitted from the infected mother-mice to the breast-fed daughter-mice prompted researchers to look for similar agent in human breast cancer (page 200). Though no such agent has yet been identified, there are reports of presence of reverse transcriptase in breast cancer cells.

ETIOPATHOGENESIS

Overall, two major etiologic factors in pathogenesis of breast cancer are: hormonal and genetic.

1. HORMONAL FACTORS Breast cancer is a hormone-dependent disease. There is sufficient evidence to suggest that excess endogenous oestrogen or exogenously administered oestrogen for prolonged duration is an important factor in the development of breast cancer. Evidences in support of

relationship of increased risk with oestrogen excess are as follows:

- i) Women with prolonged reproductive life, with menarche setting in at an early age and menopause relatively late have greater risk.
- ii) Higher risk in unmarried and nulliparous women than in married and multiparous women.
- iii) Women with first childbirth at a late age (over 30 years) are at greater risk.
- iv) Lactation and breastfeeding reduces the risk of breast cancer.
- v) Bilateral oophorectomy reduces the risk of development of breast cancer.
- vi) Functioning ovarian tumours (e.g. granulosa cell tumour) which elaborate oestrogen are associated with increased incidence of breast cancer.
- vii) Hormone replacement therapy (HRT) administered to postmenopausal women may result in increased risk of breast cancer.
- viii) Long-term use of oral contraceptives containing balanced oestrogen-progesterone preparations do not pose increased risk.
- ix) Men who have been treated with oestrogen for prostatic cancer have increased risk of developing cancer of the male breast.

Normal breast epithelium possesses oestrogen and progesterone receptors. The breast cancer cells secrete many growth factors which are oestrogen-dependent. In this way, the interplay of high circulating levels of oestrogen, oestrogen receptors and growth factors bring about progression of breast cancer.

2. GENETIC FACTORS About 10% breast cancers have been found to have inherited mutations. These mutations include the following, most important of which is *breast cancer (BRCA)* susceptibility gene in inherited breast cancer:

- a) *BRCA 1 gene* located on chromosome 17, a DNA repair gene, is implicated in both breast and ovarian cancer in inherited cases. *BRCA1* deletion is seen in about two-third of women with inherited breast cancer having family history but *BRCA1* mutation is uncommon in sporadic cases. The protein product of *BRCA* gene is a cell cycle regulated protein and it can be detected by immunohistochemistry. Men who have mutated *BRCA1* have increased risk of developing cancer of the prostate but not of male breast.
- b) *BRCA 2 gene* located on chromosome 13, another DNA repair gene, in its mutated form, has a similarly higher incidence of inherited cancer of the breast (one-third cases) and ovary in females, and prostate in men.

In *BRCA1* as well as *BRCA2*, both copies of the genes (homozygous state) must be inactivated for development of breast cancer.

c) *Mutation in p53 tumour suppressor gene* on chromosome 17 as an acquired defect accounts for 40% cases of sporadic breast cancer in women but rarely in women with family history of breast cancer. *p53* mutation is also seen in Li-Fraumeni syndrome having multiple cancers including breast cancer in young women; others are tumours of the brain, sarcomas, and adrenal cortical tumours. A variant form of Li-Fraumeni syndrome having *CHEK2* mutation also accounts for some cases of inherited breast cancer.

d) *Other mutations* seen less frequently in breast cancer include mutated form of ataxia telangiectasia (*AT*) gene, *PTEN* (phosphate and *tensin*) tumour suppressor gene.

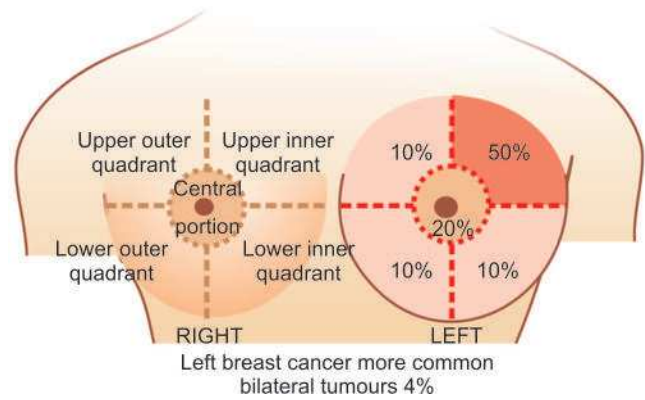

Figure 23.5 Topographic considerations in breast cancer.

GENERAL FEATURES AND CLASSIFICATION

Cancer of the breast occurs more often in left breast than the right and is bilateral in about 4% cases. Anatomically, upper outer quadrant is the site of tumour in half the breast cancers; followed in frequency by central portion, and equally in the remaining both lower and the upper inner quadrant as shown in **Fig. 23.5**.

Carcinoma of the breast arises from the ductal epithelium in 90% cases while the remaining 10% originate from the lobular epithelium. For variable period of time, the tumour cells remain confined within the ducts or lobules (non-invasive carcinoma) before they invade the breast stroma (invasive carcinoma). While only 2 types of *non-invasive carcinoma* have been described—intraductal carcinoma and lobular carcinoma *in situ*, there is a great variety of histological patterns of *invasive carcinoma breast* which have clinical correlations and prognostic implications. **Table 23.1** presents different morphologic types of carcinoma of the breast as proposed in the WHO classification with some modifications. The important morphological forms are described below.

A. NON-INVASIVE (*IN SITU*) BREAST CARCINOMA

In general, two types of non-invasive or *in situ* carcinoma—intraductal carcinoma and lobular carcinoma *in situ*, are

Table 23.1 Classification of carcinoma of the breast.

| | |
|----|--|
| A. | NON-INVASIVE (<i>IN SITU</i>) CARCINOMA |
| 1. | Intraductal carcinoma |
| 2. | Lobular carcinoma <i>in situ</i> |
| B. | INVASIVE CARCINOMA |
| 1. | Infiltrating (invasive) duct carcinoma-NOS (not otherwise specified) (80%) |
| 2. | Infiltrating (invasive) lobular carcinoma (10%) |
| 3. | Tubular (cribriform) carcinoma (6%) |
| 4. | Medullary carcinoma (2%) |
| 5. | Colloid (mucinous) carcinoma (2%) |
| 6. | Other types: Papillary carcinoma, adenoid cystic (invasive cribriform) carcinoma, secretory (juvenile) carcinoma, inflammatory carcinoma, metaplastic carcinoma. |
| C. | PAGET'S DISEASE OF THE NIPPLE |

characterised histologically by presence of tumour cells within the ducts or lobules respectively without evidence of invasion.

Intraductal Carcinoma

Carcinoma *in situ* confined within the larger mammary ducts is called intraductal carcinoma. The tumour initially begins with atypical hyperplasia of ductal epithelium followed by filling of the duct with tumour cells. Clinically, it produces a palpable mass in 30-75% of cases and presence of nipple discharge in about 30% patients. Approximately a quarter of patients of intraductal carcinoma treated with excisional biopsy alone develop ipsilateral invasive carcinoma during a follow-up period of 10 years while the chance of a contralateral breast cancer developing in patients with intraductal carcinoma is far less than that associated with *in situ* lobular carcinoma.

MORPHOLOGIC FEATURES *Grossly*, the tumour may vary from a small poorly-defined focus to 3-5 cm diameter mass. On cut section, the involved area shows cystically dilated ducts containing cheesy necrotic material (in *comedo pattern*), or the intraductal tumour may be polypoid and friable resembling intraductal papilloma (in *papillary pattern*).

Histologically, the proliferating tumour cells within the ductal lumina may have 4 types of patterns in different combinations: solid, comedo, papillary and cribriform (Fig. 23.6,A):

- i) *Solid pattern* is characterised by filling and plugging of the ductal lumina with tumour cells.
- ii) *Comedo pattern* is centrally placed necrotic debris surrounded by neoplastic cells in the duct.
- iii) *Papillary pattern* has formation of intraductal papillary projections of tumour cells which lack a fibrovascular stalk so as to distinguish it from intraductal papilloma.
- iv) *Cribriform pattern* is recognised by neat punched out fenestrations in the intraductal tumour.

Lobular Carcinoma *in Situ*

Lobular carcinoma *in situ* is not a palpable or grossly visible tumour. Patients of *in situ* lobular carcinoma treated with excisional biopsy alone develop invasive cancer of the ipsilateral breast in about 25% cases in 10 years as in intraductal carcinoma but, in addition, have a much higher incidence of developing a contralateral breast cancer (30%).

MORPHOLOGIC FEATURES *Grossly*, no visible tumour is identified.

Histologically, *in situ* lobular carcinoma is characterised by filling up of terminal ducts and ductules or acini by rather uniform cells which are loosely cohesive and have small, rounded nuclei with indistinct cytoplasmic margins (Fig. 23.6,B).

B. INVASIVE BREAST CARCINOMA

Infiltrating (Invasive) Duct Carcinoma-NOS

Infiltrating duct carcinoma-NOS (*not otherwise specified*) is the classic breast cancer and is the most common histologic pattern accounting for 80% cases of breast cancer. In fact, this is the pattern of cancer for which the terms 'cancer' and 'carcinoma' were first coined by Hippocrates. Clinically, majority of infiltrating duct carcinomas have a hard consistency due to dense collagenous stroma (scirrhous carcinoma). They are found more frequently in the left breast, often in the upper outer quadrant. Retraction of the nipple and attachment of the tumour to underlying chest wall may be present.

MORPHOLOGIC FEATURES *Grossly*, the tumour is irregular, 1-5 cm in diameter, hard cartilage-like mass that cuts with a grating sound. The sectioned surface of the tumour is grey-white to yellowish with chalky streaks and often extends irregularly into the surrounding fat (Fig. 23.7).

Histologically, as the name NOS suggests, the tumour is different from other special types in lacking a regular and uniform pattern throughout the lesion. A variety of histologic features commonly present are as under (Fig. 23.8):

- i) Anaplastic tumour cells forming solid nests, cords, poorly-formed glandular structures and some intraductal foci.
- ii) Infiltration by these patterns of tumour cells into diffuse fibrous stroma and fat.
- iii) Invasion into perivascular and perineural spaces as well as lymphatic and vascular invasion.

Infiltrating (Invasive) Lobular Carcinoma

Invasive lobular carcinoma comprises about 10% of all breast cancers. This peculiar morphologic form differs from other

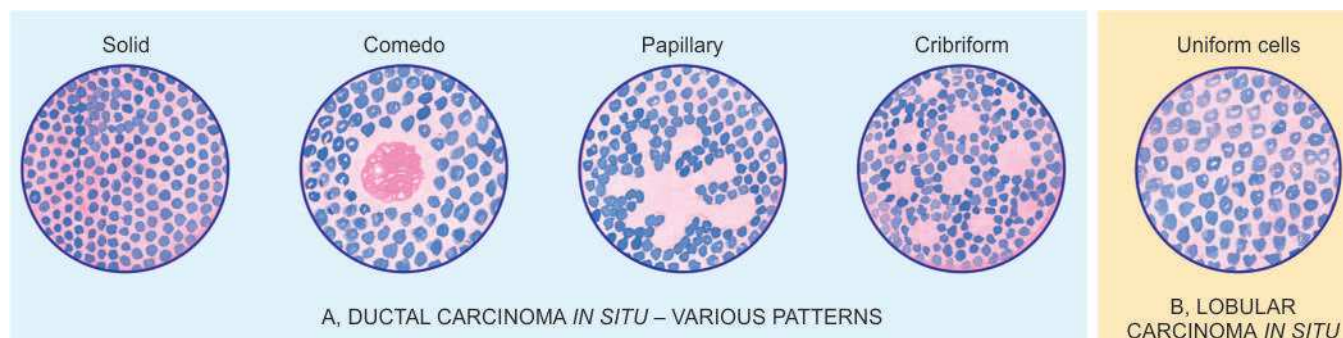

Figure 23.6 Morphologic patterns in non-invasive (*in situ*) carcinoma of breast.

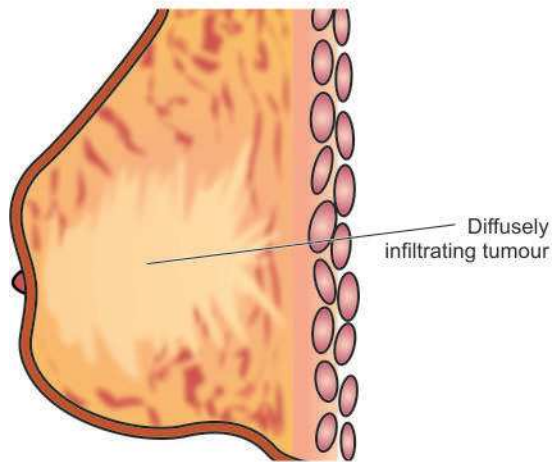

Figure 23.7 Infiltrating duct carcinoma-NOS. The breast shows a tumour extending up to nipple and areola. Cut surface shows a grey white firm tumour extending irregularly into adjacent breast parenchyma.

invasive cancers in being more frequently bilateral; and within the same breast, it may have multicentric origin.

MORPHOLOGIC FEATURES *Grossly*, the appearance varies from a well-defined scirrhous mass to a poorly-defined area of induration that may remain undetected by inspection as well as on palpation.

Histologically, there are 2 distinct features (**Fig. 23.9**):

i) Pattern A characteristic single file (Indian file) linear arrangement of stromal infiltration by the tumour cells with very little tendency to gland formation is seen. Infiltrating cells may be arranged concentrically around ducts in a target-like pattern.

ii) Tumour cytology Individual tumour cells resemble cells of *in situ* lobular carcinoma. They are round and regular with very little pleomorphism and infrequent mitoses. Some tumours may show signet-ring cells distended with cytoplasmic mucin.

Tubular Carcinoma

Tubular carcinoma comprises about 6% cases of invasive ductal carcinoma and has more favourable prognosis. These tumours are generally small (~1 cm diameter) ill-defined and gritty nodules.

Histologically, the tumour is highly well-differentiated having following characteristics:

i) Pattern The tumour is almost exclusively composed of tubules having angulated shape.

ii) Tumour cells The tumour cells are regular and form a single layer in well-defined tubules.

iii) Stroma Tubules are quite evenly distributed in dense fibrous stroma.

It may be mentioned here that presence of tubules in other histologic types of breast cancer assigns them a better prognosis (see under grading). Another rare variant forming cribriform pattern may be seen in tubular carcinoma and has similar better prognosis.

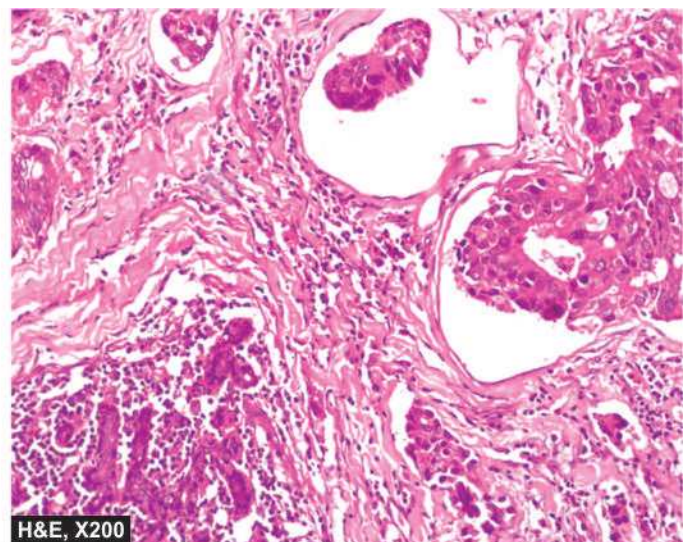

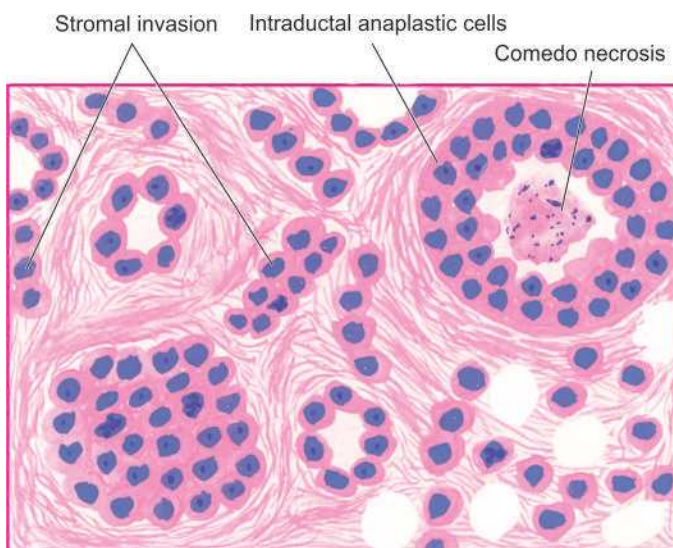

Figure 23.8 Infiltrating duct carcinoma-NOS. Microscopic features include formation of solid nests, cords, gland-like structures and intraductal growth pattern of anaplastic tumour cells. There is infiltration of densely collagenised stroma by these cells in a haphazard manner.

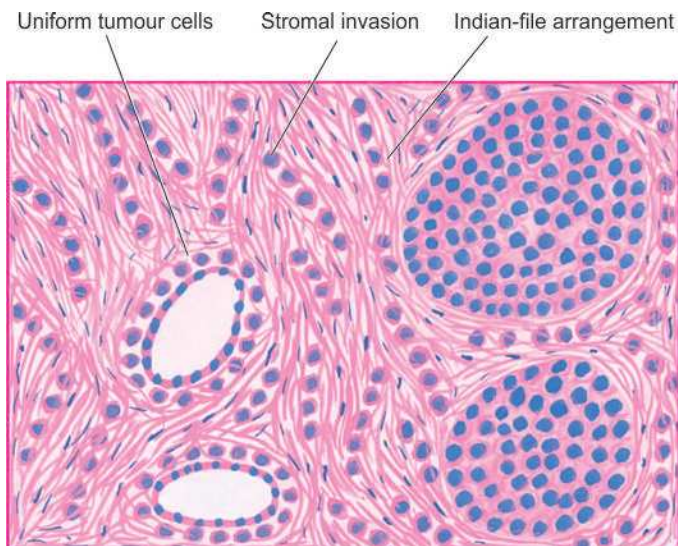

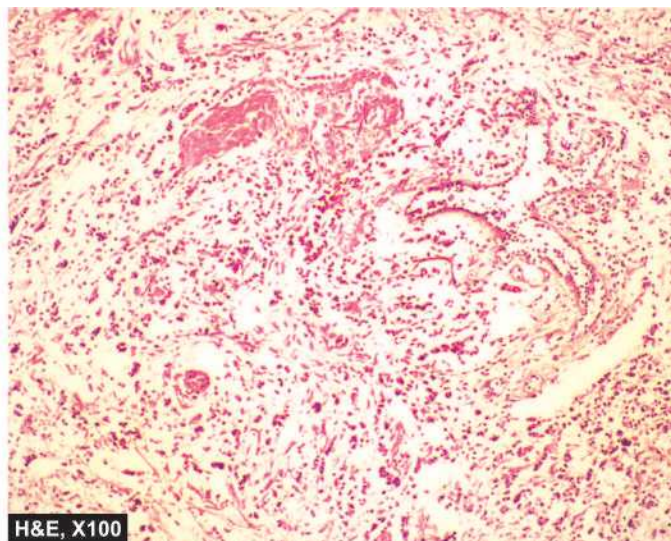

Figure 23.9 Invasive lobular carcinoma. Characteristic histologic features are: one cell wide files of round regular tumour cells ('Indian file' arrangement) infiltrating the stroma and arranged circumferentially around ducts in a target-like pattern.

Medullary Carcinoma

Medullary carcinoma is a variant of ductal carcinoma and comprises about 2% of all breast cancers. The tumour has a significantly better prognosis than the usual infiltrating duct carcinoma, probably due to good host immune response in the form of lymphoid infiltrate in the tumour stroma.

MORPHOLOGIC FEATURES *Grossly*, the tumour is characterised by a large, well-circumscribed, rounded mass that is typically soft and fleshy or brain-like and hence the alternative name of 'encephaloid carcinoma'. Cut section shows areas of haemorrhages and necrosis (**Fig. 23.10**).

Histologically, medullary carcinoma is characterised by 2 distinct features (**Fig. 23.11**):

- i) **Tumour cells** Sheets of large, pleomorphic tumour cells with abundant cytoplasm, large vesicular nuclei and many bizarre and atypical mitoses are diffusely spread in the scanty stroma.
- ii) **Stroma** The loose connective tissue stroma is scanty and usually has a prominent lymphoid component as aggregates and infiltrate.

Colloid (Mucinous) Carcinoma

This pattern of breast cancer is seen in about 2% cases, occurs more frequently in older women and is slow-growing. Colloid carcinoma has better prognosis than the usual infiltrating duct carcinoma.

MORPHOLOGIC FEATURES *Grossly*, the tumour is usually a soft and gelatinous mass with well-demarcated borders.

Histologically, colloid carcinoma contains large amount of extracellular epithelial mucin and acini filled with mucin. Cuboidal to tall columnar tumour cells, some showing mucus vacuolation, are seen floating in large lakes of mucin (**Fig. 23.12**).

Other Morphologic Forms

A few other morphologic forms of invasive breast carcinoma having clinical significance have been recognised:

I. Papillary carcinoma It is a rare variety of infiltrating duct carcinoma in which the stromal invasion is in the form of papillary structures.

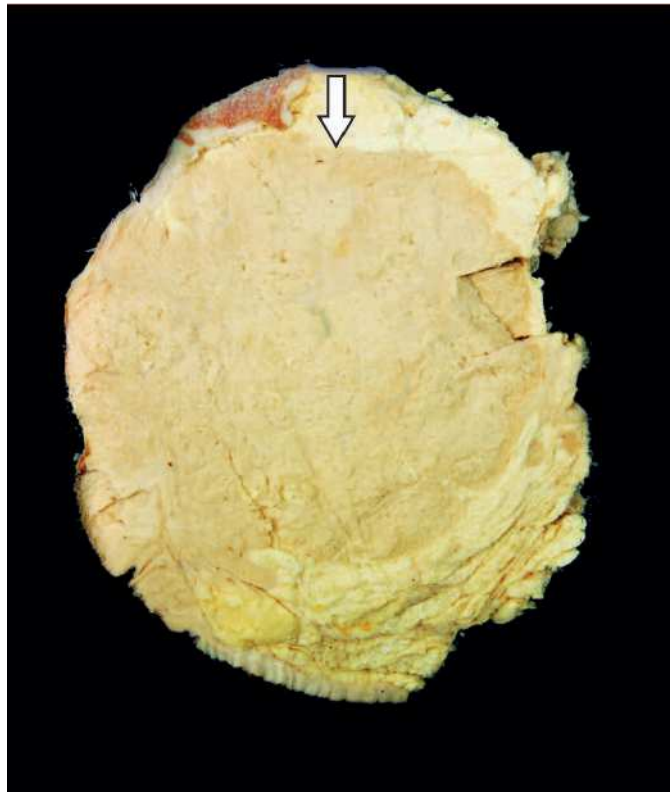

Figure 23.10 Medullary carcinoma breast. Cut surface of the breast shows a large grey white soft fleshy tumour replacing almost whole of the breast. The tumour is somewhat delineated from the adjacent breast parenchyma (arrow) as compared to irregular margin of IDC.

2. Adenoid cystic carcinoma Adenoid cystic or invasive cribriform carcinoma is a unique histologic pattern of breast cancer in which there is stromal invasion by islands of cells having characteristic cribriform (fenestrated) appearance. The tumour has an excellent prognosis.

3. Secretory (Juvenile) carcinoma This pattern is found more frequently in children and young girls and has a better prognosis. The tumour is generally circumscribed which on histologic examination shows abundant intra- and extracellular PAS-positive clear spaces due to secretory activity of tumour cells.

4. Inflammatory carcinoma Inflammatory carcinoma of the breast is a clinical entity and does not constitute a histological type. The term has been used for breast cancers in which there is redness, oedema, tenderness and rapid enlargement. Inflammatory carcinoma is associated with extensive invasion of dermal lymphatics and has a dismal prognosis.

5. Metaplastic carcinoma Rarely, invasive ductal carcinomas, besides epithelial elements, may have various components of metaplastic alterations such as squamous metaplasia, cartilaginous and osseous metaplasia, or their combinations. The term metaplastic carcinoma includes various categories such as carcinosarcoma, spindle cell carcinoma, carcinoma with osteoclast-like giant cells and squamous cell carcinoma.

C. PAGET'S DISEASE OF THE NIPPLE

Paget's disease of the nipple is an eczematoid lesion of the nipple, often associated with an invasive or non-invasive ductal carcinoma of the underlying breast. The nipple bears a crusted, scaly and eczematoid lesion with a palpable subareolar mass in about half the cases. Most of the patients with palpable mass are found to have infiltrating duct carcinoma, while those with no palpable breast lump are usually subsequently found to have intraductal carcinoma. Prognosis of patients with ductal

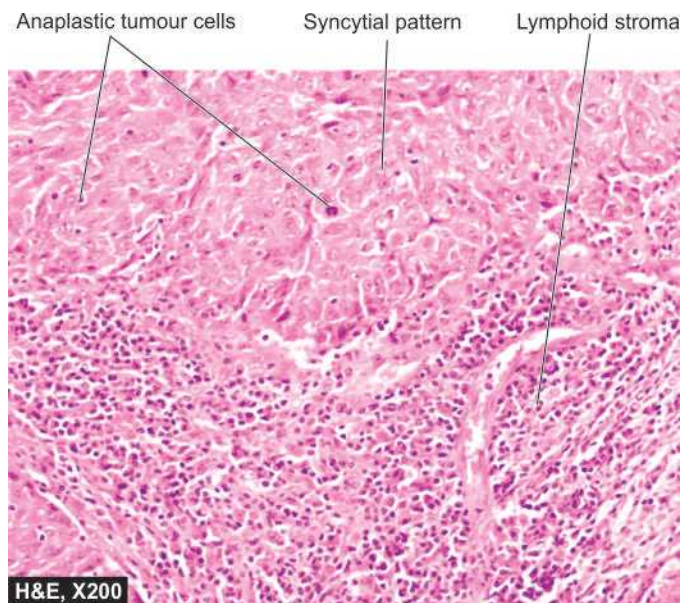

Figure 23.11 Medullary carcinoma breast. Microscopy shows two characteristic features—large tumour cells forming syncytial arrangement and stroma infiltrated richly with lymphocytes.

Figure 23.12 Colloid (mucinous) carcinoma breast. The tumour cells are seen as clusters floating in pools of abundant mucin.

carcinoma having Paget's disease is less favourable than of those who have ductal carcinoma without Paget's disease.

The *pathogenesis* of Paget's disease of the breast is explained by the following 2 hypotheses:

1. The tumour cells from the underlying ductal carcinoma have migrated up into the lactiferous ducts and invaded the epidermis producing skin lesions.
2. An alternate theory, though less reliable than the former, is that Paget's disease represents a form of carcinoma *in situ* of the epidermis itself.

MORPHOLOGIC FEATURES *Grossly*, the skin of the nipple and areola is crusted, fissured and ulcerated with oozing of serosanguineous fluid from the erosions (**Fig. 23.13, A**).

Histologically, the skin lesion is characterised by the presence of Paget's cells singly or in small clusters in the epidermis (**Fig. 23.13, B**). These cells are larger than the epidermal cells, spherical, having hyperchromatic nuclei with cytoplasmic halo that stains positively with mucicarmine. In these respects, Paget's cells are adenocarcinoma-type cells. In addition, the underlying breast contains invasive or non-invasive duct carcinoma which shows no obvious direct invasion of the skin of nipple.

GRADING, STAGING AND PROGNOSIS

Histologic grading and clinical staging of breast cancer determines the management and clinical course in these patients.

A. HISTOLOGIC GRADING The breast cancers are subdivided into various histologic grades depending upon the following parameters:

1. Histologic type of tumour Based on classification described in **Table 23.1**, various microscopic types of breast cancer can be subdivided into 3 histologic grades:

- i) *Non-metastasising*—Intraductal and lobular carcinoma *in situ*.

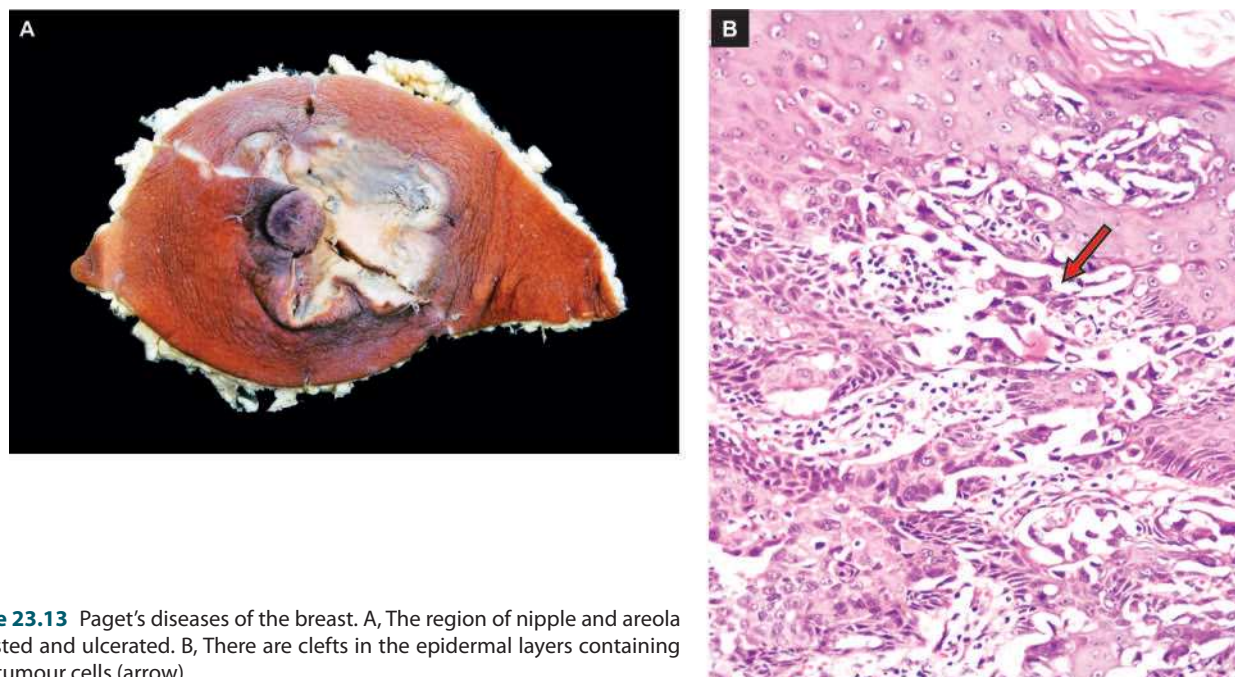

Figure 23.13 Paget's diseases of the breast. A, The region of nipple and areola is crusted and ulcerated. B, There are clefts in the epidermal layers containing large tumour cells (arrow).

ii) *Less commonly metastasising*—Medullary, colloid, papillary, tubular, adenoid cystic (invasive cribriform), and secretory (juvenile) carcinomas.

iii) *Commonly metastasising*—Infiltrating duct, invasive lobular, and inflammatory carcinomas.

2. Microscopic grade Widely used system for microscopic grading of breast carcinoma is Nottingham modification of the Bloom-Richardson system. It is based on 3 features: i) tubule formation; ii) nuclear pleomorphism; and iii) mitotic count.

3. Tumour size There is generally an inverse relationship between diameter of primary breast cancer at the time of mastectomy and long-term survival.

4. Axillary lymph node metastasis Survival rate is based on the number and level of lymph nodes involved by metastasis. More the number of regional lymph nodes involved, worse is the survival rate. Involvement of the lymph nodes from proximal to distal axilla (i.e. *level I*—superficial axilla, to *level III*—deep axilla) is directly correlated with the survival rate. In this regards, identification and dissection of sentinel lymph node followed by its histopathologic examination has attained immense prognostic value (*Sentinel lymph node* is the first node in the vicinity to receive drainage from primary cancer i.e. it stands 'sentinel' over the tumour).

5. Oestrogen and progesterone receptors (ER/PR)

Oestrogen is known to promote the breast cancer. Presence or absence of hormone receptors on the tumour cells can help in predicting the response of breast cancer to endocrine therapy (Fig. 23.14). Accordingly, patients with high levels of ER and PR on breast tumour cells have a slightly better prognosis. A recurrent tumour that is receptor-positive is more likely to respond to anti-oestrogen therapy than one that is receptor-negative.

6. HER2/neu overexpression *HER2/neu* (also called *erbB2*), a member of the family of epidermal growth factors,

is a transmembrane protein having tyrosine kinase activity. It can be detected by immunohistochemistry or by fluorescence *in situ* hybridisation (FISH) and is considered as a good predictive marker. An individual having overexpression of *HER2/neu* by tumour cells is likely to respond to higher dose of herceptin therapy but is not related to other forms of chemotherapy.

7. DNA content Tumour cell subpopulations with aneuploid DNA content as evaluated by mitotic markers (e.g. *Ki-67*) or by flow cytometry have a worse prognosis than purely diploid tumours.

B. CLINICAL STAGING The American Joint Committee (AJC) on cancer staging has modified the TNM (primary Tumour, Nodal, and distant Metastasis) staging proposed by UICC (Union International for Control of Cancer) and is shown in Table 23.2.

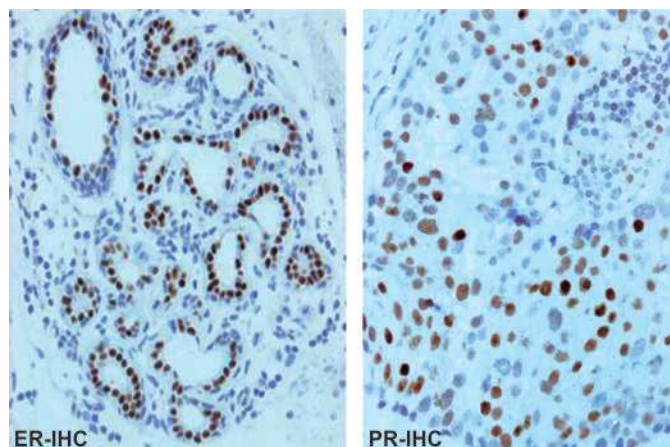

Figure 23.14 Oestrogen and progesterone hormonal receptors (ER and PR) in breast cancer. The tumour cells show nuclear positivity with ER and PR antibody immunostains.

Table 23.2 AJC clinical staging of breast cancer.

| | |
|--------------|--|
| Stage TIS: | <i>In situ</i> carcinoma (<i>in situ</i> lobular, intraductal, Paget's disease of the nipple without palpable lump) |
| Stage I: | Tumour 2 cm or less in diameter No nodal spread |
| Stage II: | Tumour > 2 cm and < 5 cm in diameter Regional lymph nodes involved |
| Stage III A: | Tumour ≥ 5 cm in diameter Regional lymph nodes involved on same side |
| Stage III B: | Tumour ≥ 5 cm in diameter Supraclavicular and infraclavicular lymph nodes involved |
| Stage IV: | Tumour of any size With or without regional spread but with distant metastasis |

Spread of breast cancer to axillary lymph nodes occurs early. Later, however, distant spread by lymphatic route to internal mammary lymphatics, mediastinal lymph nodes, supraclavicular lymph nodes, pleural lymph nodes and pleural lymphatics may occur. Common sites for haematogenous metastatic spread from breast cancer are the lungs, liver, bones, adrenals, brain and ovaries. Breast is one of the most suspected source of inapparent primary carcinoma in women presenting with metastatic carcinoma.

C. PROGNOSTIC FACTORS IN BREAST CANCER Based on current knowledge gained by breast cancer screening programmes in the West employing mammography and stereotactic biopsy, various breast cancer risk factors and prognostic factors have been described. These prognostic factors are divided into following 3 groups:

1. Potentially pre-malignant lesions These conditions are as under:

- i) *Atypical ductal hyperplasia* is associated with 4-5 times increased risk than women of the same age. Such lesions are commonest in the age group of 45-55 years.
- ii) *Clinging carcinoma* is a related lesion in the duct but different from carcinoma *in situ* and has lower risk of progression to invasive cancer than *in situ* carcinoma.
- iii) *Fibroadenoma* is a long-term risk factor (after over 20 years) for invasive breast cancer, the risk being about twice compared to controls.

2. Breast carcinoma *in situ* Following factors act as determinants:

- i) *Ductal carcinoma in situ* (comedo and non-comedo subtypes) is diagnosed on the basis of three histologic features—nuclear grade, nuclear morphology and necrosis, while *lobular neoplasia* includes full spectrum of changes of lobular carcinoma *in situ* and atypical lobular hyperplasia. Ductal carcinoma *in situ* is more important and demands most attention. Comedo type of *in situ* carcinoma has higher recurrence rate.
- ii) *Breast conservative therapy* is used more frequently nowadays in carcinoma *in situ* which requires consideration of

three factors for management: *margins*, *extent of disease*, and *biological markers*. The biological markers such as *p53* and *BCL-2* have low positivity in high-grade *in situ* ductal carcinoma and there is likelihood of recurrences after conservative surgery.

3. Invasive breast cancer Prognostic and predictive factors for invasive breast cancer have been extensively studied by univariate analysis (examining single factor separately) as well as by multivariate analysis (comparing the value of various factors included in a study). These can be broadly divided into 3 groups:

1. routine histopathology criteria;
2. hormone receptor status; and
3. biological indicators.

A summary combining all these factors is given in **Table 23.3**.

Overall, taking the most important parameter of node-positive or node-negative breast cancer, the prognosis varies—localised form of breast cancer without axillary lymph node involvement has a survival rate of 84% while survival rate falls to 56% with nodal metastases.

4. Molecular classification More recently, based on gene profiling of breast cancer by microarray, a molecular classification has been proposed. It takes into consideration patterns of gene expression by the breast cancer which may be one of the four types: luminal type A or B, *HER2/neu* type, basal-like type, and normal breast-like type. Out of all these, basal-like type has worst prognosis while luminal type A responds well to endocrine therapy and has good prognosis. However, this classification is yet to get universally acceptance.

GIST BOX 23.2 Breast Tumours

- ☐ Fibroadenoma is a benign tumour of fibrous and epithelial elements and is the most common benign tumour of the female breast in young age.
- ☐ Phyllodes tumour can be classified into benign, borderline and malignant on the basis of histologic features of stromal cells.
- ☐ Cancer of the breast is common and many risk factors have been identified: geographic and racial variation, family history, menstrual and obstetrical history, oestrogen excess and heredity.
- ☐ Initially, the tumour cells remain confined within the ducts or lobules (non-invasive carcinoma) which may be intraductal carcinoma and lobular carcinoma *in situ*.
- ☐ Most common invasive breast cancer is infiltrating duct carcinoma-NOS (not otherwise specified); others are lobular, medullary, colloid and some less common types.
- ☐ Histologic grading and clinical staging of breast cancer determines the management and clinical course of breast cancer.
- ☐ A few salient factors for favourable prognosis are: tumour size ≤ 1 cm, histologic types (medullary, tubular colloid), grade I tumour, node negative, ER-PR positive, *HER2/neu* underexpressed.

Table 23.3 Summary of prognostic markers and predictive factors for invasive breast cancer.

| FACTOR | FAVOURABLE PROGNOSIS | POOR PROGNOSIS |
|---|---|--|
| I. ROUTINE HISTOPATHOLOGY CRITERIA | | |
| i) <i>Histologic type</i> | Medullary ca., tubular ca., mucinous (colloid) ca.; lobular ca. of low grade | Inflammatory ca. |
| ii) <i>Tumour size (two dimensions)</i> | ≤ 1 cm size tumour; 10 years survival 90% in node negative | Size > 1 cm |
| iii) <i>Histologic (Nottingham) grading (Score range of 3-9) based on degree of tubule formation-1-3 score, regularity of nuclei-1-3 score, and mitoses-1-3 score</i> | Low grade (grade I) tumour = score 3-5, moderate grade (grade II) tumour = score 6-7 | High grade (grade III) tumour = score 8-9 |
| iv) <i>Axillary nodal status</i> | Node negative: recurrence after 10 years 10-30%; Number of nodes: less than 4; sentinel node negative | Node positive: recurrence after 10 years 70%; number of nodes: more than 4; sentinel node positive |
| v) <i>Lymphatic and/or vascular invasion (both extratumoural)</i> | Negative for both: good | Positive for one or both: poor |
| vi) <i>Others:</i> | | |
| a) <i>Tumour circumscription</i> | Good | Poor |
| b) <i>Inflammatory reaction</i> | May have some role | Controversial |
| c) <i>Stromal elastosis</i> | Absence good | Presence poor |
| d) <i>Intraductal component</i> | Presence good | Absence poor |
| e) <i>Skin involvement</i> | Absence good | Presence poor |
| II. HORMONE RECEPTOR STATUS | | |
| <i>Oestrogen-progesterone receptors (ER-PR)</i> | ER-PR positive cases respond better to adjuvant therapy | ER-PR negative cases respond poorly to adjuvant therapy |
| <i>HER-2/neu (C-erb B-2)</i> | Underexpression | Overexpression (predictive of response to herceptin) |
| III. BIOLOGICAL INDICATORS | | |
| i) <i>Mitotic index (by Ki67, MIB-1)</i> | Low mitotic count | High mitotic count |
| ii) <i>DNA ploidy analysis (aneuploidy, diploidy)</i> | Not related | Not related |
| iii) <i>Angiogenesis (VEGF, CD31, CD34, microvessel density counts)</i> | Angiogenic activity low | High angiogenic activity |
| iv) <i>Oncogene dysregulation</i> | | |
| a) <i>BRCA1, BRCA2</i> | BRCA negative | BRCA positive |
| b) <i>p53</i> | p53 positive respond better to chemotherapy and radiotherapy | p53 negative respond poorly to chemotherapy and radiotherapy |
| c) <i>BCL2</i> | BCL2 positive good | BCL2 negative poor |
| d) <i>Cathepsin D</i> | Absence good prognosis | Presence poor prognosis |

CLINICAL CASE 24

A 65 years old woman reports to surgeon for soreness and oozing from the nipple of her left breast. There is no history of trauma to the breast.

On physical examination, there is fissuring and ulceration of the areola and nipple. Deep palpation of the breast shows a hard lump 5 cm in diameter, with irregular margins underneath

the nipple. One lymph node 3 cm size is palpable in the apex of right axilla.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 913 (Appendix II)

24

The Skin

NORMAL STRUCTURE

The skin or the integument is the external organ that protects against mechanical trauma, UV light and infection. In addition, the skin is concerned with thermoregulation, conservation and excretion of fluid, sensory perception and, of course, has aesthetic role for appearance of the individual.

The histology of normal skin shows some variation in different parts of the body. In general, it is composed of 2 layers, the epidermis and the dermis, which are separated by an irregular border. Cone-shaped dermal papillae extend upward into the epidermis forming peg-like *rete ridges* of the epidermis. **Fig. 24.1** presents a diagrammatic representation of the main structures identifiable in a section of the normal skin while **Fig. 24.2** shows the various layers of the epidermis.

EPIDERMIS The epidermis is composed of the following 5 layers from base to the surface:

1. Basal cell layer (stratum germinatum) The basal cell layer consists of a single layer of keratinocytes that forms the junction between the epidermis and dermis. The nuclei of these cells are perpendicular to the epidermal basement membrane. These are hyperchromatic and normally contain a few mitoses indicating that the superficial epidermal layers originate from the basal cell layer. These cells are interconnected with each other and with the overlying squamous cells by *desmosomes*. Interspersed in the keratinocytes are *melanocytes*, a type of dendritic cells, in the ratio of 1:4 to 1:10 depending upon the site of the body. However, racial difference in the complexion

depend upon the content of melanin per melanocyte rather than on number of melanocytes. These cells have small nuclei with clear cytoplasm containing melanin pigment granules that determines the appearance of an individual. They are always positive with dopa reaction (page 22). The other type of dendritic cells in the basal layer are *Langerhans cells* which are bone marrow-derived cells of mononuclear-phagocyte system.

2. Prickle cell layer (Stratum spinosum, Stratum malpighii) This layer is composed of several layers of polygonal prickle cells or squamous cells. The layers become flat as they near the surface so that their long axis appears parallel to the skin surface. These cells possess intercellular bridges or tonofilaments. These intercellular cytoplasmic tonofilaments contain PAS-positive material that is precursor of keratin.

3. Granular cell layer (Stratum granulosum) This layer consists of 1 to 3 layers of flat cells containing keratohyaline basophilic granules which are PAS-negative. Granular cell layer is much thicker in palms and soles.

4. Stratum lucidum This layer is present exclusively in palms and soles as a thin homogeneous, eosinophilic, non-nucleate zone.

5. Horny layer (Stratum corneum) The stratum corneum is also normally devoid of nuclei and consists of eosinophilic layers of keratin.

Intraepidermal nerve endings are present in the form of *Merkel cells* which are touch receptors.

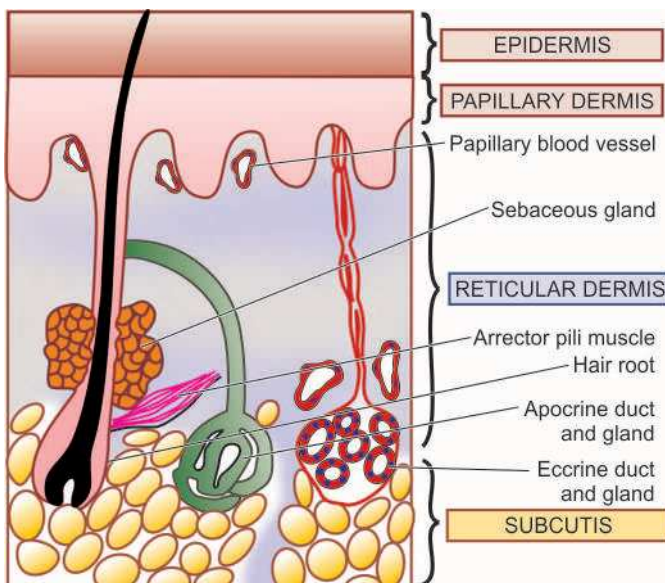

Figure 24.1 Main structures identified in a section of the normal skin.

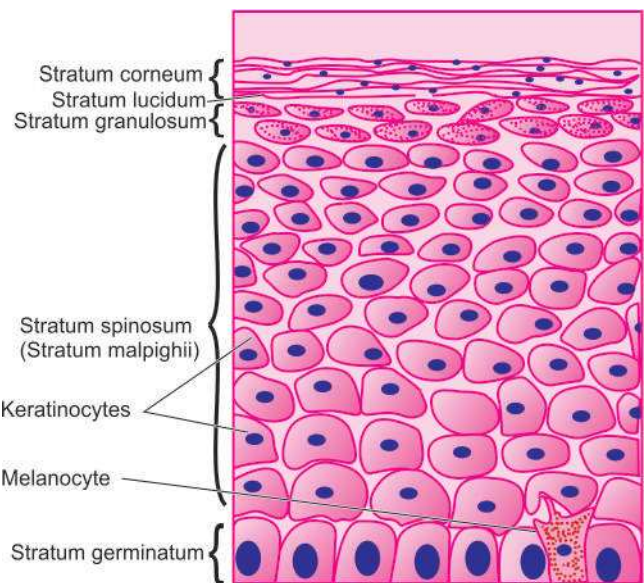

Figure 24.2 Different layers comprising the normal epidermis.

DERMIS The dermis consists of 2 parts—the superficial *pars papillaris* or *papillary dermis*, and the deeper *pars reticularis* or *reticular dermis*. The dermis is composed of fibrocollagenic tissue containing blood vessels, lymphatics and nerves. In the skin of fingers, arteriovenous shunts or *glomera* are normally present. The specialised nerve endings present at some sites perform specific functions. These are as under:

- i) *Pacinian corpuscles* concerned with pressure are present in the deep layer of skin.
- ii) *Meissner corpuscles* are touch receptors, located in the papillae of skin of palms, soles, tips of fingers and toes.
- iii) *Ruffini corpuscles* are cold receptors found in the external genitalia.
- iv) *End-bulbs of Krause* are cold receptors found in the external genitalia.

Besides these structures, the dermis contains cutaneous appendages or adnexal structures. These are sweat glands, sebaceous glands, hair follicles, arrectores pilorum and nails:

1. SWEAT GLANDS These are of 2 types—eccrine and apocrine.

i) Eccrine glands They are present all over the skin but are most numerous on the palms, soles and axillae. They are coiled tubular glands lying deep in the dermis. Their ducts pass through the epidermis on the surface of the skin as pores via which they empty their secretion i.e. sweat. The glands are lined by two main types of secretory cells: basal, acidophilic, *clear or chief cells*, and the superficial, basophilic, *dark granular cells*. The secretory cells are surrounded by myoepithelial cells.

ii) Apocrine glands Apocrine glands are encountered in some areas only—in the axillae, in the anogenital region, in the external ear as modified glands called ceruminous glands, in the eyelids as Moll's glands, and in the breast as mammary glands. Apocrine glands are also tubular glands but have larger lumina. Apocrine glands have a single layer of secretory cells which contain acidophilic, PAS-positive, prominent granular cytoplasm. The type of secretion in apocrine glands is decapitation secretion as if the cytoplasm of the secretory cells is pinched off (*apo* = off).

2. SEBACEOUS (HOLOCRINE) GLANDS Sebaceous glands are found everywhere on the skin except on the palms and soles. They are often found in association with hair but can be seen in a few areas devoid of hair as modified sebaceous glands such as in the external auditory meatus, nipple and areola of male and female breast, labia minora, prepuce, and meibomian glands of the eyelids. Sebaceous glands are composed of lobules of sebaceous cells containing small round nuclei and abundant fatty, network-like cytoplasm.

3. HAIR The hair grows from the bottom of the follicle. It has, therefore, an intracutaneous portion present in the hair follicle and the shaft. The hair follicle consists of epithelial and connective tissue components. The hair shaft is made up of an outer sheath and pigmented cortex and inner medulla.

4. ARRECTORES PILORI These are small bundles of smooth muscle attached to each hair follicle. When the muscle contracts, the hair becomes more erect, the follicle is dragged upwards so as to become prominent on the surface of the skin producing what is known as '*goose pimple skin*'.

5. NAILS The nails are thickenings of the deeper part of the stratum corneum that develop at specially modified portion of the skin called nail bed. The nail is composed of clear horny cells, resembling stratum lucidum but these cells are much more keratinised.

HISTOPATHOLOGIC TERMS

Before describing pathology of common skin diseases, the following pathologic terms in common use need to be defined for understanding of dermatopathology:

Acanthosis Thickening of the epidermis due to hyperplasia of stratum malpighii.

Acantholysis Loss of cohesion between epidermal cells with formation of intraepidermal space containing oedema fluid and detached epithelial cells.

Dyskeratosis Abnormal development of epidermal cells resulting in rounded cells devoid of their prickles and having pyknotic nuclei. Dyskeratosis is a feature of premalignant and malignant lesions and is rarely seen in benign conditions.

Hyperkeratosis Thickening of the horny layer.

Parakeratosis Abnormal keratinisation of the cells so that the horny layer contains nucleated keratinocytes rather than the normal non-nucleate keratin layer.

Spongiosis Intercellular oedema of the epidermis which may progress to vesicle formation in the epidermis.

Pigment incontinence Loss of melanin pigment from damaged basal cell layer so that the pigment accumulates in the melanophages in the dermis.

GIST BOX 24.1

Normal Structure of Skin

- ☐ Skin has 2 layers, the epidermis and the dermis. Cone-shaped dermal papillae extend upward into the epidermis forming peg-like rete ridges.
- ☐ Various layers of the epidermis from below upwards are stratum germinatum, stratum malpighii, stratum granulosum, stratum lucidum (in palms and soles) and stratum corneum.
- ☐ The dermis has fibrocollagenic tissue containing blood vessels, lymphatics and nerves, and adnexal structures (sweat glands, sebaceous glands, hair follicles, arrectores pilorum and nails).

DERMATOSES

Dermatosis is a common term used for any skin disorder. Dermatitis may be of various types such as genetic, inflammatory, infectious, granulomatous, connective tissue, bullous and scaling type. A few common examples of each of these groups are described below.

I. GENETIC DERMATOSES

1. ICHTHYOSIS Two important forms of ichthyosis are—*ichthyosis vulgaris* and *sex-linked ichthyosis*.

◆ **Ichthyosis vulgaris** is an autosomal dominant disorder. It is more common and appears a few months after birth as scaly lesions on the extensor surfaces of the extremities.

Histologically, the characteristic feature is association of hyperkeratosis with thin or absent granular layer.

◆ **Sex-linked ichthyosis** is a sex-(X) linked recessive disorder. It begins shortly after birth and affects extensor as well as flexor surfaces but palms and hands are spared.

Histologically, there is hyperkeratosis with normal or thickened granular cell layer and acanthosis.

2. KERATOSIS PALMARIS ET PLANTARIS The condition occurs as both autosomal dominant and autosomal recessive forms. It mainly affects the palms and soles as localised or diffuse lesions.

Histologically, there is marked hyperkeratosis, hypergranulosis, acanthosis and mild inflammatory infiltrate in the upper dermis.

3. XERODERMA PIGMENTOSUM This is an autosomal recessive disorder in which sun-exposed skin is more vulnerable to damage. The condition results from decreased ability to repair the sunlight-induced damage to DNA (page 209). Patients of xeroderma pigmentosum are more prone to develop various skin cancers like squamous cell carcinoma, basal cell carcinoma and melanocarcinoma.

Histologically, the changes include hyperkeratosis, thinning and atrophy of stratum malpighii, chronic inflammatory cell infiltrate in the dermis and irregular accumulation of melanin in the basal cell layer. Changes of skin cancers mentioned above may occur when the disease is in advanced stage.

4. DARIER'S DISEASE (KERATOSIS FOLLICULARIS) The condition is either transmitted as autosomal dominant disorder or as a mutation. In typical cases, there is extensive papular eruption.

Histologically, the characteristic changes are hyperkeratosis, papillomatosis and dyskeratosis. Dyskeratosis results in the formation of '*corps ronds*' (present in the granular layer as a central homogeneous basophilic dyskeratotic mass surrounded by a clear halo) and '*grains*' (having grain-shaped elongated nuclei surrounded by homogeneous dyskeratotic material) and there is appearance of suprabasal clefts containing acantholytic cells. The dermis often shows chronic inflammatory cell infiltrate.

5. URTICARIA PIGMENTOSA Urticaria pigmentosa may occur as congenital form or may appear without any family history in the adolescents. Clinically, the condition presents as extensive pigmented macules.

Histologically, the epidermis is normal except for an increase in melanin pigmentation in the basal cell layer. The characteristic feature is the presence of numerous mast cells in the dermis.

6. ATAXIA TELANGIECTASIA An autosomal recessive disorder, ataxia appears in infancy, while telangiectasia appears

in childhood. The lesions are located on the conjunctivae, cheeks, ears and neck. These children are more prone to develop infections, especially of lungs, and lymphoma-leukaemia.

Histologically, the papillary dermis shows numerous dilated blood vessels.

II. NON-INFECTIOUS INFLAMMATORY DERMATOSES

A very large number of skin diseases have acute or chronic inflammation as a prominent feature. A few selected examples of non-infectious acute and chronic inflammatory dermatoses which have not been covered in other groups of dermatoses are given below.

1. DERMATITIS (ECZEMA) The pathologic term dermatitis is synonymous with the clinical term eczema. Both refer to inflammatory response to a variety of agents acting on the skin from outside or from within the body such as chemicals and drugs, hypersensitivity to various antigens and haptens etc. Accordingly, clinical types such as contact dermatitis, atopic dermatitis, drug-induced dermatitis, photo-eczematous dermatitis and primary irritant dermatitis are described. Many idiopathic varieties of skin disorders such as pompholyx, seborrheic dermatitis, exfoliative dermatitis (erythroderma) and neurodermatitis (lichen simplex chronica) are also included under this heading. In general, these conditions are clinically characterised by itching, erythema with oedema, oozing and scaling. However, irrespective of the clinical type of dermatitis, the histopathologic picture is similar.

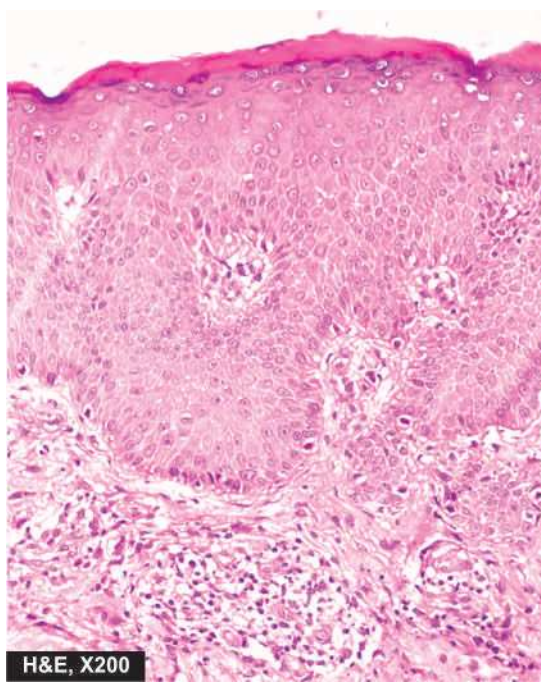

Histologically, dermatitis reaction may be acute, subacute or chronic:

◆ **Acute dermatitis** is characterised by considerable spongiosis (intercellular oedema) that may lead to formation of intraepidermal vesicles or bullae. The vesicles and bullae as well as the oedematous epidermis are permeated by acute inflammatory cells. The upper dermis shows congested blood vessels and mononuclear inflammatory cell infiltrate, especially around the small blood vessels.

◆ **Subacute dermatitis** may follow acute dermatitis. Spongiosis and vesicles are smaller than in acute dermatitis. The epidermis shows moderate acanthosis and varying degree of parakeratosis in the horny layer with formation of surface crusts containing degenerated leucocytes, bacteria and fibrin. The dermis contains perivascular mononuclear infiltrate. The classical example of subacute dermatitis is *nummular dermatitis*.

◆ **Chronic dermatitis** shows hyperkeratosis, parakeratosis and acanthosis with elongation of the rete ridges and broadened dermal papillae. Vesicles are absent but slight spongiosis may be present. The upper dermis shows perivascular chronic inflammatory infiltrate and fibrosis (**Fig. 24.3**). The most characteristic example of chronic dermatitis is *lichen simplex chronicus*.

2. URTICARIA Urticaria or hives is the presence of transient, recurrent, pruritic wheals (i.e. raised erythematous areas of oedema). Hereditary angioneurotic oedema is an uncommon variant of urticaria in which there is recurrent oedema not only

H&E, X200

Figure 24.3 Chronic dermatitis (eczema). The epidermis shows hyperkeratosis, acanthosis and broadened papillae and spongiosis of the epidermal layers. The dermis shows mild perivascular chronic inflammatory cell infiltrate.

on the skin but also on the oral, laryngeal and gastrointestinal mucosa (page 82).

Histologically, there is dermal oedema and a perivascular mononuclear infiltrate. There is localised mast cell degranulation by sensitisation with specific IgE antibodies but no increase in dermal mast cells (*c.f.* mastocytosis in which there is increase in dermal mast cells).

3. MILIARIA Miliaria is a condition in which there is cutaneous retention of sweat due to obstruction of sweat ducts. There are 2 types of miliaria: miliaria crystallina and miliaria rubra.

◆ **Miliaria crystallina** occurs when there is obstruction of sweat duct within the stratum corneum. It occurs in areas of the skin exposed to sun or may occur during a febrile illness.

Histologically, there are intracorneal or subcorneal vesicles which are in continuity with underlying sweat ducts.

◆ **Miliaria rubra** occurs when there is obstruction of sweat ducts within the deeper layers of the epidermis. It is seen more often in areas of skin covered by clothes following profuse sweating and the lesions are itchy.

Histologically, there are spongiotic vesicles in the stratum malpighii similar to those seen in dermatitis. These vesicles are in continuity with a sweat duct. Adjacent dermis usually shows chronic inflammatory infiltrate.

4. PANNICULITIS (ERYTHEMA NODOSUM AND ERYTHEMA INDURATUM) Panniculitis is inflammation of the subcutaneous fat. Panniculitis may be acute or chronic. Generally, panniculitis appears as nodular lesions,

predominantly on the lower legs. The following types of panniculitis are described:

◆ **Erythema nodosum**, acute or chronic, is the most common form. The lesions consist of tender red nodules, 1-5 cm in diameter, seen more often on the anterior surface of the lower legs. Erythema nodosum is often found in association with bacterial or fungal infections, drug intake, inflammatory bowel disease and certain malignancies.

◆ **Erythema induratum** is a less common variety. The lesions are chronic, painless, slightly tender, recurrent and found on the calves of lower legs.

Histologically, the early lesions show necrotising vasculitis involving the blood vessels in the deep dermis and subcutis. In chronic stage, there is inflammatory infiltrate consisting of lymphocytes, histiocytes and multinucleate giant cells. The infiltrate is located in the septa separating the lobules of fat.

5. ACNE VULGARIS Acne vulgaris is a very common chronic inflammatory dermatosis found predominantly in adolescents in both sexes. The lesions are seen more commonly on the face, upper chest and upper back. The appearance of lesions around puberty is related to physiologic hormonal variations. The condition affects the hair follicle, the opening of which is blocked by keratin material resulting in formation of *comedones*. Comedones may be open having central black appearance due to oxidation of melanin called *black heads*, or they may be in closed follicles referred to as *white heads*. A closed comedone may get infected and result in pustular acne.

Histologically, a comedone consists of keratinised cells, sebum and bacteria. The hair follicle containing a comedone is surrounded by lymphocytic infiltrate in papular acne, and neutrophilic infiltrate in pustular acne. Sometimes, the wall of the distended follicle is disrupted so that the contents escape into the dermis where they may incite granulomatous reaction.

III. INFECTIOUS DERMATOSES

Microorganisms such as bacteria, viruses and fungi are responsible for a large number of dermatoses. Some common examples of each category are described below.

1. IMPETIGO Impetigo is a common superficial bacterial infection caused by staphylococci and streptococci. The condition may occur in children or in adults and more commonly involves hands and face. The lesions appear as vesico-pustules which may rupture and are followed by characteristic yellowish crusts.

Histologically, the characteristic feature is the subcorneal pustule which is a collection of neutrophils under the stratum corneum. Often, a few acantholytic cells and gram-positive bacteria are found within the pustule. The upper dermis contains severe inflammatory reaction composed of neutrophils and lymphoid cells.

2. VERRUCAE (WARTS) Verrucae or warts are common viral lesions of the skin. They are caused by human papillomaviruses (HPV) that belong to papovavirus group, a

Table 24.1 Correlation of HPV types with disease.

| | DISEASE | COMMON TYPE | MALIGNANT POTENTIAL |
|-----|---|-------------|---------------------|
| 1. | Common wart (verruca vulgaris) | 1, 2 | 41 |
| 2. | Palmoplantar wart | 1, 2 | — |
| 3. | Flat wart (verruca plana) | 3, 10 | 41 |
| 4. | Anogenital warts (condyloma acuminatum) | 6, 11 | 30, 45 |
| 5. | Bowen's disease | 16 | 31 |
| 6. | Bowenoid papulosis | 16 | 39, 45 |
| 7. | Laryngeal papilloma | 6, 11 | — |
| 8. | Conjunctival papilloma | 6, 11, 16 | 16 |
| 9. | Epidermodysplasia verruciformis | 2, 3, 9, 10 | 5, 8 |
| 10. | Cervical carcinoma | 16, 18 | 16, 18, 31, 33 |

type of DNA oncogenic virus (page 218). More than 100 HPV types have been identified. But it must be appreciated that various types of HPVs produce not only different morphologic lesions but also have variable oncogenic potential as summed up in **Table 24.1**. Infection with HPV is acquired by direct contact or by autoinoculation. Verrucae may undergo spontaneous regression in a few months to 2 years, or may spread to other sites. Depending upon the clinical appearance and location, they are classified into different types described below.

i) Verruca vulgaris is the most common human wart, commonly caused by HPV-1 and 2. The lesions are often multiple, less than 1 cm in size, circumscribed, firm, elevated papules occurring more commonly on the dorsal surfaces of hands and fingers.

ii) Verruca plana on the other hand, is flat or slightly elevated wart, common on the face and dorsal surface of hands and is usually associated with HPV-10.

iii) Verruca plantaris or plantar warts occur on the sole of the foot and is caused by HPV-1. They are covered with a thick callus. They may, therefore, resemble calluses or a verrucous carcinoma.

iv) Epidermodysplasia verruciformis resembles verruca plana but differs by having familial occurrence with autosomal recessive inheritance. The genome of HPV types 5 and 8 have been found in some of these tumours. Epidermodysplasia verruciformis is of special clinical significance as it may undergo malignant change, usually into Bowen's disease, and occasionally into squamous cell carcinoma.

v) Condyloma acuminatum or venereal wart or anogenital wart occurs on the penis, on the vulva and around the anus (page 702). They are commonly caused by HPV-6. The lesions appear as soft, papillary, cauliflower-like mass that may grow fairly large in size (giant condyloma acuminata). In rare cases, transformation into verrucous carcinoma may occur.

Histologically, prototype of verruca is common viral wart having following features (**Fig. 24.4**):

- Papillomatosis (papillary folds).
- Acanthosis (hyperplasia of stratum malpighii) containing foci of vacuolated cells in the upper stratum malpighii.
- Hyperkeratosis with parakeratosis.
- Clumped keratohyaline granules in the granular cells in the valleys between adjacent papillae.
- Elongation of rete ridges with their lower tips bent inwards.
- Virus-infected epidermal cells contain prominent vacuolation (koilocytosis) and keratohyaline granules of intracytoplasmic keratin aggregates due to viral cytopathic effects. These cells on electron microscopy reveal numerous intranuclear viral particles.

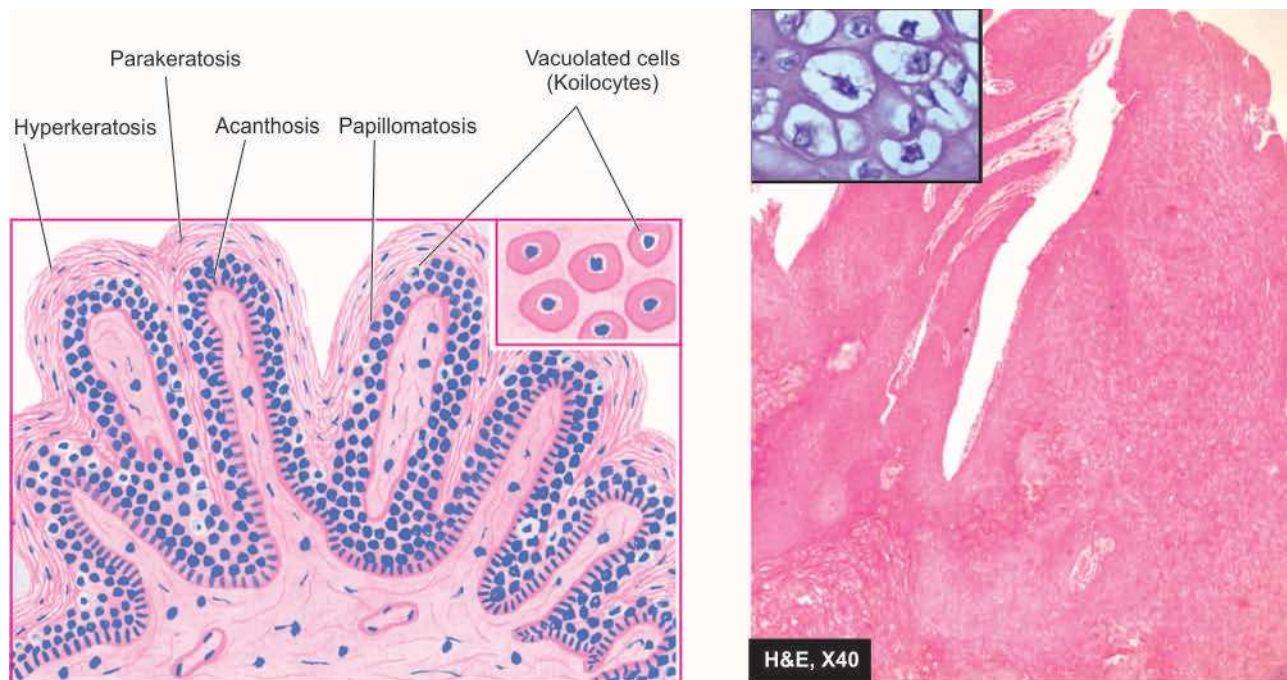

Figure 24.4 Typical appearance of a verruca. The histologic features include papillomatosis, acanthosis, hyperkeratosis with parakeratosis and elongated rete ridges appearing to point towards the centre. Foci of vacuolated cells (koilocytes) are found in the upper stratum malpighii. *Inset* shows koilocytes and virus-infected keratinocytes containing prominent keratohyaline granules.

3. MOLLUSCUM CONTAGIOSUM Molluscum contagiosum is a common self-limiting contagious lesion caused by a poxvirus which is a DNA virus. It is more common in children and young adults. Infection is acquired by direct contact. Clinically, the lesions are often multiple, discrete, waxy, papules, about 5 mm in diameter and are seen more frequently on the face and trunk. In a fully-developed lesion, small amount of paste-like material can be expressed on pressing.

Histologically, typical lesion consists of sharply circumscribed cup-like epidermal lesion growing down into the dermis. The proliferating epidermal cells contain the pathognomonic intracytoplasmic eosinophilic inclusion bodies called *molluscum bodies* (Fig. 24.5). These bodies contain numerous viral particles.

4. VIRAL EXANTHEMATA Viral exanthemata are a group of contagious conditions in which the epidermal cells are destroyed by replicating viruses causing eruption or rash. There are predominantly two groups of viruses which may cause exanthem. These are: the *poxvirus group* (e.g. smallpox or variola, cowpox or vaccinia), and the *herpesvirus group* (e.g. chickenpox or varicella, herpes zoster or shingles, herpes simplex). Clinically, these conditions have different presentations but the eruptive lesions may look alike and are, therefore, considered together.

Variola (smallpox) has been globally eradicated since 1978. The route of infection is via upper respiratory tract or mouth followed by viraemia and characteristic skin lesions. **Vaccinia (cowpox)** is primarily a disease of the teats and udders of cows but humans are infected by milking the infected animals. **Varicella (chickenpox)** and **herpes zoster (shingles)** are both caused by a common virus, varicella-zoster virus. Chickenpox is transmitted by the respiratory route followed by viraemia and successive crops of lesions. Herpes zoster is different manifestation of infection with the same viral agent after years of latency. It is a disease of the nerves and the tissues supplied by the nerves. The condition is characterised by sharp burning pain, often disproportionate to the rash. **Herpes simplex**, caused by HSV-1, and another related herpetic infection, **herpes genitalis**, caused by HSV-2,

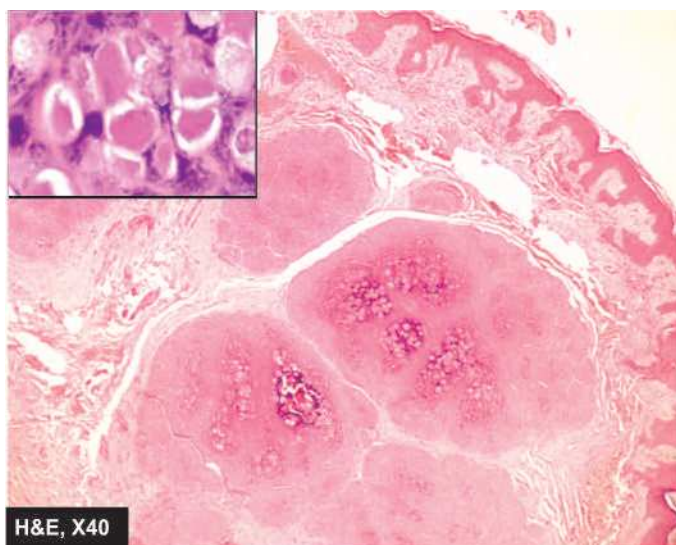

Figure 24.5 Molluscum contagiosum. The epidermal layers show numerous molluscum bodies which are intracytoplasmic inclusions. Inset shows close-up view of molluscum bodies.

are characterised by transmission by direct physical contact and prolonged latency. The vesicular lesions are often located on the skin, especially the facial skin around lips and external nares; other sites are mucosal surfaces and eyes.

Histologically, the characteristic feature of viral exanthemata is the formation of intra-epidermal vesicles or bullae due to cytopathic effects of viruses. In the early stage, there is proliferation of epidermal cells and formation of multinucleate giant cells. This is followed by intracellular oedema and ballooning degeneration that progresses on to rupture of the cells with eventual formation of vesicles or bullae.

5. SUPERFICIAL MYCOSES Superficial fungal infections of the skin are localised to stratum corneum (page 174). These include some of the common dermatophytes such as *Trichophyton rubrum* and *Pityrosporum*. Clinically, these fungal infections are labelled according to the region involved. These are as follows:

- i) **Tinea capitis** occurring on the scalp, especially in children.
- ii) **Tinea barbae** affecting the region of beard in adult males.
- iii) **Tinea corporis** involving the body surface at all ages.
- iv) **Tinea cruris** occurs most frequently in the region of groin in obese men, especially in hot weather.
- v) **Tinea pedis** or 'athlete foot' is located in the web spaces between the toes.
- vi) **Onychomycosis** shows disintegration of the nail substance.
- vii) **Tinea versicolor** caused by *Malassezia furfur* generally affects the upper trunk.

Histologically, fungal hyphae (or mycelia) and arthrospores of dermatophytes are present in the stratum corneum of skin, nails or hair. Hyphae may be septate or nonseptate. Spores are round to oval bodies which grow by budding. Special stains can be used to demonstrate the fungi. These are: *periodic acid-Schiff (PAS) reaction* which stains the fungi deep pink to red (Fig. 24.6), and Grocott's *methenamine silver nitrate method* that stains fungi black.

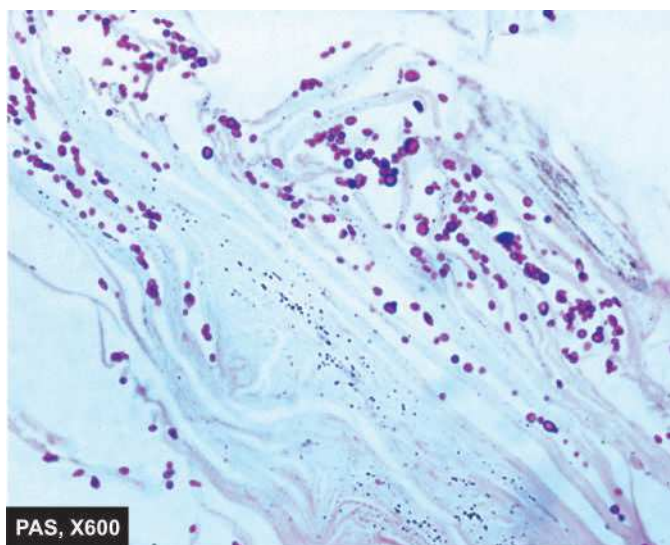

Figure 24.6 Tinea capitis in the skin. The stratum corneum around the hair follicle shows presence of numerous arthrospores and hyphae.

IV. GRANULOMATOUS DISEASES

In many skin diseases, the host may respond by granulomatous inflammation to a variety of microbial agents and nonmicrobial material. Tuberculosis of the skin is the classical example in which typical tubercles are formed; other conditions are leprosy, syphilis, sarcoidosis, deep fungal infection etc. These conditions have already been discussed in Chapter 5. Nonmicrobial agents which can incite granulomatous inflammation are keratin, hair, thorns, talc, minerals like beryllium, asbestos and tattoo pigment etc.

Important representative examples of granulomatous inflammation—*lupus vulgaris*, *cutaneous sarcoidosis* and *granuloma annulare*, are described here.

1. LUPUS VULGARIS The lesions of lupus vulgaris, the prototype of skin tuberculosis, are found most commonly on the head and neck, especially skin of the nose. They are yellowish-brown to reddish-brown tiny nodules (apple-jelly nodules).

Histologically, the nodules consist of well-defined tubercles lying in the upper dermis. They consist of accumulation of epithelioid cells surrounded by lymphoid cells. Caseation necrosis may be slight or absent. Langhans' and foreign body type of giant cells are often present (Fig. 24.7). The condition needs to be distinguished from sarcoidosis of the skin (vide infra). Tubercle bacilli are present in very small numbers that are hard to demonstrate by acid-fast staining.

2. CUTANEOUS SARCOIDOSIS Sarcoidosis is a systemic granulomatous disease of unknown etiology (page 154). The lesions appear in the lungs, skin, eyes, nose and lymph nodes. Cutaneous manifestations appear as presenting feature in about a quarter of patients and include erythema nodosum, or brown-red jelly-like papules or plaques with central clearing. When these lesions are seen around nose, eyes and cheeks they are referred to as *lupus pernio*.

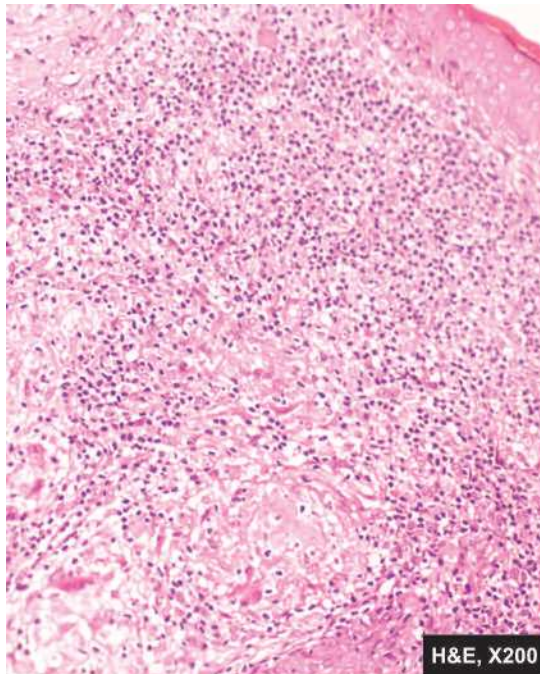

Figure 24.7 Lupus vulgaris. The dermis contains caseating epithelioid cell granulomas having giant cells and lymphocytes.

Microscopically, characteristic feature is the presence of non-caseating epithelioid cell granulomas having Langhans' giant cells but having paucity of lymphocytes, also called 'naked granulomas' (Fig. 24.8). Fibrinoid necrosis and presence of intracellular inclusions such as asteroid bodies are some other features which may be seen.

3. GRANULOMA ANNULARE The lesions of granuloma annulare are often numerous. Dermal nodules are arranged in a ring-like fashion, commonly on the hands and feet. The condition appears to have correlation with diabetes mellitus.

Histologically, the centre of the lesion shows a well-demarcated focus of complete collagen degeneration. These foci are surrounded by an infiltrate composed largely of histiocytes and some mononuclear inflammatory cells forming a palisade arrangement and are therefore also referred to as palisading granulomas.

V. CONNECTIVE TISSUE DERMATOSES

Group of diseases caused by self-antigens or autoimmune diseases are included under connective tissue diseases. A list of such diseases along with their etiology and pathogenesis is given on page 61. Morphology of skin lesions of two important representative examples—*lupus erythematosus* and *systemic sclerosis (scleroderma)*, is given below. Another connective tissue disease of unknown etiology, lichen sclerosus et atrophicus, is also considered here.

1. LUPUS ERYTHEMATOSUS Two types of lupus erythematosus are recognised—a chronic form, *discoid lupus erythematosus (DLE)* which is confined to the skin; and a systemic form, *systemic lupus erythematosus (SLE)* that has widespread visceral vascular lesions. The discoid variety is more common which is generally benign, while systemic form

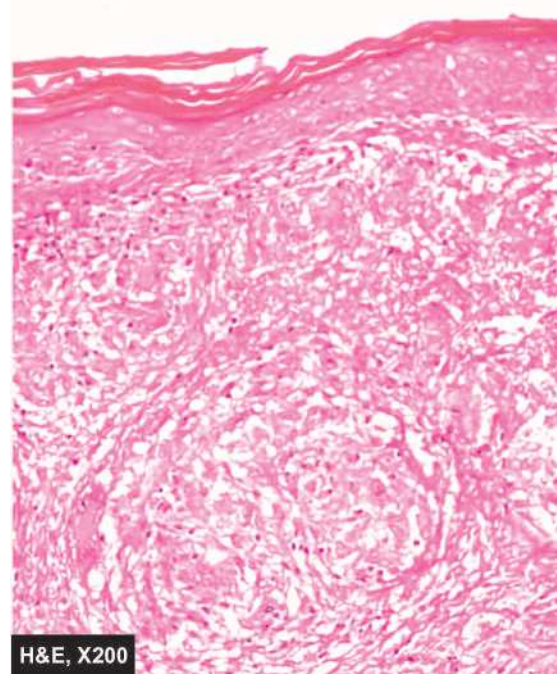

Figure 24.8 Cutaneous sarcoidosis. The dermis shows non-caseating epithelioid granulomas having Langhans' giant cells and paucity of lymphocytes, termed as naked granulomas.

may be fatal, usually from renal involvement. The diagnosis is made on the basis of clinical, serologic and pathologic changes. The characteristic cutaneous lesions in DLE consist of well-defined erythematous discoid patches associated with scaling and atrophy and often limited to the face. In contrast, cutaneous lesions in SLE are present only in a small proportion of cases and consist of erythematous, slightly oedematous patches which are without significant scaling and without atrophy.

Histologically, cutaneous lesion in DLE and SLE may not be distinguishable in all cases. The important features are as follows (Fig. 24.9):

- i) Hyperkeratosis with keratotic plugging.
- ii) Thinning and flattening of rete malpighii.
- iii) Hydropic degeneration of basal layer.
- iv) Patchy lymphoid infiltrate around cutaneous adnexal structures.
- v) Upper dermis showing oedema, vasodilatation and extravasation of red cells.

Direct immunofluorescence reveals granular deposits of immunoglobulins, most commonly IgG and IgM, and components of complement on the basement membrane of the affected skin in both DLE and SLE. High serum titres of antinuclear antibodies and demonstration of LE cells (page 64) are other notable features, especially in SLE.

2. SYSTEMIC SCLEROSIS (SCLERODERMA) Two types of systemic sclerosis or scleroderma are identified: a localised form called *morphea*, and a generalised form called *progressive systemic sclerosis*. A variant of progressive systemic sclerosis is *CREST syndrome*. (C = calcinosis, R = Raynaud's phenomenon, E = esophageal dysmotility, S = sclerodactyly and T = telangiectasia). Etiology and pathogenesis of these conditions

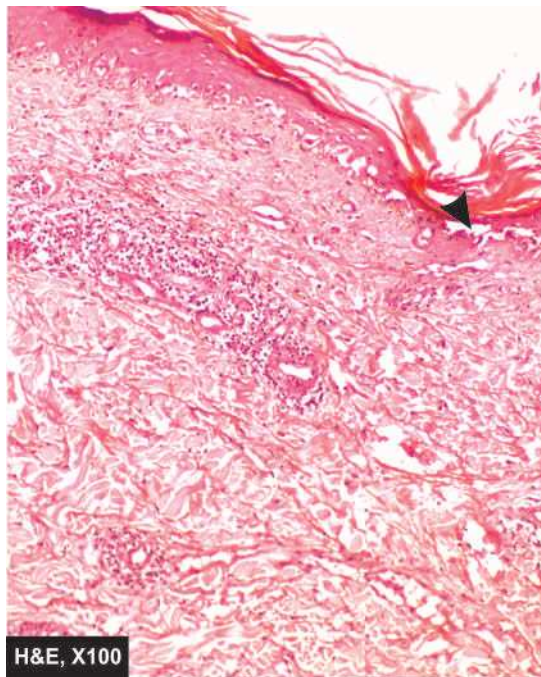

Figure 24.9 Discoid lupus erythematosus (DLE). The epidermis is flat and is devoid of rete ridges. There is hyperkeratosis and follicular plugging. The basal layer shows hydropic degeneration and loss of dermo-epidermal junction (arrow). The upper dermis is oedematous and shows moderate lymphocytic infiltration.

are already described (page 64). *Morphea* consists of lesions limited to the skin and subcutaneous tissue, while progressive systemic sclerosis consists of extensive involvement of the skin and the subcutaneous tissue and has visceral lesions too. The lesions generally begin in the fingers and distal extremities and then extend proximally to involve the arms, shoulders, neck and face.

Histologically, there is thickening of the dermal collagen extending into the subcutaneous tissue. There is pronounced chronic inflammatory infiltrate in the affected area. The epidermis is often thin, devoid of rete ridges and adnexal structures, and there is hyalinised thickening of the walls of dermal arterioles and capillaries. Subcutaneous calcification may develop.

3. LICHEN SCLEROSUS ET ATROPHICUS This condition involves genital skin most frequently and is often the only site of involvement. It occurs in both sexes, more commonly in women than in men. It is termed *kraurosis vulvae* in women while the counterpart in men is referred to as *balanitis xerotica obliterans*. Occasionally, the condition may coexist with *morphea*. Clinically, the condition may simulate malignancy.

Histologically, the characteristic features are as under:

- i) Hyperkeratosis with follicular plugging.
- ii) Thinning and atrophy of the epidermis.
- iii) Hydropic degeneration of the basal layer.
- iv) Upper dermis showing oedema and hyaline appearance of collagen.
- v) Inflammatory infiltrate in mid-dermis.

VI. NON-INFECTIOUS BULLOUS DERMATOSES

This is a group of skin diseases characterised by bullae and vesicles. A *bulla* is a cavity formed in the layers of the skin and contains blood, plasma, epidermal cells or inflammatory cells, while a *vesicle* is a small bulla less than 5 mm in diameter. *Blister* is the common term used for both bulla and vesicle. The blister can be located at different sites such as subcorneal, intra-epidermal (suprabasal or subcorneal) and subepidermal. These blisters can appear in infectious as well as in noninfectious dermatoses. A few common examples of noninfectious dermatoses are pemphigus, pemphigoid, dermatitis herpetiformis and erythema multiforme and are illustrated in Fig. 24.10.

1. PEMPHIGUS Pemphigus is an autoimmune bullous disease of the skin and mucosa which has 4 clinical and pathologic variants: pemphigus vulgaris, pemphigus vegetans, pemphigus foliaceus and pemphigus erythematosus.

All forms of pemphigus have acantholysis as common histologic feature. Sera from these patients contain IgG antibodies to cement substance of skin and mucosa.

i) Pemphigus vulgaris is the most common type characterised by the development of flaccid bullae on the skin and oral mucosa. These bullae break easily leaving behind denuded surface.

Histologically, the bullae are suprabasal in location so that the basal layer remains attached to dermis like a row of tombstones. The bullous cavity contains serum and acantholytic epidermal cells (Fig. 24.11).

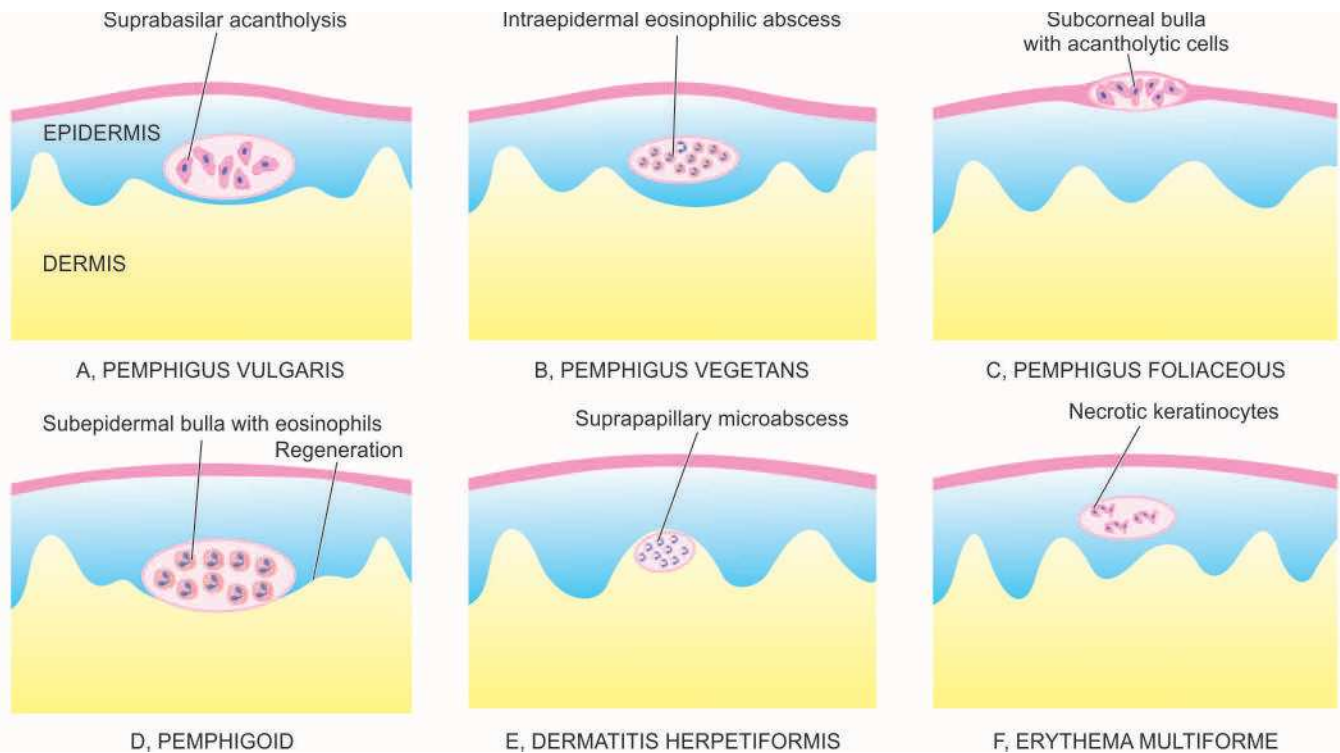

Figure 24.10 Location of bullae and vesicles in non-infectious bullous dermatoses. A, *Pemphigus vulgaris*: The bulla is predominantly suprabasilar in position and contains acantholytic cells. B, *Pemphigus vegetans*: An intraepidermal abscess composed of eosinophils is seen. C, *Pemphigus foliaceus*: The bulla is superficial in subcorneal position and contains acantholytic cells. D, *Pemphigoid*: The bulla containing eosinophils is subepidermal with regeneration of the epidermis at the periphery. E, *Dermatitis herpetiformis*: There is a papillary microabscess composed of neutrophils. F, *Erythema Multiforme*: The affected area shows necrotic keratinocytes and inflammatory cells.

ii) **Pemphigus vegetans** is an uncommon variant consisting of early lesions resembling pemphigus vulgaris. But later, verrucous vegetations are found on the skin and oral mucosa instead of bullous lesions.

Histologically, there is considerable acanthosis and papillomatosis. Intraepidermal abscesses composed almost entirely of eosinophils are diagnostic of pemphigus vegetans (Fig. 24.4,B).

iii) **Pemphigus foliaceus** is characterised by quite superficial bullae which leave shallow zones of erythema and crust.

Histologically, superficial subcorneal bullae are found which contain acantholytic epidermal cells.

iv) **Pemphigus erythematosus** is an early form of pemphigus foliaceus. The distribution of clinical lesions is similar to lupus erythematosus involving face.

Histologically, the picture is identical to that of pemphigus foliaceus.

2. PEMPHIGOID This is a form of bullous disease affecting skin or the mucous membranes. Three variants have been described—*localised form* occurring on the lower extremities; *vesicular form* consisting of small tense blisters; and *vegetating form* having verrucous vegetations found mainly in the axillae and groins.

Histologically, the characteristic distinguishing feature from pemphigus is the subepidermal location of the

non-acantholytic bullae. With passage of time, there is some epidermal regeneration from the periphery at the floor of the bulla. The bullous cavity contains fibrin network and many mononuclear inflammatory cells and

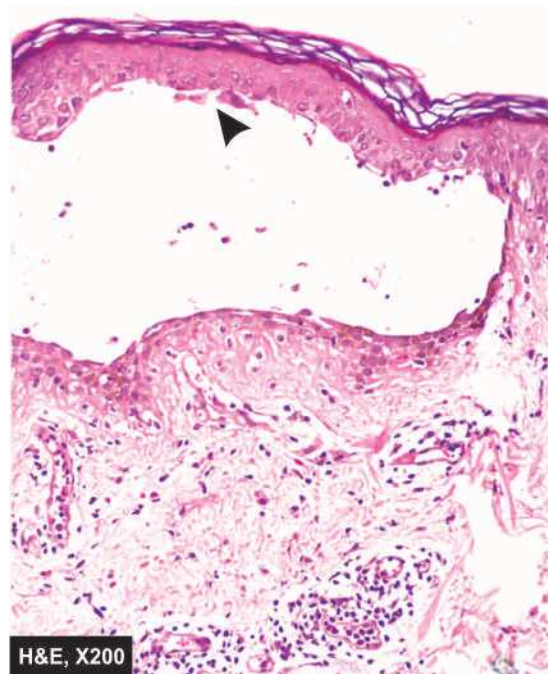

Figure 24.11 Pemphigus vulgaris. An intraepidermal bulla in suprabasal location containing acantholytic cells (arrow) is seen.

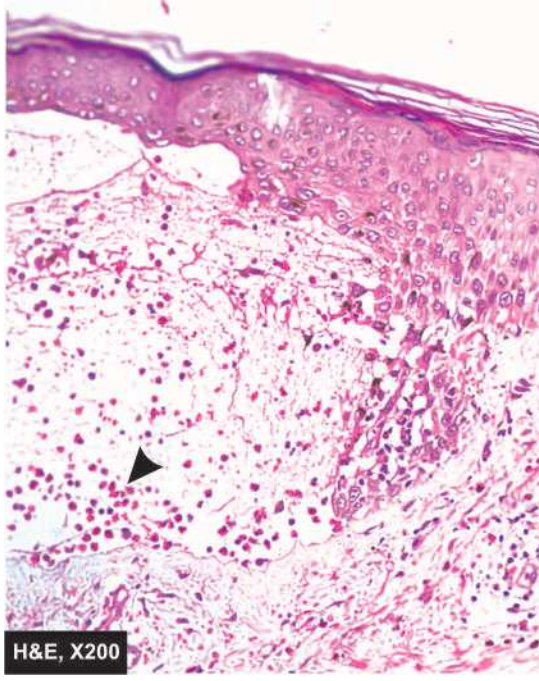

Figure 24.12 Bullous pemphigoid. The skin shows non-acantholytic subepidermal bulla containing microabscess of eosinophils (arrow).

many eosinophils (**Fig. 24.12**). Dermal changes seen in inflammatory bullae consist of infiltrate of mononuclear cells, a few eosinophils and neutrophils.

3. DERMATITIS HERPETIFORMIS Dermatitis herpetiformis is a form of chronic, pruritic, vesicular dermatosis. The lesions are found more commonly in males in 3rd to 4th decades of life. The disease has an association with gluten-sensitive enteropathy (coeliac disease). Both dermatitis herpetiformis and gluten-sensitive enteropathy respond to a gluten-free diet. The pathogenesis of the disease is not quite clear but probably individuals with certain histocompatibility types develop IgA and IgG antibodies to gliadin which is a fraction of gluten present in the flour (page 558).

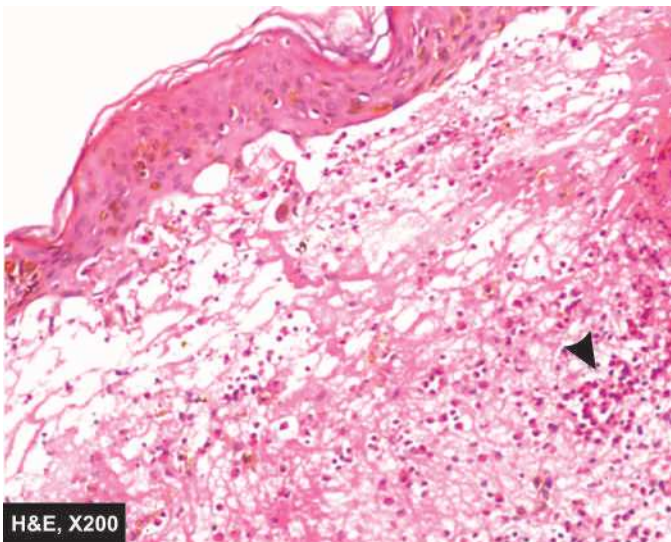

Figure 24.13 Dermatitis herpetiformis. The tips of dermal papillae show neutrophilic microabscess (arrow) causing dermo-epidermal separation at tips.

Histologically, the early lesions of dermatitis herpetiformis consist of neutrophilic micro-abscesses at the tips of papillae, producing separation or blister between the papillary dermis and the epidermis (**Fig. 24.13**). The older blisters contain fair number of eosinophils causing confusion with bullous pemphigoid. Direct immunofluorescence shows granular deposits of IgA at the papillary tips in dermatitis herpetiformis.

4. ERYTHEMA MULTIFORME This is an acute, self-limiting but recurrent dermatosis. The condition occurs due to hypersensitivity to certain infections and drugs, and in many cases, it is idiopathic. As the name suggests, the lesions are *multiform* such as macular, papular, vesicular and bullous. Quite often, the lesions have symmetric involvement of the extremities. *Stevens-Johnson syndrome* is a severe, at times fatal, form of involvement of skin and mucous membranes of the mouth, conjunctivae, genital and perianal area. Another variant termed *toxic epidermal necrolysis* consists of diffuse necrosis of the epidermis and mucosa, exposing the dermis giving the skin a scalded appearance.

Histologically, the changes vary according to the clinical multiform stage.

- i) *Early lesions* show oedema and lymphocytic infiltrate at the dermoepidermal junction. The superficial dermis shows perivascular lymphocytic infiltrate.
- ii) Later stage is associated with migration of lymphocytes upwards into the epidermis resulting in epidermal necrosis and blister formation (**Fig. 24.14**).

VII. SCALING DERMATOSES

The skin surface in some chronic inflammatory dermatoses is roughened due to excessive and abnormal scale formation and desquamation. Common examples of this group are psoriasis and lichen planus. Hereditary ichthyosis having similar scaly lesions has already been described.

1. PSORIASIS Psoriasis is a chronic inflammatory dermatosis that affects about 2% of the population. It usually appears

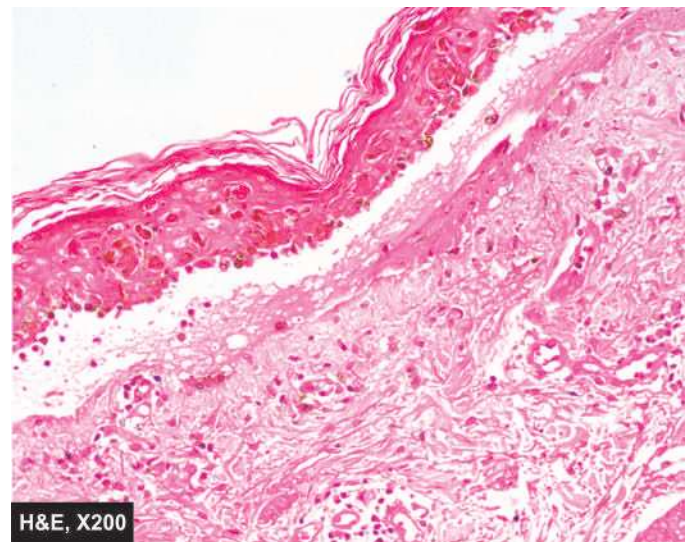

Figure 24.14 Erythema multiforme. There is pronounced dermo-epidermal interface dermatitis. There is oedema and necrosis of keratinocytes at the junction and mild lymphocytic infiltrate.

first between the age of 15 and 30 years. The lesions are characterised by brownish-red papules and plaques which are sharply demarcated and are covered with fine, silvery white scales. As the scales are removed by gentle scrapping, fine bleeding points appear termed *Auspitz sign*. Commonly involved sites are the scalp, upper back, sacral region and extensor surfaces of the extremities, especially the knees and elbows. In about 25% of cases, peculiar pitting of nails is seen. Psoriatic arthritis resembling rheumatoid arthritis is produced in about 5% of cases but rheumatoid factor is absent.

Histologically, the following features are observed in fully-developed lesions (Fig. 24.15):

- i) Acanthosis with regular downgrowth of rete ridges to almost the same dermal level with thickening of their lower portion.
- ii) Elongation and oedema of the dermal papillae with broadening of their tips.
- iii) Suprapapillary thinning of stratum malpighii.
- iv) Absence of granular cell layer.
- v) Prominent parakeratosis.
- vi) Presence of Munro microabscesses in the parakeratotic horny layer is diagnostic of psoriasis.

2. LICHEN PLANUS Lichen planus is a chronic dermatosis characterised clinically by irregular, violaceous, shining, flat-topped, pruritic papules. The lesions are distributed symmetrically with sites of predilection being flexor surfaces of the wrists, forearms, legs and external genitalia. Buccal mucosa is also involved in many cases of lichen planus.

Histologically, the characteristic features are as under (Fig. 24.16):

- i) Marked hyperkeratosis.
- ii) Focal hypergranulosis.

- iii) Irregular acanthosis with elongated saw-toothed rete ridges.
- iv) Liquefactive degeneration of the basal layer.
- v) A band-like dermal infiltrate of mononuclear cells, sharply demarcated at its lower border and closely hugging the basal layer.

VIII. METABOLIC DISEASES OF SKIN

Skin is involved in a variety of systemic metabolic derangements. The examples include the following:

1. Amyloidosis (primary as well as secondary, page 66).
2. Lipoid proteinosis is rare.
3. Porphyria of various types (page 24).
4. Calcinosis cutis
5. Gout due to urate deposits or tophi (page 845).
6. Ochronosis due to alkaptonuria (page 22).
7. Mucinosi seen in myxoedema (page 794).
8. Idiopathic haemochromatosis with skin pigmentation (page 611).

Many of these conditions have been discussed elsewhere in the book; calcinosis cutis is briefly considered below.

CALCINOSIS CUTIS There are four types of calcification in the skin:

- i) Metastatic calcinosis cutis
- ii) Dystrophic calcinosis cutis
- iii) Idiopathic calcinosis cutis
- iv) Subepidermal calcified nodule

i) Metastatic calcinosis cutis develops due to hypercalcaemia or hyperphosphataemia as discussed on page 36.

ii) Dystrophic calcinosis cutis results when there is deposition of calcium salts at damaged tissue.

iii) Idiopathic calcinosis cutis resembles dystrophic type but is not associated with any underlying disease. A special

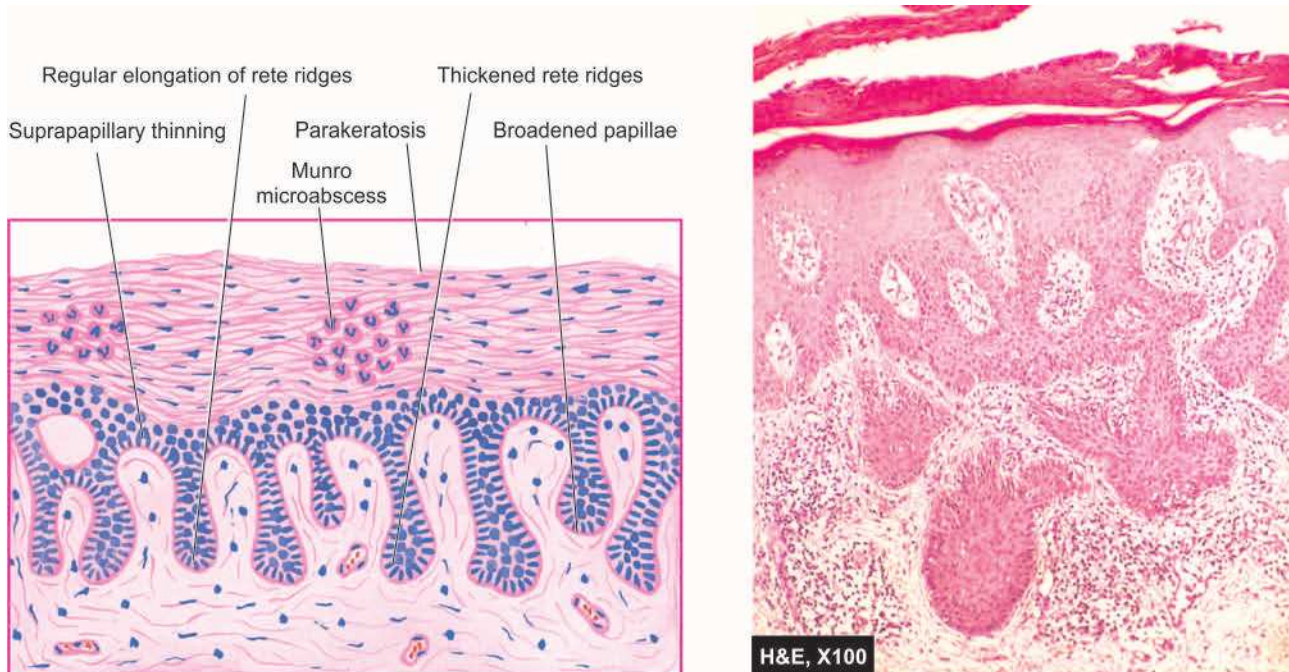

Figure 24.15 Psoriasis. There is regular elongation of the rete ridges with thickening of their lower portion. The papillae are elongated and oedematous with suprapapillary thinning of epidermis. There is marked parakeratosis with diagnostic Munro microabscesses in the parakeratotic layer.

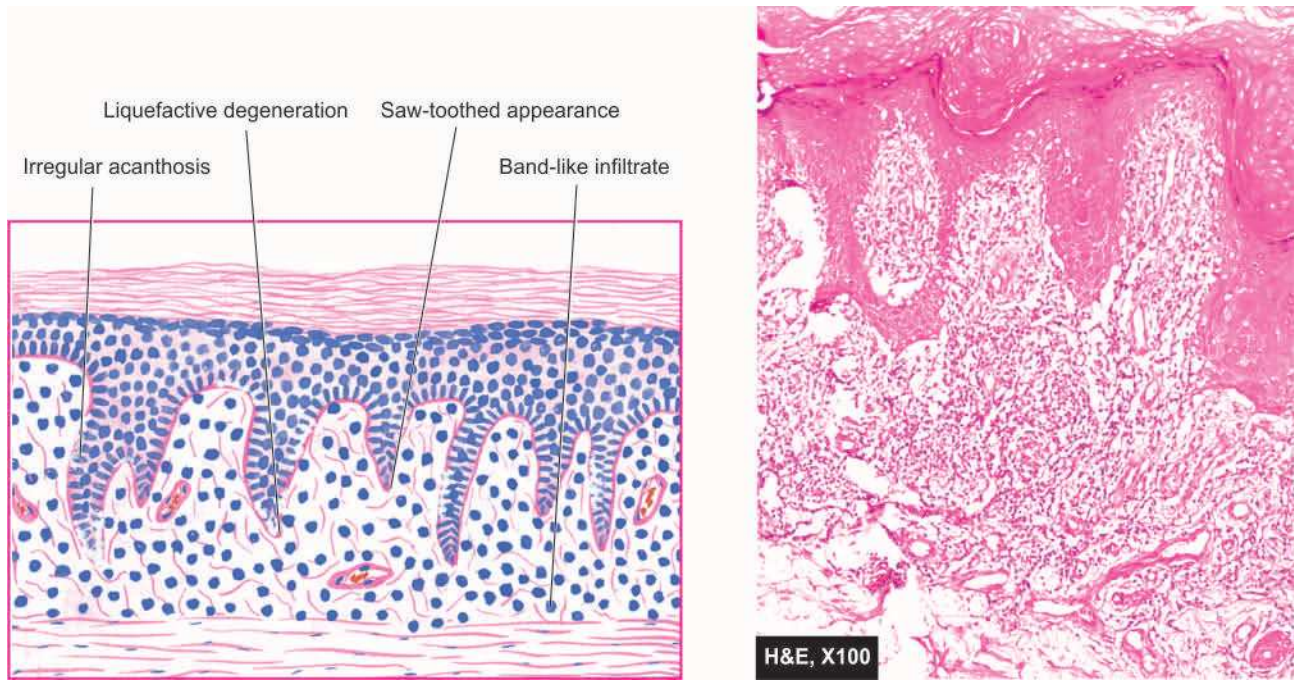

Figure 24.16 Lichen planus. There is hyperkeratosis, focal hypergranulosis and irregular acanthosis with elongated saw-toothed rete ridges. The basal layer shows liquefactive degeneration. The upper dermis shows a band-like mononuclear infiltrate with a sharply-demarcated lower border.

manifestation of idiopathic calcinosis cutis is *tumoral calcinosis* in which there are large subcutaneous calcified masses, often accompanied by foreign body giant cell reaction. Calcium may discharge from the surface of the lesion. *Idiopathic calcinosis of the scrotum* consists of multiple asymptomatic nodules of the scrotal skin (**Fig. 24.17**).

iv) Subepidermal calcified nodule or *cutaneous calculus* is a single raised hard calcified nodule in the upper dermis.

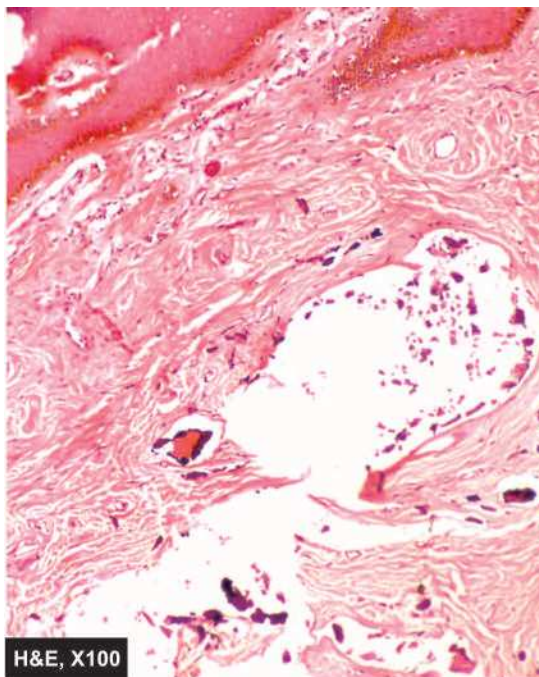

Figure 24.17 Idiopathic calcinosis cutis. The subcutaneous tissue shows masses or nodules of calcium salt surrounded by foreign body giant cells.

GIST BOX 24.2

Dermatoses

- ▣ Dermatoses are any form of skin disorder e.g. genetic, inflammatory, infectious, granulomatous, connective tissue, bullous and scaling type.
- ▣ Common examples of genetic dermatoses are ichthyosis, xeroderma pigmentosum and urticaria pigmentosa.
- ▣ A few non-infectious inflammatory dermatoses are eczema, urticaria, miliaria, panniculitis, and acne.
- ▣ Common infectious dermatoses are impetigo, verrucae, viral exanthemata, and superficial mycoses.
- ▣ Granulomatous dermatoses are lupus vulgaris, sarcoidosis and granuloma annulare.
- ▣ Examples of connective tissue dermatoses are DLE and SLE, scleroderma.
- ▣ Some common non-infectious bullous dermatoses are pemphigus, pemphigoid, dermatitis herpetiformis, erythema multiforme.
- ▣ Common scaling dermatoses are psoriasis and lichen plans.

TUMOURS AND TUMOUR-LIKE LESIONS

The skin is the largest organ of the body. Tumours and tumour-like lesions may arise from different components of the skin such as surface epidermis, epidermal appendages and dermal tissues. Each of these tissues may give rise to benign and malignant tumours as well as tumour-like lesions. Besides these, there is a group of conditions and lesions which are precancerous. Another group of tumours have their origin from elsewhere in the body but are cellular migrants to the skin. A comprehensive list of tumours and tumour-like lesions of the skin is presented in **Table 24.2**. It is beyond the scope of this book to describe all these tumours and lesions, for

which the interested reader may consult specialised work on dermatopathology. Some important and common examples of these conditions are considered here.

I. TUMOURS AND CYSTS OF THE EPIDERMIS

A. BENIGN TUMOURS

1. SQUAMOUS PAPILLOMA Squamous papilloma is a benign epithelial tumour of the skin. Though considered by many authors to include common viral warts (*verrucae*) and condyloma acuminata, true squamous papillomas differ from these viral lesions. If these 'viral tumours' are excluded, squamous papilloma is a rare tumour.

Histologically, squamous papillomas are characterised by hyperkeratosis, acanthosis with elongation of rete ridges and papillomatosis (Fig. 24.18). The *verrucae*, in addition to these features, have foci of vacuolated cells in the acanthotic stratum malpighii, vertical tiers of parakeratosis between the adjacent papillae and irregular clumps of keratohyaline granules in the virus-infected granular cells lying in the valleys between the papillae (page 763).

2. SEBORRHEIC KERATOSIS Seborrheic keratosis is a very common lesion in middle-aged adults. There may be only one lesion, but more often these are many. The common locations are trunk and face. They are sharply-demarcated, brownish, smooth-surfaced, measuring a few millimeters in diameter.

Histologically, the pathognomonic feature is a sharply-demarcated exophytic tumour overlying a straight line from the normal epidermis at one end of the tumour to the normal epidermis at the other end. The other features are papillomatosis, hyperkeratosis and acanthosis as seen in squamous cell papillomas (Fig. 24.19).

3. FIBROEPITHELIAL POLYPS Also known by other names such as 'skin tags', 'acrochordons' and 'soft fibromas', these are the most common cutaneous lesions. They are often multiple, soft, small (a few mm in size), bag-like tumours commonly seen on the neck, trunk and axillae.

Histologically, the tumours are composed of loosely-arranged fibrovascular cores with overlying hyperplastic epidermis (Fig. 24.20).

B. EPITHELIAL CYSTS

Various cysts in the skin may arise from downward growth of the epidermis and the appendages. These cysts often contain paste-like pultaceous material containing keratin, sebaceous secretions and lipid-containing debris. Depending upon the structure of the cyst wall, these cysts are of various types as under:

1. EPIDERMAL CYST These intradermal or subcutaneous cysts, commonly called sebaceous cysts, are common and may occur spontaneously or due to implantation of the epidermis into the dermis or subcutis (implantation cysts). Most frequent sites are the skin of face, scalp, neck and trunk.

Histologically, epidermal cysts have a cyst wall composed of true epidermis with laminated layers of keratin (Fig. 24.21). Rupture of the cyst may incite foreign body giant cell inflammatory reaction in the wall.

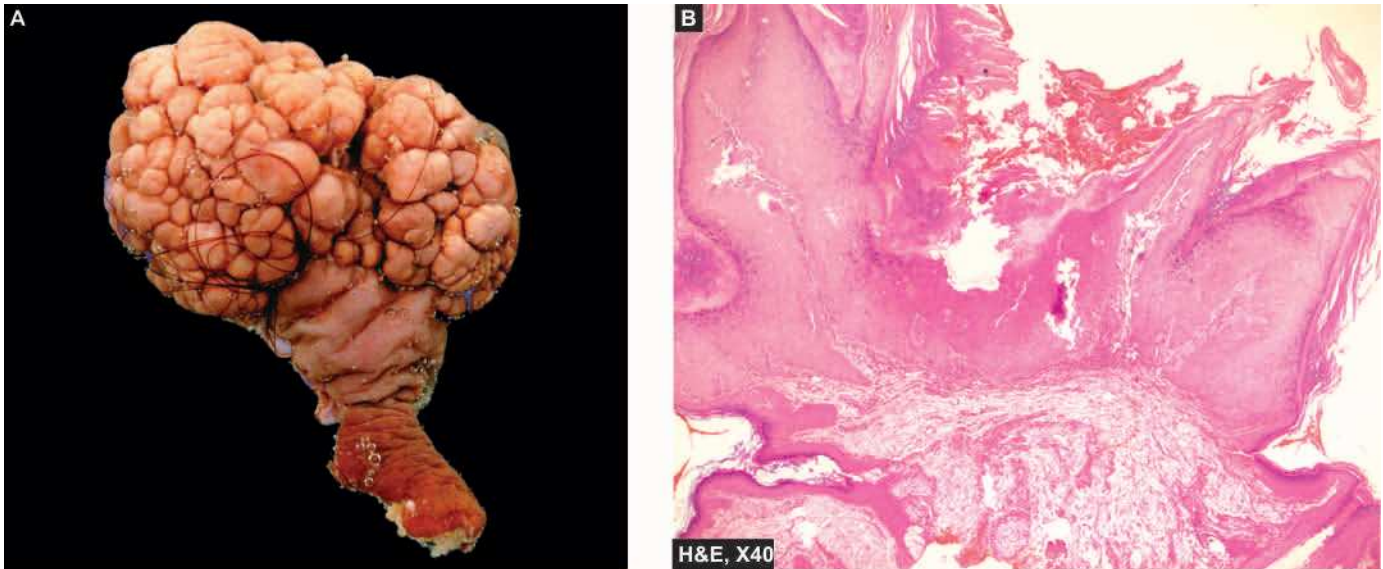

Figure 24.18 Squamous cell papilloma. A, The skin surface shows a papillary growth with a pedicle while the surface is smooth. B, Microscopy resembles verruca but differs from it by not having vacuolated koilocytic cells in stratum malpighii.

2. PILAR (TRICHILEMMAL, SEBACEOUS) CYST These cysts clinically resemble epidermal cysts but occur more frequently on the scalp and are less common than the epidermal cysts.

Histologically, the cyst wall is composed of palisading squamous epithelial cells having abruptly keratinised layer without an intervening granular cell layer. These squamous cells undergo degeneration towards the cyst cavity. Rupture of the cyst wall is common and leads to foreign body giant cell inflammatory reaction. Calcification in the cyst wall is often present.

3. DERMOID CYST These are subcutaneous cysts often present since birth. Dermoid cysts are more common on the face, along the lines of embryonic closure.

Histologically, the cyst wall contains epidermis as well as appendages such as hair follicles, sebaceous glands and sweat glands (**Fig. 24.22**).

4. STEATOCYSTOMA MULTIPLEX This is an inherited autosomal dominant disorder having multiple cystic nodules, 1-3 cm in size. They are more common in the axillae, sternum and arms.

Histologically, the cyst walls are composed of several layers of epithelial cells and contain lobules of sebaceous glands in the cyst wall.

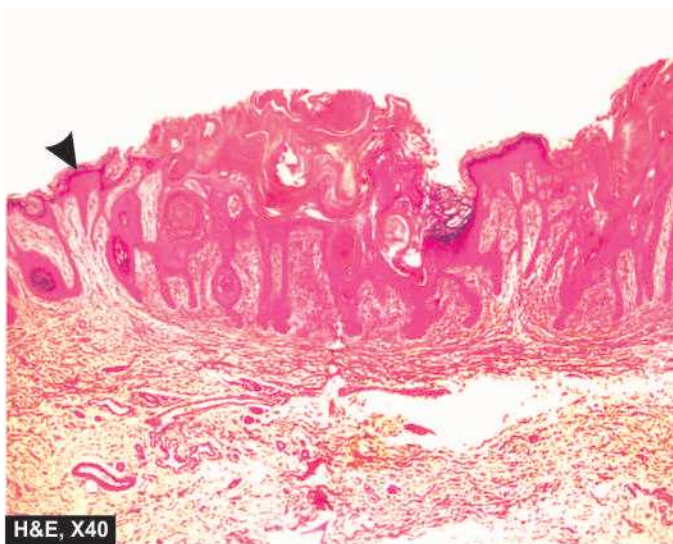

Figure 24.19 Seborrheic keratosis. The border of the elevated lesion at the lateral margin is in a straight line from the normal uninvolved epidermis (arrow). The other features include papillomatosis, hyperkeratosis and acanthosis.

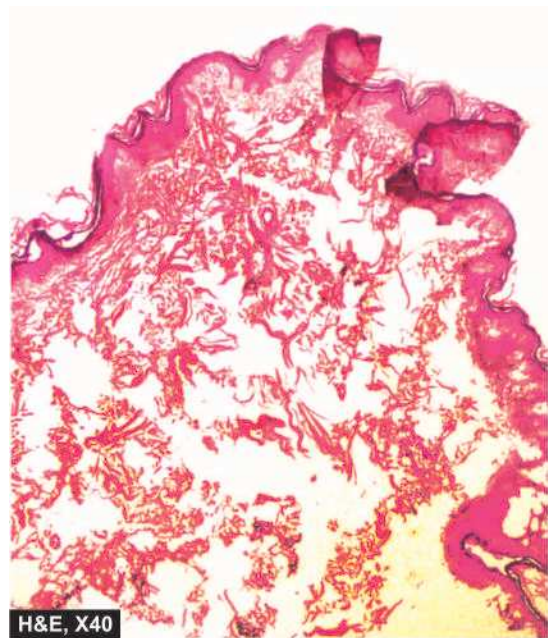

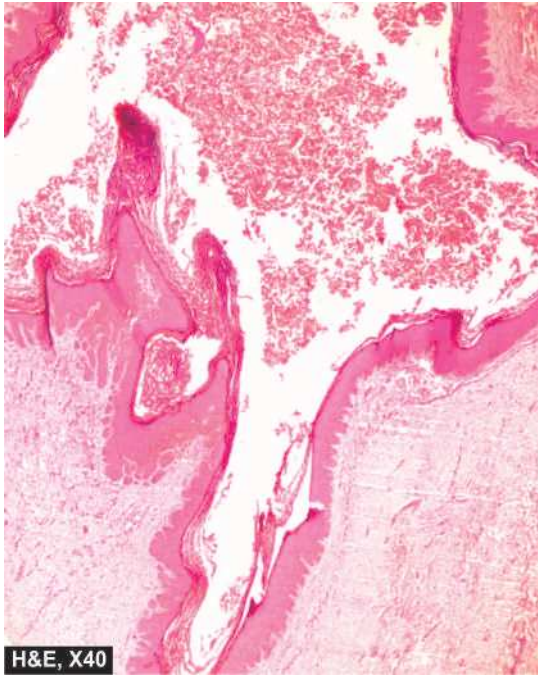

Figure 24.20 Fibroepithelial polyp (acrochordon or soft fibroma). The epidermis is raised as polypoid mass over dense hyalinised fibrous connective tissue in the dermis.

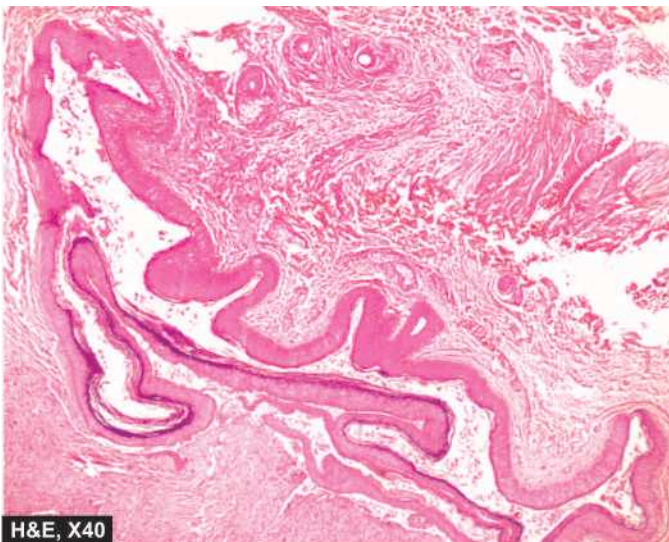

H&E, X40

Figure 24.21 Epidermal inclusion cyst. The cyst wall is composed of all layers of the epidermis and has laminated layers of keratin towards the lumen of the cyst.

C. PRE-MALIGNANT LESIONS

1. SOLAR KERATOSIS (ACTINIC KERATOSIS, SENILE KERATOSIS) Solar (sun-induced) or actinic (induced by a variety of rays) keratoses are multiple lesions occurring in sun-exposed areas of the skin in fair-skinned elderly people. Similar lesions may be induced by exposure to ionising radiation, hydrocarbons and arsenicals. The condition is considered to be a forerunner of invasive squamous cell and/or basal cell carcinoma. Clinically, the lesions are tan-brown, erythematous, about 1 cm in diameter with rough, sandpaper-like surface and are seen more commonly on the dorsum of the hands and on the balded portion of the skin.

H&E, X40

Figure 24.22 Dermoid cyst. In addition to features of epidermal cyst, dermoid cyst has adnexal structures in the cyst wall (i.e. hair follicles, sweat and sebaceous glands).

Histologically, solar keratoses are squamous cell carcinoma *in situ* with the following characteristic features:

- i) Considerable hyperkeratosis.
- ii) Marked acanthosis.
- iii) Dyskeratosis and dysplasia of the epidermal cells showing features such as hyperchromatism, loss of polarity, pleomorphism and increased number of mitotic figures.
- iv) Non-specific chronic inflammatory cell infiltrate in the upper dermis encroaching upon the basement membrane of the epidermis.

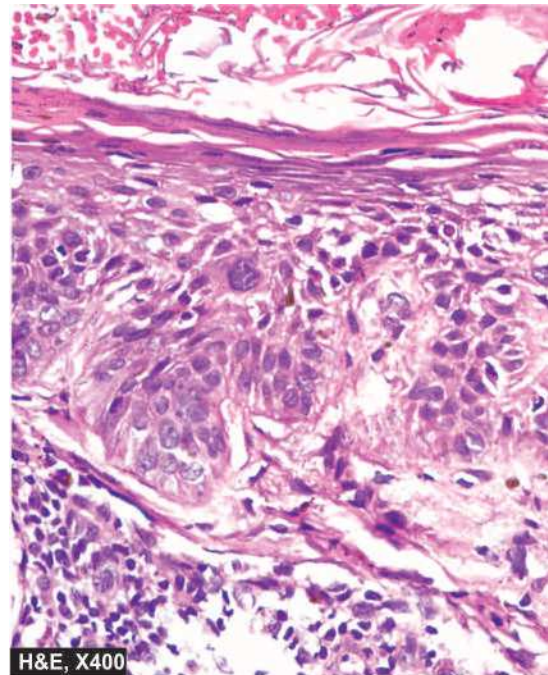

2. BOWEN'S DISEASE Bowen's disease is also a carcinoma *in situ* of the entire epidermis but differs from solar keratosis in having solitary lesion often that may occur on sun-exposed as well as sun-unexposed skin. The condition may occur anywhere on the skin but is found more often on the trunk, buttocks and extremities. Clinically, the lesions of Bowen's disease are sharply circumscribed, rounded, reddish-brown patches which enlarge slowly.

Histologically, the characteristic features are as under (**Fig. 24.23**):

- i) Marked hyperkeratosis.
- ii) Pronounced parakeratosis.
- iii) Marked epidermal hyperplasia with disappearance of dermal papillae.
- iv) Scattered bizarre dyskeratotic cells distributed throughout the epidermis.

Bowen's disease, unlike solar keratosis which invariably leads to invasive cancer, may remain confined to the surface for many years.

3. XERODERMA PIGMENTOSUM This condition is a hypersensitivity of the skin to sunlight that is determined by a

H&E, X400

Figure 24.23 Bowen's disease. The epidermis is thick with loss of rete ridges but the normal base to surface maturation of epidermal layers is effaced. Instead, there are bizarre atypical squamous cells but the border between the epidermis and dermis is intact i.e. the basement membrane is not breached.

recessive gene. The disorder may lead to multiple malignancies of the skin such as basal cell carcinoma, squamous cell carcinoma and malignant melanoma. Xeroderma pigmentosum has already been described under *genetic dermatoses*.

D. MALIGNANT TUMOURS

1. SQUAMOUS CELL CARCINOMA Two important factors in the pathogenesis of squamous cell carcinoma are: *prolonged sun exposure* and *immunosuppression*. In such cases, DNA damage is induced followed by *p53* mutation and other events leading to dysregulation of signaling pathway. Various predisposing conditions include the following:

- i) Xeroderma pigmentosum
- ii) Epidermodysplasia verruciformis induced by HPV
- iii) Solar keratosis
- iv) Chronic inflammatory conditions such as chronic ulcers and draining osteomyelitis
- v) Old burn scars (Marjolin's ulcers)
- vi) Chemical burns
- vii) Psoriasis
- viii) HIV infection
- ix) Ionising radiation
- x) Industrial carcinogens (coal tars, oils etc)
- xi) In the case of cancer of oral cavity, chewing betel nuts and tobacco.

Cancer of scrotal skin in chimney-sweeps was the first cancer in which an occupational carcinogen (soot) was implicated. '*Kangari cancer*' of the skin of inner side of thigh and lower abdomen common in natives of Kashmir is another example of skin cancer due to chronic irritation (*Kangari* is an earthenware pot containing glowing charcoal embers used by Kashmiris close to their abdomen to keep them warm).

Squamous cell carcinoma may arise on any part of the skin and mucous membranes lined by squamous epithelium. Most common locations are the face, pinna of the ears, back of hands and mucocutaneous junctions such as on the lips, anal canal and glans penis. Cutaneous squamous carcinoma arising

in a pre-existing inflammatory and degenerative lesion has a higher incidence of developing metastases.

MORPHOLOGIC FEATURES *Grossly*, squamous carcinoma of the skin and squamous-lined mucosa can have one of the following two patterns (**Fig. 24.24**):

- i) More commonly, an *ulcerated growth* with elevated and indurated margin is seen.
- ii) Less often, a raised *fungating or polypoid verrucous* lesion without ulceration is found.

Microscopically, squamous cell carcinoma is an invasive carcinoma of the surface epidermis characterised by the following features (**Fig. 24.25**):

- i) There is irregular downward proliferation of epidermal cells into the dermis.
- ii) Depending upon the grade of malignancy, the masses of epidermal cells show atypical features such as variation in cell size and shape, nuclear hyperchromatism, absence of intercellular bridges, individual cell keratinisation and occurrence of atypical mitotic figures.
- iii) Better-differentiated squamous carcinomas have whorled arrangement of malignant squamous cells forming horn pearls. The centres of these horn pearls may contain laminated, keratin material.
- iv) Higher grades of squamous carcinomas, however, have fewer or no horn pearls and may instead have highly atypical cells.
- v) An uncommon variant of squamous carcinoma may have spindle-shaped tumour cells (*spindle cell carcinoma*).
- vi) Adenoid changes may be seen in a portion of squamous cell carcinoma (*adenoid squamous cell carcinoma*).
- vii) *Verrucous carcinoma* (Ackerman tumour) is a low-grade variant located most commonly in oral cavity in which the superficial portion of the tumour resembles verruca (hyperkeratosis, parakeratosis, acanthosis and papillomatosis) but differs from it in having downward proliferation as broad masses of well-differentiated

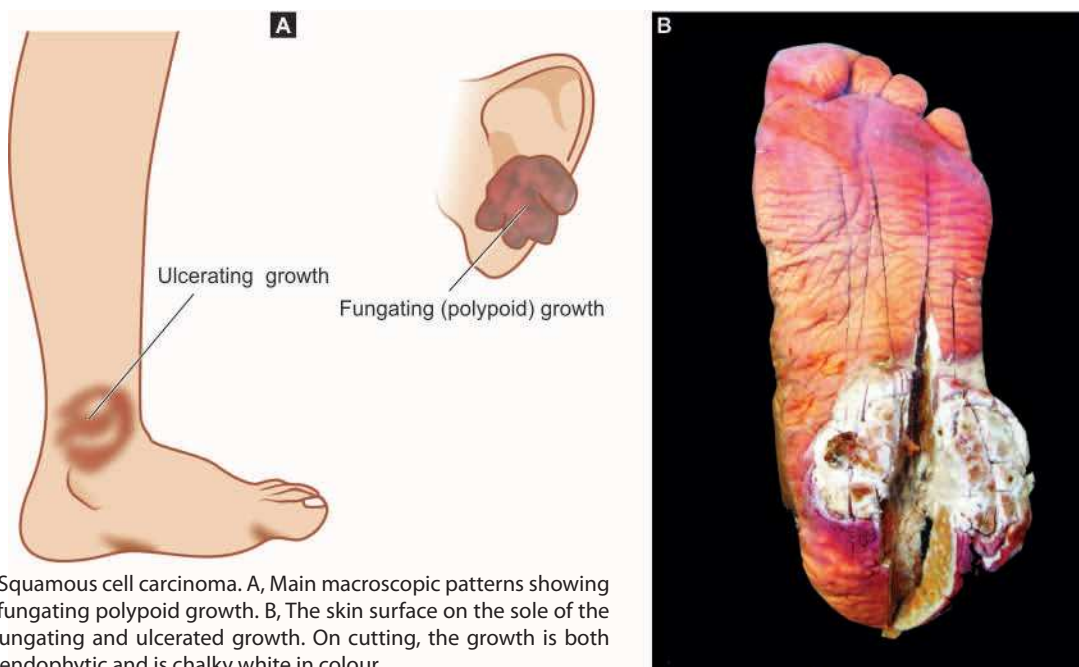

Figure 24.24 Squamous cell carcinoma. A, Main macroscopic patterns showing ulcerated and fungating polypoid growth. B, The skin surface on the sole of the foot shows a fungating and ulcerated growth. On cutting, the growth is both exophytic and endophytic and is chalky white in colour.

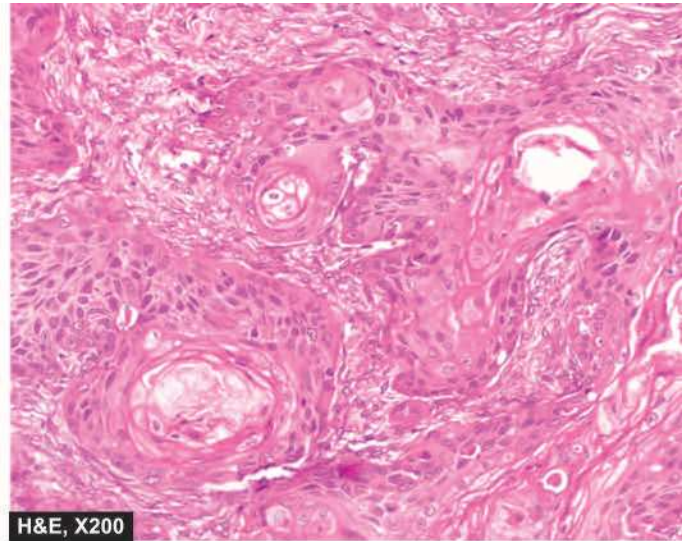

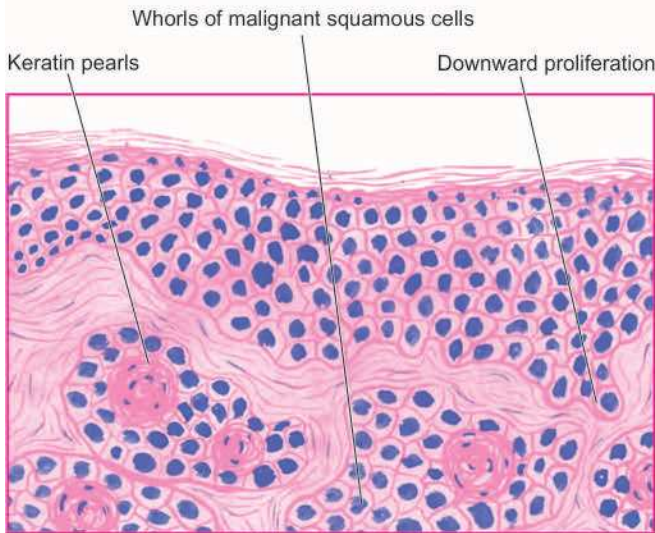

Figure 24.25 Microscopic features of well-differentiated squamous cell carcinoma. The dermis is invaded by downward proliferating epidermal masses of cells which show atypical features. A few horn pearls with central laminated keratin are present. There is inflammatory reaction in the dermis between the masses of tumour cells.

squamous epithelium into deeper portion of the tumour. However, there is lack of cellular atypia.

viii) All variants of squamous cell carcinoma show inflammatory reaction between the collections of tumour cells, while in *pseudocarcinomatous hyperplasia* there is permeation of the epithelial proliferations by inflammatory cells.

It is customary with pathologists to label squamous cell carcinomas with descriptive terms such as: well-differentiated, moderately-differentiated, undifferentiated, keratinising, non-keratinising, spindle cell type etc.

Overall prognosis of squamous cell carcinoma induced by actinic keratosis is excellent. Superficial invasive tumour may metastasise locally. Prognosis of deeply invading tumour depends upon the stage (TNM staging).

2. BASAL CELL CARCINOMA (RODENT ULCER) Typically, the basal cell carcinoma is a locally invasive, slow-growing tumour of middle-aged that rarely metastasises. It occurs exclusively on hairy skin, the most common location (90%) being the face, usually above a line from the lobe of the ear to the corner of the mouth (**Fig. 24.26**).

Following conditions predispose an individual to develop basal cell carcinoma:

- Light-skinned people who have little melanin.
- Prolonged exposure to strong sunlight like in those living in Australia and New Zealand.
- Inherited defect in DNA repair mechanism in xeroderma pigmentosum.
- Nevoid basal cell carcinoma syndrome* It is an autosomal dominant condition in which multiple basal cell carcinomas appear at a young age (under 20 years). These individuals inherit one defective allele (*PTCH* gene on chromosome 9) while another allele undergoes mutation early in life by sun exposure (Hudson's two hit hypothesis).

MORPHOLOGIC FEATURES *Grossly*, the most common pattern is a nodulo-ulcerative basal cell carcinoma in which a slow-growing small nodule undergoes central ulceration with pearly, rolled margins. The tumour enlarges in size

by burrowing and by destroying the tissues locally like a rodent and hence the name 'rodent ulcer'. However, less frequently non-ulcerated nodular pattern, pigmented basal cell carcinoma and fibrosing variants are also encountered.

Histologically, the most characteristic feature is the proliferation of basaloid cells (resembling basal layer of epidermis). A variety of patterns of these cells may be seen: solid masses, masses of pigmented cells, strands and nests of tumour cells in morphea pattern, keratotic masses, cystic change with sebaceous differentiation, and adenoid pattern with apocrine or eccrine differentiation. The most common pattern is *solid basal cell carcinoma* in which the dermis contains irregular masses of basaloid cells having characteristic peripheral palisaded appearance of the nuclei (**Fig. 24.27**). A superficial multicentric variant composed of multiple foci of tumour cells present in the dermis, especially in the trunk, has also been described.

3. METATYPICAL CARCINOMA (BASOSQUAMOUS CELL CARCINOMA) Metatypical or basosquamous cell carcinoma

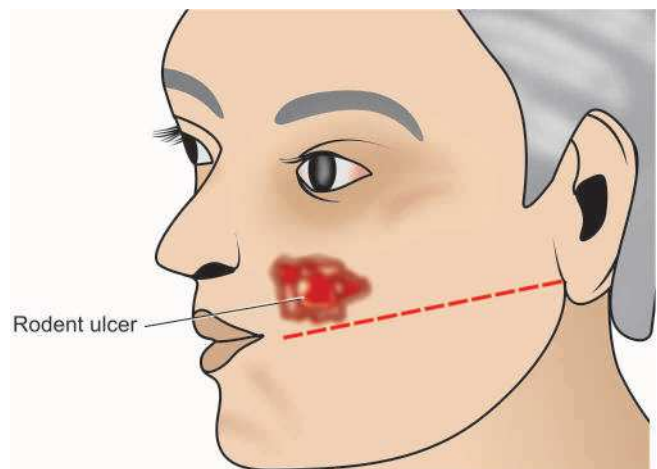

Figure 24.26 Common location and macroscopic appearance of basal cell carcinoma (rodent ulcer).

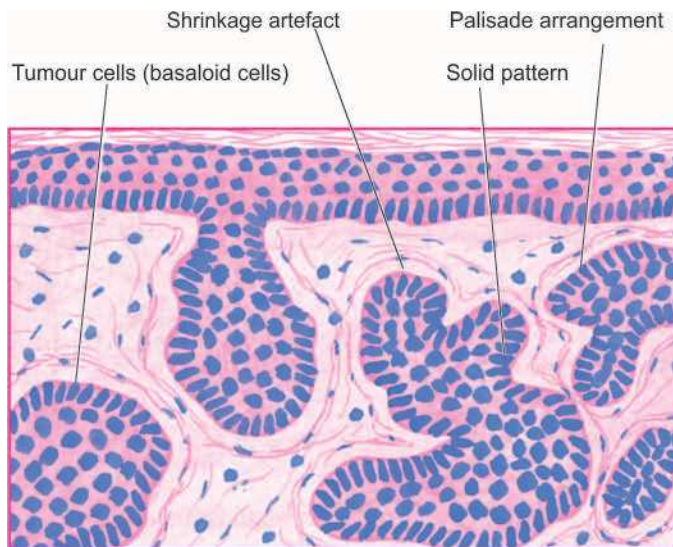

Figure 24.27 Solid basal cell carcinoma. The dermis is invaded by irregular masses of basaloid cells with characteristic peripheral palisaded appearance. The masses of tumour cells are separated from dermal collagen by a space called shrinkage artefact.

is the term used for a tumour in which the cell type and arrangement of cells cause difficulty in deciding between basal cell carcinoma and squamous cell carcinoma. The tumour masses are composed of malignant squamous cells with horn pearls and the outer row of dark-staining basal cells. These tumours have a high malignant potential and may occasionally metastasise.

II. ADNEXAL (APPENDAGEAL) TUMOURS

Tumours arising from epidermal adnexa or appendages can differentiate towards hair follicles, sebaceous glands and sweat glands (apocrine and eccrine glands). Most of the adnexal tumours are benign but a few malignant variants also exist.

A. TUMOURS OF HAIR FOLLICLE

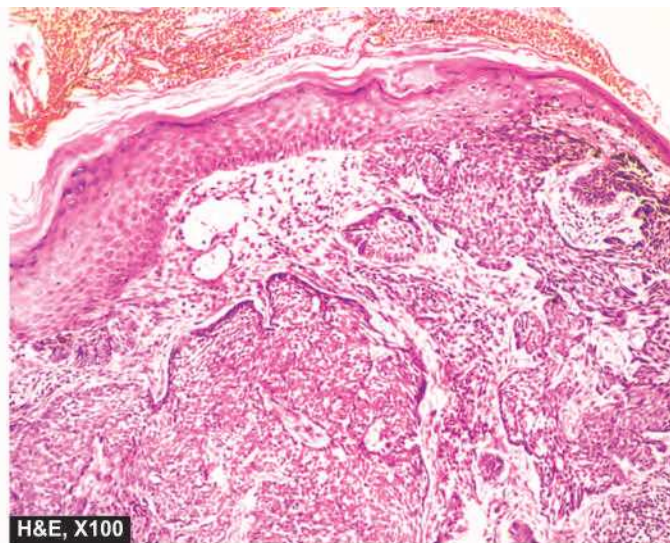

These are uncommon benign tumours. Two important examples are trichoepithelioma and pilomatricoma.

1. TRICHOEPITHELIOMA (BROOKE'S TUMOUR) This tumour may occur as a solitary lesion or as multiple inherited lesions, predominantly on the face, scalp and neck.

Histologically, the tumour is often circumscribed. The most characteristic histologic feature is the presence of multiple horn cysts having keratinised centre and surrounded by basophilic cells resembling basal cells. These horn cysts simulate abortive pilar structures which are interconnected by epithelial tracts.

2. PILOMATRICOMA (CALCIFYING EPITHELIOMA OF MALHERBE) Pilomatricoma usually occurs as a solitary lesion, more often on the face and upper extremities. It may be seen at any age. The lesions vary in size from 0.5-5 cm and appear as well-demarcated dark red nodules.

Histologically, the circumscribed tumour is located in deeper dermis and subcutis. The masses of tumour cells embedded in cellular stroma characteristically consist of 2 types of cells: the *peripheral basophilic cells* resembling

hair matrix cells, and the *inner shadow cells* having central unstained shadow in place of the lost nucleus. Areas of calcification are present within lobules of shadow cells in three-fourth of the tumours (**Fig. 24.28**).

B. TUMOURS OF SEBACEOUS GLANDS

Tumours originating from sebaceous glands are commonly benign (e.g. naevus sebaceus and sebaceous adenoma) but sebaceous carcinoma may occasionally occur.

1. NAEVUS SEBACEUS Naevus sebaceus of Jadassohn occurs mainly on the scalp or face as a solitary lesion that may be present at birth. Initially, the lesion appears as a hairless plaque, but later it becomes verrucous and nodular.

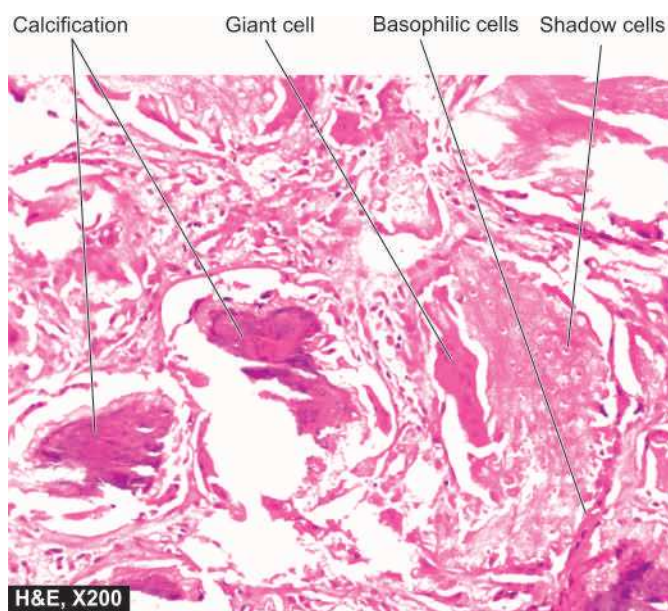

Figure 24.28 Pilomatricoma (calciifying epithelioma of Malherbe). The tumour shows islands and lobules within the dermis which are composed of two types of cells: outer basophilic cells and inner shadow cells. Areas of calcification are also seen.

Histologically, naevus sebaceus is characterised by hyperplasia of immature sebaceous glands and pilar structures. The overlying epidermis shows papillary acanthosis.

2. SEBACEOUS ADENOMA Sebaceous adenoma occurs in middle-aged persons, most commonly on the face.

Histologically, it is sharply demarcated from the surrounding tissue. The tumour is composed of irregular lobules of incompletely differentiated sebaceous glands.

3. SEBACEOUS CARCINOMA Sebaceous carcinoma is a rare tumour that may occur anywhere in the body except the palms and soles. Variants of sebaceous carcinoma are carcinoma of the Meibomian glands of the eyelids (page 492) and carcinoma of the ceruminous glands in the external meatus.

Histologically, the tumour is composed of variable-sized lobules of poorly-differentiated cells containing some sebaceous cells. The tumour cells show marked cytologic atypia such as pleomorphism and hyperchromasia.

C. TUMOURS OF SWEAT GLANDS

A large number of lesions develop from sweat gland structures, either from apocrine or eccrine glands. These are more commonly benign but sweat gland carcinoma may also occur.

1. ECCRINE TUMOURS Depending upon the portion of eccrine sweat gland from which the tumour takes origin, the eccrine tumours are of 3 types:

- i) *arising from intraepidermal portion of the duct* e.g. eccrine poroma;
- ii) *arising from intradermal portion of the duct* e.g. hidradenoma; and
- iii) *arising from secretory coils* e.g. eccrine spiradenoma.

◆ **Eccrine poroma** This tumour arises from intraepidermal portion of the sweat gland duct. The tumour is found more commonly on the sole and hands.

Histologically, it consists of tumour cells arising from the lower portion of the epidermis and extending downward into dermis as broad anastomosing bands. The tumour cells are, however, different from squamous cells. They are smaller in size, cuboidal in shape and have deeply basophilic nucleus.

◆ **Eccrine hidradenoma** Hidradenoma originates from the intradermal portion of the eccrine sweat duct. The tumour may occur anywhere in the body.

Histologically, hidradenoma consists of solid masses and cords of tumour cells which may have an occasional duct-like structure containing mucin. The tumour cells are round to polygonal and may have clear or eosinophilic cytoplasm.

◆ **Eccrine spiradenoma** This is found as a solitary, painful, circumscribed nodule in the dermis.

Histologically, the tumour consists of lobules which are surrounded by a thin capsule. The tumour lobules contain 2 types of epithelial cells like in the secretory coils of the eccrine sweat gland. Peripheral cells are small with dark

nuclei, while the centre of lobules contains large cells with pale nuclei. An occasional area may show glandular structures.

2. APOCRINE TUMOURS Apocrine sweat glands may give rise to tumours; the two common examples being papillary hidradenoma and cylindroma.

◆ **Papillary hidradenoma** Papillary hidradenoma or hidradenoma papilliferum is usually located as a small lesion commonly in women in the skin of the anogenital area.

Histologically, it is a circumscribed tumour in the dermis under a normal epidermis. Papillary hidradenoma represents an adenoma with apocrine differentiation and containing papillary, tubular and cystic structures. The tumour cells lining these structures resemble apocrine epithelium with features of decapitation secretions.

◆ **Cylindroma** Also called as 'turban tumour' due to its common location on the scalp, cylindroma may occur as both solitary and multiple lesions.

Histologically, the tumour is composed of irregular islands of tumour cells creating a pattern resembling jigsaw puzzle. The islands are surrounded by a hyaline sheath. The tumour cells comprising the islands consist of 2 types of epithelial cells: *peripheral small cells* with dark nuclei, and *inner large cells* with light staining nuclei. Some of the islands may contain tubular lumina containing amorphous material.

3. SWEAT GLAND CARCINOMA Rarely, the eccrine and apocrine gland tumours described above may turn malignant. All these carcinomas are adenocarcinomas and must be distinguished from metastatic adenocarcinoma in the skin.

III. MELANOCYTIC TUMOURS

Melanocytic tumours may arise from one of the three cell types: naevus cells, epidermal melanocytes and dermal melanocytes.

◆ Benign tumours originating from *naevus cells* are called naevocellular naevi.

◆ The examples of benign tumours *arising from epidermal melanocytes* are lentigo, freckles, pigmentation associated with Albright's syndrome and *café-au-lait* spots of neurofibromatosis (page 886).

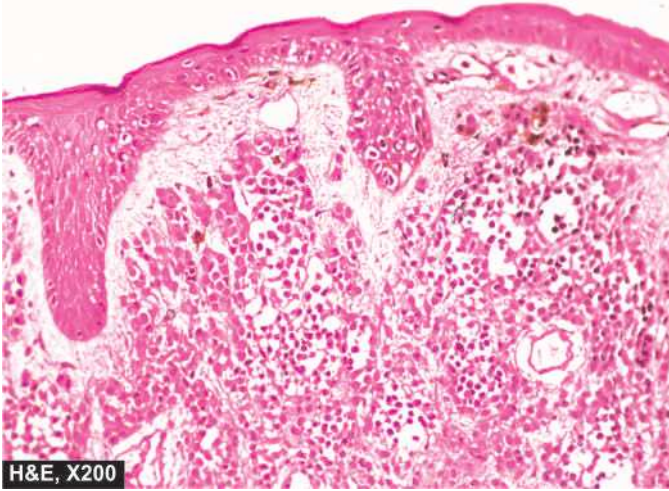

◆ Benign tumours *derived from dermal melanocytes* are Mongolian spots, naevi of Ota and of Ito and the blue naevus.

◆ **Malignant melanoma** is the malignant counterpart of melanocytic tumours.

The important examples amongst these are described below.

1. NAEVOCELLULAR NAEVI Pigmented naevi or moles are extremely common lesions on the skin of most individuals. They are often flat or slightly elevated lesions; rarely they may be papillomatous or pedunculated. Most naevi appear in adolescence and in early adulthood due to hormonal influence but rarely may be present at birth. They are mostly tan to brown and less than 1 cm in size.

Histologically, irrespective of the histologic types, all naevocellular naevi are composed of 'naevus cells' which

H&E, X200

Figure 24.29 Intradermal naevus showing nests of naevus cells which are typically uniform and present in the dermis. Melanin pigment in naevus cells is coarse and irregular.

are actually identical to melanocytes but differ from melanocytes in being arranged in clusters or nests. Naevus cells are cuboidal or oval in shape with homogeneous cytoplasm and contain large round or oval nucleus. Melanin pigment is abundant in the naevus cells present in the lower epidermis and upper dermis, but the cells in the mid-dermis and lower dermis hardly contain any melanin (**Fig. 24.29**).

The important *histological variants* of naevi are as under:

- i) Lentigo** is the replacement of the basal layer of the epidermis by melanocytes.
- ii) Junctional naevus** is the one in which the naevus cells lie at the epidermal-dermal junction. The naevus cells form well-circumscribed nests.
- iii) Compound naevus** is the commonest type of pigmented naevus. These lesions, in addition to the junctional activity as in junctional naevi, show nests of naevus cells in the dermis to a variable depth.
- iv) Intradermal naevus** shows slight or no junctional activity. The lesion is mainly located in the upper dermis as nests and cords of naevus cells. Multinucleate naevus cells are common.
- v) Spindle cell (epithelioid) naevus or juvenile melanoma** is a compound naevus with junctional activity. The naevus cells are, however, elongated and epithelioid in appearance which may or may not contain melanin. Juvenile melanoma is important since it is frequently confused with malignant melanoma histologically.
- vi) Blue naevus** is characterised by dendritic spindle naevus cells rather than the usual rounded or cuboidal naevus cells. These cells are often quite rich in melanin pigment.
- vii) Dysplastic naevi** are certain atypical naevi which have increased risk of progression to malignant melanoma. These lesions are larger than the usual acquired naevi, are often multiple, and appear as flat macules to slightly elevated plaques with irregular borders and variable pigmentation. Many of the cases are familial and inheritable. Dysplastic naevi have melanocytic proliferation at the epidermo-dermal junction with some cytologic atypia.

2. MALIGNANT MELANOMA Malignant melanoma or melanocarcinoma arising from melanocytes is one of the most rapidly spreading malignant tumour of the skin that can occur at all ages. The etiology is unknown but there is role of excessive exposure of white skin to sunlight e.g. higher incidence in New Zealand and Australia where sun exposure is high. Besides the skin, melanomas may occur at various other sites such as oral and anogenital mucosa, oesophagus, conjunctiva, orbit (page 493) and leptomeninges. The common sites on the skin are the trunk (*in men*), legs (*in women*); other locations are face, soles, palms and nail-beds.

Some high risk factors associated with increased incidence of malignant melanoma are as under:

- i) Persistent change in appearance of a mole.
- ii) Presence of pre-existing naevus (especially dysplastic naevus).
- iii) Family history of melanoma in a patient of atypical mole.
- iii) Higher age of the patient.
- iv) More than 50 moles 2 mm or more in diameter.

Molecular studies in familial and hereditary cases have revealed germline mutation in *CDKN2A* gene which encodes for cyclin-dependent kinase inhibitor, mutational loss of *PTEN* gene and mutation in several other tumour suppressor genes but not *p53*.

Clinically, melanoma often appears as a flat or slightly elevated naevus which has variegated pigmentation, irregular borders and, of late, has undergone secondary changes of ulceration, bleeding and increase in size. Many of the malignant melanomas, however, arise *de novo* rather than from a pre-existing naevus. Malignant melanoma can be differentiated from benign pigmented lesions by subtle features as summed up in **Table 24.3**; the dermatologists term this as ABCD of melanoma (acronym for Asymmetry, Border irregularity, Colour change and Diameter >6 mm).

MORPHOLOGIC FEATURES *Grossly*, depending upon the clinical course and prognosis, cutaneous malignant melanomas are of the following 5 types:

- i) Lentigo maligna melanoma** This often develops from a pre-existing lentigo (a flat naevus characterised by replacement of basal layer of epidermis by naevus cells). It is essentially a malignant melanoma *in situ*. It is slow-growing and has good prognosis.
- ii) Superficial spreading melanoma** This is a slightly elevated lesion with variegated colour and ulcerated surface. It often develops from a superficial spreading melanoma *in situ* (pagetoid melanoma) in 5 to 7 years. The prognosis is worse than for lentigo maligna melanoma.
- iii) Acral lentiginous melanoma** This occurs more commonly on the soles, palms and mucosal surfaces (**Fig. 24.30**). The tumour often undergoes ulceration and early metastases. The prognosis is worse than that of superficial spreading melanoma.
- iv) Nodular melanoma** This often appears as an elevated and deeply pigmented nodule that grows rapidly and undergoes ulceration. This variant carries the worst prognosis.
- v) Desmoplastic melanoma** In this variant, the tumour has a fibrotic stroma, neural invasion and frequent local recurrences.

Table 24.3 Distinguishing features of benign mole and malignant melanoma.

| FEATURE | BENIGN MOLE | MALIGNANT MELANOMA |
|-----------------------------|---|---|
| 1. <i>Clinical features</i> | | |
| i) Symmetry | Symmetrical | A = Asymmetry |
| ii) Border | Well-demarcated | B = Border irregularity |
| iii) Colour | Uniformly pigmented | C = Colour change |
| iv) Diameter | Small, less than 6 mm | D = Diameter more than 6 mm |
| 2. <i>Common locations</i> | Skin of face, mucosa | Skin; mucosa of nose, bowel, anal region |
| 3. <i>Histopathology</i> | | |
| i) Architecture | Nests of cells | Various patterns: solid sheets, alveoli, nests, islands |
| ii) Cell morphology | Uniform looking naevus cells | Malignant cells, atypia, mitoses, nucleoli |
| iii) Melanin pigment | Irregular, coarse clumps | Fine granules, uniformly distributed |
| iv) Inflammation | May or may not be present | Often present |
| 4. <i>Spread</i> | Remains confined, poses cosmetic problem only | Haematogenous and/or lymphatic spread early |

Histologically, irrespective of the type of malignant melanoma, the following characteristics are observed (Fig. 24.31):

i) Origin The malignant melanoma, whether arising from a pre-existing naevus or starting *de novo*, has marked junctional activity at the epidermo-dermal junction and grows downward into the dermis.

ii) Tumour cells The malignant melanoma cells are usually larger than the naevus cells. They may be epithelioid or spindle-shaped, the former being more common. The tumour cells have amphophilic cytoplasm and large, pleomorphic nuclei with conspicuous nucleoli. Mitotic figures are often present and multinucleate giant cells may occur. These tumour cells may be arranged in various patterns such as solid masses, sheets, island, alveoli etc.

iii) Melanin Melanin pigment may be present (melanotic) or absent (amelanotic melanoma) without any prognostic influence. The pigment, if present, tends to be in

the form of uniform fine granules (unlike the benign naevi in which coarse irregular clumps of melanin are present). At times, there may be no evidence of melanin in H&E stained sections but Fontana-Masson stain or *dopa reaction* reveals melanin granules in the cytoplasm of tumour cells. Immunohistochemically, melanoma cells are positive for HMB-45 (most specific), S-100 and Melan-A.

iv) Inflammatory infiltrate Some amount of inflammatory infiltrate is present in the invasive melanomas. Infrequently, partial spontaneous regression of the tumour occurs due to destructive effect of dense inflammatory infiltrate.

Depending upon the depth of invasion into the dermis, Clark has described following 5 levels:

Level I: Malignant melanoma cells confined to the epidermis and its appendages.

Level II: Extension into the papillary dermis.

Level III: Extension of tumour cells upto the interface between papillary and reticular dermis.

Level IV: Invasion of reticular dermis.

Level V: Invasion of the subcutaneous fat.

The prognosis for patients with malignant melanoma depends upon the stage at presentation. AJCC staging for melanoma takes into account the microscopic depth of invasion of the primary tumour, ulceration, nodal metastasis and presence of metastatic disease in internal sites. Metastatic spread of malignant melanoma is very common and takes place via lymphatics to the regional lymph nodes and through blood to distant sites like lungs, liver, brain, spinal cord, and adrenals. Just as in breast cancer, sentinel lymph node biopsy is quite helpful in evaluation of regional nodal status.

IV. TUMOURS OF THE DERMIS

All the tissue elements of the dermis such as fibrous tissue, adipose tissue, neural tissue, endothelium and smooth muscle are capable of transforming into benign and malignant tumours. Many of the examples of these tumours are discussed

Figure 24.30 Malignant melanoma of the oral cavity. The hemimaxillectomy specimen shows an elevated blackish ulcerated area with irregular outlines.

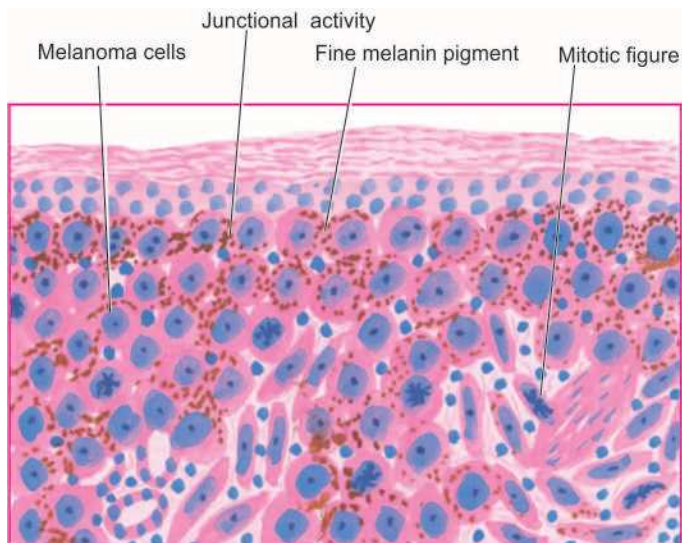

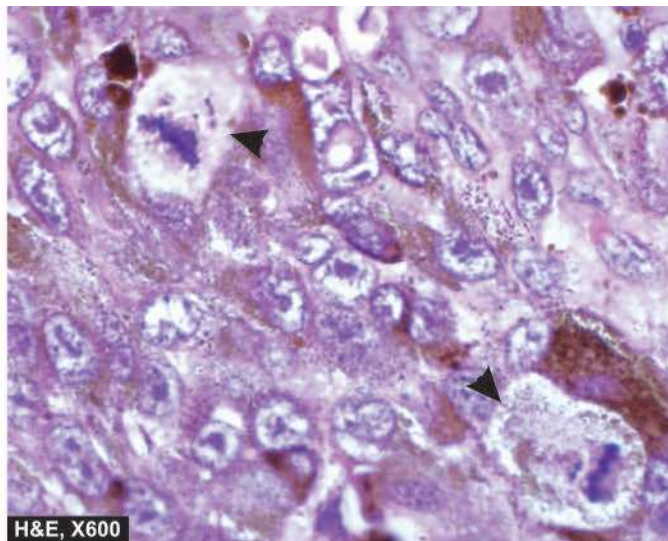

Figure 24.31 Malignant melanoma shows junctional activity at the dermal-epidermal junction. Tumour cells resembling epithelioid cells with pleomorphic nuclei and prominent nucleoli are seen as solid masses in the dermis. Many of the tumour cells contain fine granular melanin pigment. Photomicrograph shows a prominent atypical mitotic figure (arrow).

as soft tissue tumours in Chapter 27 but a few representative dermal neoplasms are described below.

1. DERMATOFIBROMA AND MALIGNANT FIBROUS HISTIOCYTOMA These soft tissue tumours are composed of cells having mixed features of fibroblasts, myofibroblasts, histiocytes and primitive mesenchymal cells. The histogenesis of these tumours is not quite clear but probably they arise from multi-directional differentiation of the primitive mesenchymal cells. The tumours appear at any age but are more common in advanced age. The commonest sites are the lower and upper extremities, followed in decreasing frequency, by abdominal cavity and retroperitoneum. The benign variant is also known by various synonyms like dermatofibroma, histiocytoma, sclerosing haemangioma, fibroxanthoma and xanthogranuloma. Benign histiocytomas are often small but malignant fibrous histiocytomas may be of enormous size. They are circumscribed but unencapsulated.

Histologically, the tumours are composed of spindle-shaped fibrohistiocytoid cells which are characteristically arranged in cartwheel or storiform pattern. The benign variety contains uniform spindle-shaped cells with admixture of numerous foamy histiocytes. The malignant fibrous histiocytoma shows pleomorphic tumour cells and some multinucleate giant cells in a stroma that may show myxoid change and inflammatory infiltrate.

2. DERMATOFIBROSARCOMA PROTUBERANS This is a low-grade fibrosarcoma that rarely metastasises but is locally recurrent. The tumour usually forms a solid nodule, within the dermis and subcutaneous fat, protruding the epidermis outwards. Sometimes multiple nodules may form.

Histologically, the tumour is very cellular and is composed of uniform fibroblasts arranged in a cartwheel or storiform pattern. A few mitoses are often present. The overlying epidermis is generally thin and stretched and may be ulcerated. The subcutaneous fat is frequently invaded by the tumour cells (**Fig. 24.32**).

3. XANTHOMAS These are solitary or multiple tumour-like lesions, often associated with high levels of serum cholesterol and phospholipids. Many of the cases result from familial hyperlipidaemia. They may occur at different sites such as buttocks, knees, elbows, tendo-Achilles, palmar creases and on the eyelids (referred to as xanthelasma).

Histologically, xanthomas are composed of dermal collections of benign-appearing foamy histiocytes. Multinucleate tumour giant cells surrounded by lipid-laden cytoplasm are often present.

V. CELLULAR MIGRANT TUMOURS

All the tumours described above arise from progenitor cells in the skin only. However, there are some tumours which have

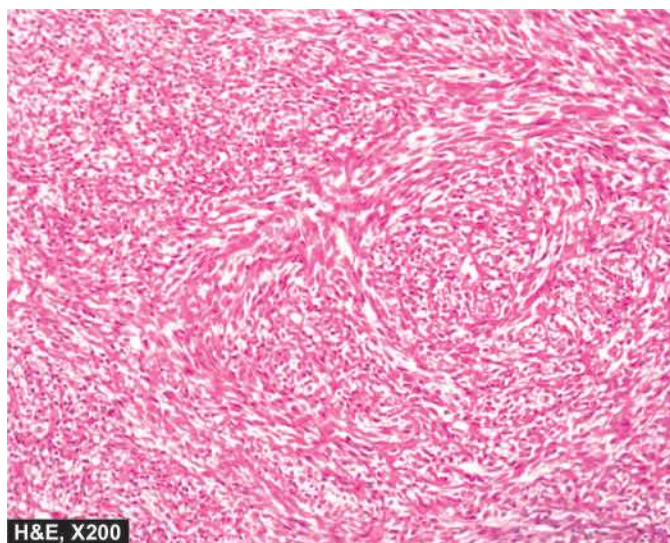

Figure 24.32 Dermatofibrosarcoma protuberans. The tumour cells are arranged in storiform or cartwheel pattern. The tumour cells are spindled admixed with histiocytes and show moderate anisocytosis and anisonucleosis.

their precursor cells elsewhere in the body, but are cellular immigrants to the skin. The examples are Langerhans' cell histiocytosis (page 365), mycosis fungoides, mastocytosis, lymphomas and leukaemias (page 353). Mycosis fungoides is considered here.

MYCOSIS FUNGOIDES (CUTANEOUS T-CELL LYMPHOMA)

AND SEZARY SYNDROME Mycosis fungoides or cutaneous T-cell lymphoma (CTCL) is the commonest form of lymphoma in the skin having an indolent course but in advanced stage, mycosis fungoides may disseminate to the lymph nodes and other organs. Clinically, mycosis fungoides may manifest in 3 stages:

- i) **Premycotic stage** in which the lesions are erythematous, red-brown, scaly and pruritic, resembling eczema or psoriasis.
- ii) **Infiltrative stage** has slightly elevated, bluish-red, firm plaques.
- iii) **Fungoid (Tumour) stage** is characterised by red-brown nodules of tumour which often undergo ulceration.

The etiology of mycosis fungoides or CTCL has been found to be the same as for adult T cell lymphoma-leukaemia syndrome which is human T cell-leukaemia virus-I (HTLV-1) as discussed on page 359.

Sézary syndrome is a variant of CTCL, often due to dissemination of underlying CTCL to the blood and infiltration into the skin causing generalised erythroderma, lymphadenopathy and hepatosplenomegaly.

The condition is found more frequently beyond 4th decade of life. Lesions may affect different body surfaces but often involve the trunk, extremities, face and scalp.

Histologically, the condition has the following characteristics:

- i) Initially, lower portion of the epidermis contains hyperchromatic enlarged lymphocytes. In about half the cases, there is formation of intraepidermal clusters of atypical lymphoid cells forming *Darier-Pautrier's microabscesses* which is a misnomer as it does not contain pus cells.
- ii) Later, there are band-like sharply demarcated aggregates of polymorphous cellular infiltrate in the dermis including atypical lymphoid cells (*Sézary-Lutzner cells*) and multinucleated cells.
- iii) The individual mycosis cells are malignant T lymphocytes which have hyperchromatic and cerebriform nuclei and express CD4 and HLA-DR antigen.

Besides CTCL, other forms of cutaneous lymphomas are adult T cell leukaemia-lymphoma (ATLL), anaplastic large cell

lymphoma (ALCL), lymphomatoid papulosis and cutaneous B cell lymphoma.

GIST BOX 24.3

Tumours and Tumour-like Lesions of Skin.

- ☐ Common examples of benign tumours and cysts of epidermis are squamous papilloma, seborrheic keratosis, stromal polyps and epithelial cysts (epidermoid, pilar, dermoid).
- ☐ A few important premalignant conditions of epidermis are solar keratosis, Bowen's disease and xeroderma pigmentosum.
- ☐ Squamous cell carcinoma may arise on skin or squamous mucosa. It may be well-differentiated, moderately-differentiated, undifferentiated, keratinising, non-keratinising, spindle cell type.
- ☐ Basal cell carcinoma is a locally invasive, slow-growing tumour of middle-aged that rarely metastasises. It occurs exclusively on hairy skin, most commonly on the face.
- ☐ Malignant melanoma arising from melanocytes is one of the most rapidly spreading malignant tumour of the skin that can occur at all ages.
- ☐ Tumours arising from epidermal adnexa or appendages can differentiate towards hair follicles, sebaceous glands and sweat glands (apocrine and eccrine glands). Adnexal tumours are mostly benign but a few malignant variants also exist.
- ☐ Mycosis fungoides or cutaneous T-cell lymphoma (CTCL) is the T cell migrant lymphoma in the skin which has an indolent course.

CLINICAL CASE 25

A 60 years old male complains of a tiny persisting ulcer on his forehead for 6 months. There is a history of presence of small waxy nodule initially for about one year which slowly increased in size followed by its ulceration.

On examination, there is a single nodule with central ulceration, 4 mm in diameter, having pearly white rolled up margins. There is no regional lymphadenopathy.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 913 (Appendix II)

25

The Endocrine System

BASIC CONCEPT OF ENDOCRINES

The development, structure and functions of human body are governed and maintained by 2 mutually interlinked systems—the *endocrine system* and the *nervous system* (Chapter 28); a third system combining features of both these systems is appropriately called *neuroendocrine system*.

NEUROENDOCRINE SYSTEM

This system forms a link between endocrine glands and nervous system. The cells of this system elaborate polypeptide hormones; owing to these biochemical properties, it has also been called as *APUD cell system* (acronym for Amine Precursor Uptake and Decarboxylation properties). However, though having common biochemical properties, the cells of this system are widely distributed in the body in different anatomic areas; hence it is currently called *dispersed neuroendocrine system*. Cells comprising this system are as under:

1. *Neuroendocrine cells* which are present in the gastric and intestinal mucosa and elaborate peptide hormones.
2. *Neuroganglia cells* lie in the ganglia cells in the sympathetic chain and elaborate amines.
3. *Adrenal medulla* elaborates epinephrine and norepinephrine.
4. *Parafollicular C cells* of the thyroid secrete calcitonin.
5. *Islets of Langerhans* in the pancreas (included in both endocrine and neuroendocrine systems) secrete insulin.
6. *Isolated cells in the left atrium* of the heart secrete atrial natriuretic (salt-losing) peptide hormone.

In addition to above, other non-endocrine secretions include neurotransmitter substances such as *acetylcholine* and *dopamine* released from neural synapses, and *erythropoietin* and *vitamin D₃* elaborated from the kidney.

THE ENDOCRINE SYSTEM

Anatomically, the endocrine system consists of 6 distinct organs: pituitary, adrenals, thyroid, parathyroids, gonads, and pancreatic islets; the last one is included in neuroendocrine system also). Understanding the pathology of these endocrine organs requires the knowledge of overall framework of hormone secretions, their actions and broad principles of feedback mechanisms.

Broadly speaking, human hormones are divided into 5 major classes which are further grouped under two headings depending upon their site of interactions on the target cell receptors (whether cell membrane or nuclear receptor):

Group I: Those interacting with cell-surface membrane receptors:

1. *Amino acid derivatives*: thyroid hormone, catecholamines.

2. *Small neuropeptides*: gonadotropin-releasing hormone (GnRH), thyrotropin-releasing hormone (TRH), somatostatin, vasopressin.

Group II: Those interacting with intracellular nuclear receptors:

3. *Large proteins*: insulin, luteinising hormone (LH), parathormone hormone.
4. *Steroid hormones*: cortisol, estrogen.
5. *Vitamin derivatives*: retinol (vitamin A) and vitamin D.

The *synthesis* of these hormones and their precursors takes place through a prescribed genetic pathway that involves: transcription → mRNA → protein synthesis → post-translational protein processing → intracellular sorting/membrane integration → secretion.

Major functions of hormones are as under:

- i) *Growth and differentiation of cells*: by pituitary hormones, thyroid, parathyroid, steroid hormones.
- ii) *Maintenance of homeostasis*: by thyroid (by regulating BMR), parathormone, mineralocorticoids, vasopressin, insulin.
- iii) *Reproduction*: sexual development and activity, pregnancy, foetal development, menopause etc.

A basic feature of all endocrine glands is the existence of both negative and positive **feedback control system** that *stimulates* or *regulates* hormone production in a way that levels remain within the normal range (abbreviated as S or R respectively with the corresponding hormone e.g. TSH-TRH pathway, GnRH-LH/FSH pathway etc). This system is commonly termed *hypothalamic-pituitary hormone axis* for different hormones schematically illustrated in **Fig. 25.1**. The stimulatory or regulatory action by endocrine hormonal secretions may follow paracrine or autocrine pathways:

◆ *Paracrine regulation* means that the stimulatory/regulatory factors are released by one type of cells but act on another adjacent cell of the system.

◆ *Autocrine regulation* refers to action of the factor on the same cell that produced it.

With this brief overview of principles of physiology of hormones, we now turn to the study of diseases of the endocrine organs. In general, pathologic processes affecting endocrine glands with resultant hormonal abnormalities may occur from following processes:

Hyperfunction This results from excess of hormone secreting tissues e.g. hyperplasia, tumours (adenoma, carcinoma), ectopic hormone production, excessive stimulation from inflammation (often autoimmune), infections, iatrogenic (drugs-induced, hormonal administration).

Hypofunction Deficiency of hormones occurs from destruction of hormone-forming tissues from inflammation (often autoimmune), infections, iatrogenic (e.g. surgical removal, radiation damage), developmental defects (e.g. Turner's

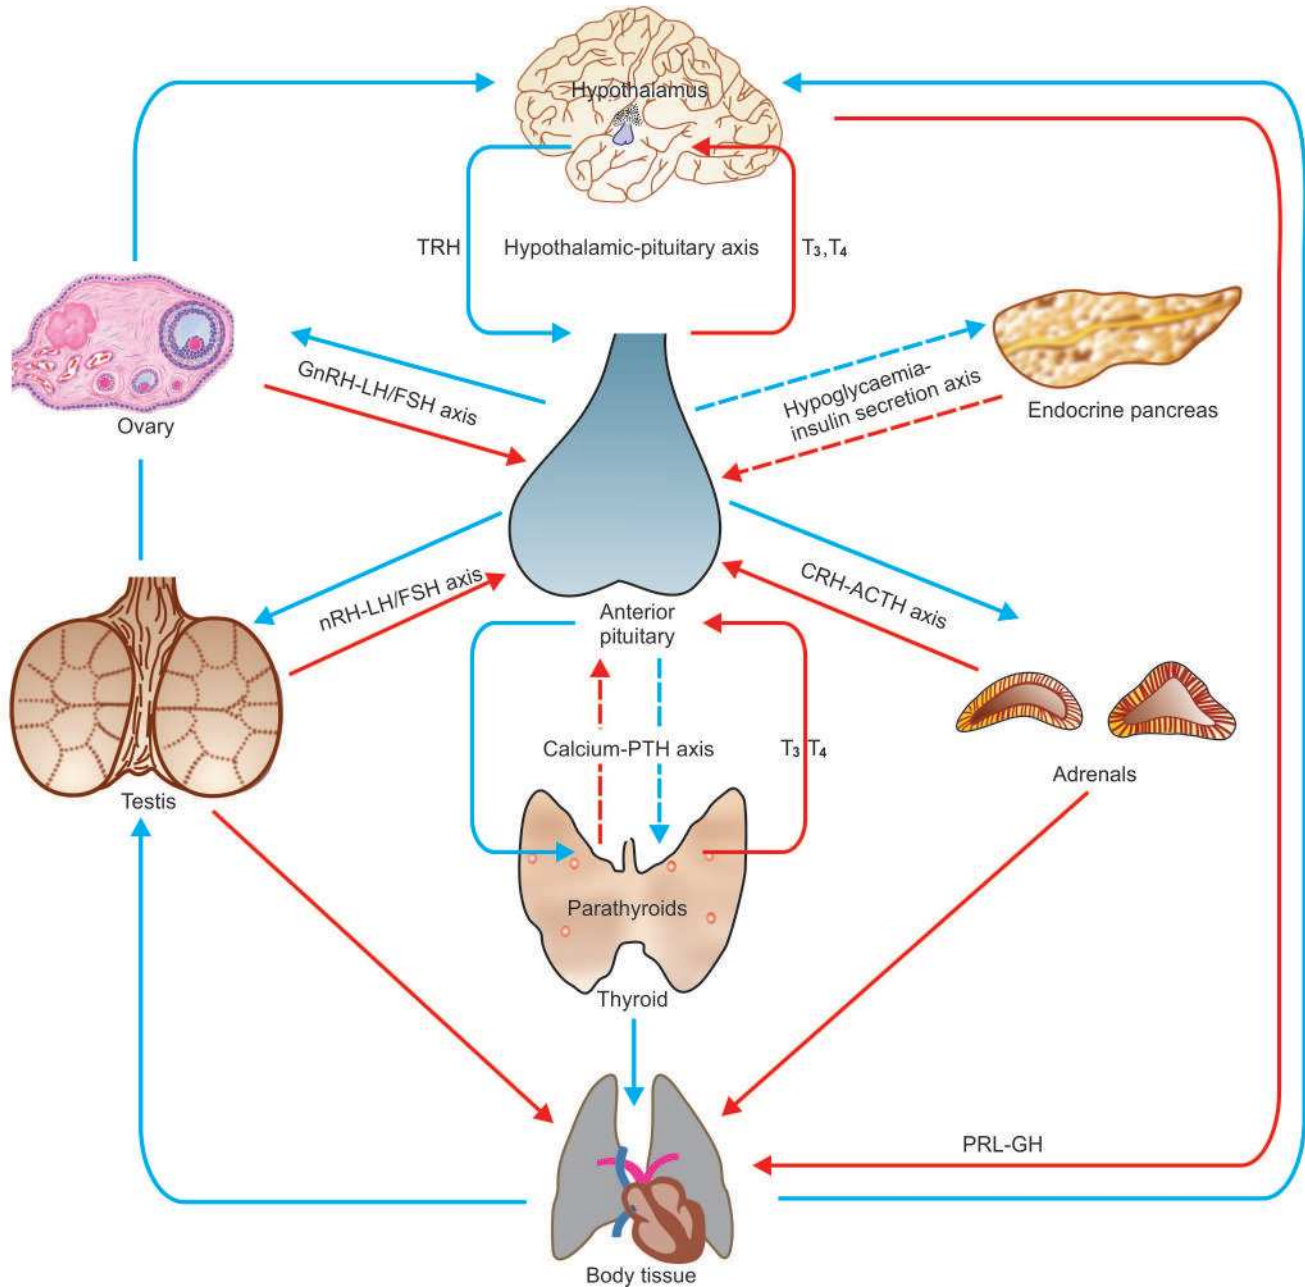

Figure 25.1 Endocrine organs and the presence of feedback controls. Both positive and negative feedback controls exist for each endocrine gland having a regulating (R) and stimulating (S) hormone. Those acting through hypothalamic-pituitary axis include: thyroid hormones on TRH-TSH axis, cortisol on CRH-ACTH axis, gonadal steroids on GnRH-LH/FSH axis and insulin-like GH on GHRH-GH axis. Those independent of pituitary control (shown by interrupted arrows) have also feedback controls by calcium on PTH, and hypoglycaemia on insulin release by pancreatic islets.

syndrome, hypoplasia), enzyme deficiency, haemorrhage and infarction (e.g. Sheehan's syndrome), nutritional deficiency (e.g. iodine deficiency).

Hormone resistance There may be adequate or excessive production of a hormone but there is peripheral resistance, often from inherited mutations in receptors (e.g. defect in membrane receptors, nuclear receptors or receptor for signal transduction).

GIST BOX 25.1 Miscellaneous Endocrine Tumours

Neuroendocrine system forms a link between endocrine glands and nervous system. The cells comprising this system lie at different places in the body, hence called dispersed neuroendocrine system.

- These include neuroendocrine cells in gastric and intestinal mucosa, neuroganglia cells, adrenal medulla, parafollicular C cells of the thyroid, islets of Langerhans and isolated cells in the left atrium.
- Anatomically, endocrine system consists of 6 distinct organs: pituitary, adrenals, thyroid, parathyroids, gonads, and pancreatic islets.
- A basic feature of all endocrine glands is the existence of both negative and positive feedback control system that stimulates or regulates hormone production in a way that levels remain within the normal range.
- Diseases of endocrine glands occur due to their hyper- or hypo- function or from peripheral resistance of the hormone.

NORMAL STRUCTURE

ANATOMY The pituitary gland or hypophysis in an adult weighs about 500 mg and is slightly heavier in females. It is situated at the base of the brain in a hollow called *sella turcica* formed out of the sphenoid bone. The gland is composed of 2 major anatomic divisions: anterior lobe (adenohypophysis) and posterior lobe (neurohypophysis).

◆ The **anterior lobe or adenohypophysis** is an ectodermal derivative formed from Rathke's pouch which is an upward diverticulum from the primitive buccal cavity. The adenohypophysis has no direct neural connection but has indirect connection through capillary portal circulation by which the anterior pituitary receives the blood which has already passed through the hypothalamus.

◆ The **posterior lobe or neurohypophysis** is a down-growth from the primitive neural tissue. The neurohypophysis, therefore, has direct neural connection superiorly with the hypothalamus.

HISTOLOGY AND FUNCTIONS The histology and functions of the anterior and posterior lobes of the pituitary gland are quite distinct.

A. ANTERIOR LOBE (ADENOHYPOPHYSIS) It is composed of round to polygonal epithelial cells arranged in cords and islands having fibrovascular stroma. These epithelial cells, depending upon their staining characteristics and functions, are divided into 3 types, each of which performs separate functions:

1. Chromophil cells with acidophilic granules These cells comprise about 40% of the anterior lobe and are chiefly located in the lateral wings. The acidophils are further of 2 types:

- i) *Somatotrophs (GH cells)* which produce growth hormone (GH).
- ii) *Lactotrophs (PRL cells)* which produce prolactin (PRL).

Cells containing both GH and PRL called *mammotrophs* are also present.

2. Chromophil cells with basophilic granules These cells constitute about 10% of the anterior lobe and are mainly found in the region of median wedge. The chromatophils include 3 types of cells:

- i) *Gonadotrophs (FSH-LH cells)* which are the source of the FSH and LH or interstitial cell stimulating hormone (ICSH).
- ii) *Thyrotrophs (TSH cells)* are the cells producing TSH.
- iii) *Corticotrophs (ACTH-MSH cells)* produce ACTH, melanocyte stimulating hormone (MSH), β -lipoprotein and β -endorphin.

3. Chromophobe cells without visible granules These cells comprise the remainder 50% of the adenohypophysis. These cells by light microscopy contain no visible granules, but on electron microscopy reveal sparsely granulated corticotrophs, thyrotrophs and gonadotrophs.

All these functions of the adenohypophysis are under the indirect *control* of the hypothalamus through stimulatory and inhibitory factors synthesised by the hypothalamus which reach the anterior lobe through capillary portal blood.

B. POSTERIOR LOBE (NEUROHYPOPHYSIS) The neurohypophysis is composed mainly of interlacing nerve fibres in which are scattered specialised glial cells called *pituicytes*.

These nerve fibres on electron microscopy contain granules of neurosecretory material made up of 2 octapeptides—*vasopressin or antidiuretic hormone (ADH)*, and *oxytocin*, both of which are produced by neurosecretory cells of the hypothalamus but are stored in the cells of posterior pituitary.

1. ADH It causes reabsorption of water from the renal tubules and is essential for maintenance of osmolality of the plasma. Its deficiency results in diabetes insipidus characterised by uncontrolled diuresis and polydipsia.

2. Oxytocin It causes contraction of mammary myoepithelial cells resulting in ejection of milk from the lactating breast and causes contraction of myometrium of the uterus at term.

It is obvious from the description above that pituitary, though a tiny organ, is concerned with a variety of diverse functions in the body. The pituitary gland and hypothalamus are so closely interlinked that diseases of the pituitary gland involve the hypothalamus, and dysfunctions of the hypothalamus cause secondary changes in the pituitary. The pituitary gland is involved in several diseases which include: *non-neoplastic* (e.g. inflammations, haemorrhage, trauma, infarction and many other endocrine diseases) and *neoplastic* diseases. However, functionally and morphologically, diseases of the pituitary can be classified as below, each of which includes diseases of the anterior and posterior pituitary and the hypothalamus, separately:

- i) Hyperpituitarism
- ii) Hypopituitarism
- iii) Pituitary tumours

HYPERPITUITARISM

Hyperpituitarism is characterised by oversecretion of one or more of the pituitary hormones. Such hypersecretion may be due to diseases of the anterior pituitary, posterior pituitary or hypothalamus. For all practical purposes, however, hyperfunction of the anterior pituitary is due to the development of a hormone-secreting pituitary adenoma (discussed later), and rarely, a carcinoma. For each of the hormonal hyperfunction of the anterior pituitary, posterior pituitary and hypothalamus, a clinical syndrome is described. A few important syndromes are as follows:

A. HYPERFUNCTION OF ANTERIOR PITUITARY

Three common syndromes of adenohypophyseal hyperfunction are: gigantism and acromegaly, hyperprolactinaemia and Cushing's syndrome.

GIGANTISM AND ACROMEGALY Both these clinical syndromes result from sustained excess of growth hormone (GH), most commonly by somatotroph (GH-secreting) adenoma.

Gigantism When GH excess occurs prior to epiphyseal closure, gigantism is produced. Gigantism, therefore, occurs in prepubertal boys and girls and is much less frequent than acromegaly. The main clinical feature in gigantism is the excessive and proportionate growth of the child. There is enlargement as well as thickening of the bones resulting in considerable increase in height and enlarged thoracic cage.

Acromegaly Acromegaly results when there is overproduction of GH in adults following cessation of bone growth and is more common than gigantism. The term 'acromegaly' means increased growth of extremities (*acro*=extremity). There is

enlargement of hands and feet, coarseness of facial features with increase in soft tissues, prominent supraorbital ridges and a more prominent lower jaw which when clenched results in protrusion of the lower teeth in front of upper teeth (*prognathism*). Other features include enlargement of the tongue and lips, thickening of the skin and kyphosis. Sometimes, a few associated features such as TSH excess resulting in thyrotoxicosis, and gonadotropin insufficiency causing amenorrhoea in the females and impotence in the male, are found.

PROLACTINAEMIA Prolactinaemia is lactotroph (PRL-secreting) pituitary adenoma, also called prolactinoma having excessive production of prolactin. Occasionally, hyperprolactinaemia results from hypothalamic inhibition of PRL secretion by certain drugs (e.g. chlorpromazine, reserpine and methyl-dopa). In the female, hyperprolactinaemia causes *amenorrhoea-galactorrhoea syndrome* characterised clinically by infertility and expression of a drop or two of milk from breast, not related to pregnancy or puerperium. In the male, it may cause *impotence* or *reduced libido*. These features result either from associated inhibition of gonadotropin secretion or interference in gonadotropin effects.

CUSHING'S SYNDROME Pituitary-dependent Cushing's syndrome results from ACTH excess. Most frequently, it is caused by corticotroph (ACTH-secreting) adenoma. Cushing's syndrome is discussed under diseases of the adrenal gland on page 788.

B. HYPERFUNCTION OF POSTERIOR PITUITARY AND HYPOTHALAMUS

Lesions of posterior pituitary and hypothalamus are uncommon. Two of the syndromes associated with hyperfunction of the posterior pituitary and hypothalamus are: inappropriate release of ADH and precocious puberty.

INAPPROPRIATE RELEASE OF ADH Inappropriate release of ADH results in its excessive secretion which manifests clinically by passage of concentrated urine due to increased reabsorption of water and loss of sodium in the urine, consequent hyponatraemia, haemodilution and expansion of intra- and extracellular fluid volume. Inappropriate release of ADH occurs most often in paraneoplastic syndrome e.g. in oat cell carcinoma of the lung, carcinoma of the pancreas, lymphoma and thymoma. Infrequently, lesions of the hypothalamus such as trauma, haemorrhage and meningitis may produce ADH hypersecretion. Rarely, pulmonary diseases such as tuberculosis, lung abscess, pneumoconiosis, empyema and pneumonia may cause overproduction of ADH.

PRECOCIOUS PUBERTY A tumour in the region of hypothalamus or the pineal gland may result in premature release of gonadotropins causing the onset of pubertal changes prior to the age of 9 years. The features include premature development of genitalia both in the male and in the female, growth of pubic hair and axillary hair. In the female, there is breast growth and onset of menstruation.

HYPOPITUITARISM

In hypopituitarism, there is usually deficiency of one or more of the pituitary hormones affecting either anterior pituitary, or posterior pituitary and hypothalamus.

A. HYPOFUNCTION OF ANTERIOR PITUITARY

Adenohypophyseal hypofunction is invariably due to destruction of the anterior lobe of more than 75% because the anterior pituitary possesses a large functional reserve. This may result from anterior pituitary lesions or pressure and destruction from adjacent lesions. Lesions of the anterior pituitary include nonsecretory (chromophobe) adenoma, metastatic carcinoma, craniopharyngioma, trauma, postpartum ischaemic necrosis (Sheehan's syndrome), empty-sella syndrome, and rarely, tuberculosis. Though a number of syndromes associated with deficiency of anterior pituitary hormones have been described, two important syndromes are panhypopituitarism and dwarfism.

PANHYPOPITUITARISM The classical clinical condition of major anterior pituitary insufficiency is called panhypopituitarism. Three most common causes of panhypopituitarism are: non-secretory (chromophobe) adenoma (discussed later), Sheehan's syndrome and Simmond's disease, and empty-sella syndrome.

Sheehan's syndrome and Simmond's disease Pituitary insufficiency occurring due to postpartum pituitary (Sheehan's) necrosis is called Sheehan's syndrome, whereas occurrence of similar process without preceding pregnancy as well as its occurrence in males is termed Simmond's disease. The main pathogenetic mechanism underlying Sheehan's necrosis is the enlargement of the pituitary occurring during pregnancy which may be followed by hypotensive shock precipitating ischaemic necrosis of the pituitary. Other mechanisms hypothesised are: DIC following delivery, traumatic injury to vessels, and excessive haemorrhage. Patients with long-standing diabetes mellitus appear to be at greater risk of developing this complication.

The first *clinical manifestation* of Sheehan's syndrome is failure of lactation following delivery which is due to deficiency of prolactin. Subsequently, other symptoms develop which include loss of axillary and pubic hair, amenorrhoea, sterility and loss of libido. Concomitant deficiency of TSH and ACTH may result in hypothyroidism and adrenocortical insufficiency.

MORPHOLOGIC FEATURES Sheehan's syndrome during early stage shows ischaemic necrosis and haemorrhage in the anterior pituitary, while later necrotic tissue is replaced by fibrous tissue.

Empty-sella syndrome Empty-sella syndrome is characterised by the appearance of an empty sella and features of panhypopituitarism. Most commonly, it results from herniation of subarachnoid space into the sella turcica due to an incomplete diaphragma sella creating an empty sella. Other less common causes are Sheehan's syndrome, infarction and scarring in an adenoma, irradiation damage, or surgical removal of the gland.

PITUITARY DWARFISM Severe deficiency of GH in children before growth is completed results in retarded growth and pituitary dwarfism. Most commonly, isolated GH deficiency is the result of an inherited autosomal recessive disorder. Less often, it may be due to a pituitary adenoma or craniopharyngioma, infarction and trauma to the pituitary. The clinical features of inherited cases of pituitary dwarfism

appear after one year of age. These include proportionate retardation in growth of bones, normal mental state for age, poorly-developed genitalia, delayed puberty and episodes of hypoglycaemia. Pituitary dwarf must be distinguished from hypothyroid dwarf (cretinism) in which there is achondroplasia and mental retardation (page 794).

B. HYPOFUNCTION OF POSTERIOR PITUITARY AND HYPOTHALAMUS

Insufficiency of the posterior pituitary and hypothalamus is uncommon. The only significant clinical syndrome due to hypofunction of the neurohypophysis and hypothalamus is diabetes insipidus.

DIABETES INSIPIDUS Deficient secretion of ADH causes diabetes insipidus. The causes of ADH deficiency are: inflammatory and neoplastic lesions of the hypothalamo-hypophyseal axis, destruction of neurohypophysis due to surgery, radiation, head injury, and lastly, are those cases where no definite cause is known and are labelled as idiopathic. The main features of diabetes insipidus are excretion of a very large volume of dilute urine of low specific gravity (below 1.010), polyuria and polydipsia.

PITUITARY TUMOURS

Tumours of the anterior pituitary are more common than those of the posterior pituitary and hypothalamus. The most common of the anterior pituitary tumours are adenomas; primary and metastatic carcinomas being rare. Craniopharyngioma and granular cell tumour (choristoma) are the other benign pituitary tumours found occasionally.

All pituitary tumours, whether benign or malignant, cause symptoms by following 2 ways:

1. Pressure effects These are caused by expansion of the lesion resulting in destruction of the surrounding glandular tissue by pressure atrophy. This causes erosion and enlargement of sella turcica, upward extension of the tumour damaging the optic chiasma, optic nerves, neurohypophysis and adjacent cranial nerves, and rarely, downward extension into the nasopharynx.

2. Hormonal effects Depending upon their cell types, pituitary adenomas produce excess of pituitary hormones and the corresponding clinical syndromes of hyperpituitarism. Infarction and destruction of adenoma may cause symptoms of hypopituitarism.

PITUITARY ADENOMAS

Adenomas are the most common pituitary tumours. They are conventionally classified according to their H & E staining characteristics of granules into acidophil, basophil and chromophobe adenomas. However, this *morphologic classification* is considered quite inadequate because of the significant functional characteristics of each type of adenoma including the chromophobe adenoma, which on H & E staining does not show visible granules. As a result of advances in the ultrastructural and immunocytochemical studies, a functional classification of pituitary adenoma has emerged. **Table 25.1** presents a classification of pituitary adenomas based on functional features as correlated with morphologic features of older classification. The syndromes produced by the tumours have been described already.

MORPHOLOGIC FEATURES *Grossly*, pituitary adenomas range in size from small foci of less than 10 mm in size (termed microadenoma) to large adenomas several centimeters in diameter (> 1 cm called macroadenomas). They are spherical, soft and encapsulated.

Histologically, by light microscopy of H & E stained sections, an adenoma is composed predominantly of one of the normal cell types of the anterior pituitary i.e. acidophil, basophil or chromophobe cells. These cells may have following 3 types of patterns:

1. *Diffuse pattern* is composed of polygonal cells arranged in sheets with scanty stroma.
2. *Sinusoidal pattern* consists of columnar or fusiform cells with fibrovascular stroma around which the tumour cells are arranged (**Fig. 25.2**).
3. *Papillary pattern* is composed of columnar or fusiform cells arranged about fibrovascular papillae.

Functionally, most common pituitary adenomas, in decreasing order of frequency, are: lactotroph (PRL-secreting) adenoma, somatotroph (GH-secreting) adenoma and corticotroph (ACTH-secreting) adenoma. Infrequently, mixed somatotroph-lactotroph (GH-PRL-secreting) adenoma, gonadotroph (FSH-LH-secreting) adenomas and null-cell (endocrinologically inactive) adenomas or oncocytoma are found. Pleurihormonal-pituitary adenoma, on the other hand, may have multiple hormone elaborations. Functional classification of pituitary adenoma can be done by carrying out specific immunostains against the hormone products.

Table 25.1 Morphologic and functional classification of pituitary adenomas.

| FUNCTIONAL TYPE | FREQUENCY | HORMONES PRODUCED | CLINICAL SYNDROME |
|---|-----------|-------------------|---|
| 1. Lactotroph adenoma (<i>Prolactinoma</i>) | 20-30% | PRL | Hypogonadism, galactorrhoea |
| 2. Somatotroph adenoma | 5% | GH | Acromegaly/gigantism |
| 3. Mixed somatotroph-lactotroph adenoma | 5% | PRL, GH | Acromegaly, hypogonadism, galactorrhoea |
| 4. Corticotroph adenoma | 10-15% | ACTH | Cushing's syndrome |
| 5. Gonadotroph adenoma | 10-15% | FSH-LH | Inactive or hypogonadism |
| 6. Thyrotroph adenoma | 1% | TSH | Thyrotoxicosis |
| 7. Null cell adenoma/oncocytoma | 20% | Nil | Pituitary failure |
| 8. Pleurihormonal adenoma | 15% | Multiple hormones | Mixed |

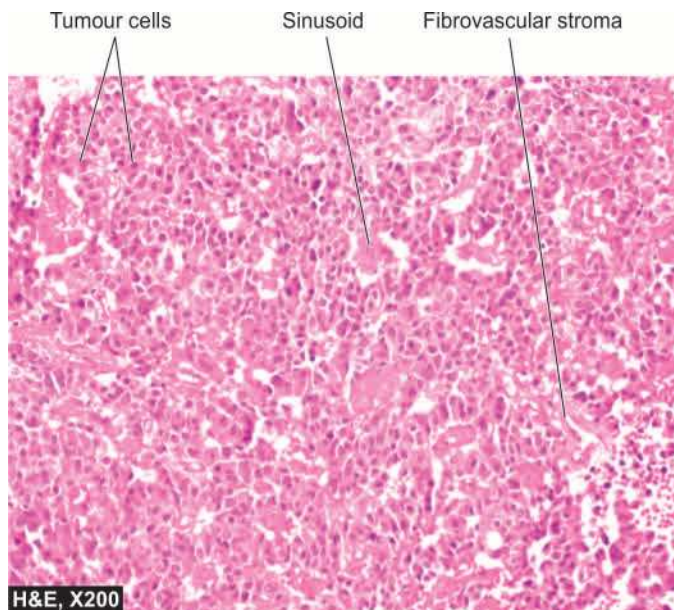

Figure 25.2 Pituitary adenoma, sinusoidal pattern.

Pituitary adenomas occur in the age group of 3rd to 6th decade of life. They are mostly sporadic. Less than 5% are familial having germline mutation in *MEN1* gene. The latter cases occur as a part of multiple endocrine neoplasia type I (MEN-I) in which pituitary adenoma is associated with adenomas of pancreatic islets and parathyroids (page 819). Sporadic cases appear to be due to genetic abnormalities of signaling pathways, particularly G protein mutations.

Clinically, patients of pituitary adenomas generally have combination of features of Zollinger-Ellison's syndrome, hyperparathyroidism and hyperpituitarism.

CRANIOPHARYNGIOMA

Craniopharyngioma is a benign tumour arising from remnants of Rathke's pouch. It has 2 peaks of occurrence: children and young adults in 1st to 2nd decade and then in adults past 6th decade. The tumour, though benign, compresses as well as invades the adjacent structures extensively.

MORPHOLOGIC FEATURES *Grossly*, the tumour is encapsulated, adherent to surrounding structures and is typically cystic, reddish-grey mass. The fluid in the cystic cavity typically has colour and consistency of machinery oil.

Histologically, craniopharyngioma closely resembles ameloblastoma of the jaw (page 513). There are 2 distinct histologic features:

1. Stratified squamous epithelium frequently lining a cyst and containing loose stellate cells in the centre.
2. Solid ameloblastic areas.

GIST BOX 25.2

Diseases of Pituitary Gland

- Hyperpituitarism is oversecretion of one or more of the pituitary hormones due to diseases of the anterior pituitary (e.g. gigantism, acromegaly, prolactinoma, Cushing's syndrome), posterior pituitary or hypothalamus (e.g. inappropriate release of ADH, precocious puberty).

- In hypopituitarism, there is usually deficiency of one or more of the pituitary hormones affecting either anterior pituitary (e.g. Sheehan's syndrome, empty sella syndrome, dwarfism), or posterior pituitary and hypothalamus (e.g. diabetes insipidus).
- Major pituitary tumours are adenomas (micro- and macroadenomas) and craniopharyngioma.

ADRENAL GLAND

NORMAL STRUCTURE

ANATOMY The adrenal glands lie at the upper pole of each kidney. Each gland weighs approximately 4 gm in the adult but in children the adrenals are proportionately larger. On sectioning, the adrenal is composed of 2 distinct parts: an outer yellow-brown *cortex* and an inner grey *medulla*. The anatomic and functional integrity of adrenal cortices are essential for life, while it does not hold true for adrenal medulla.

HISTOLOGY AND PHYSIOLOGY Microscopically and functionally, cortex and medulla are quite distinct.

ADRENAL CORTEX It is composed of 3 layers:

- 1. Zona glomerulosa** is the outer layer and comprises about 10% of the cortex. It consists of cords or columns of polyhedral cells just under the capsule. This layer is responsible for the synthesis of *mineralocorticoids*, the most important of which is aldosterone, the salt and water regulating hormone.
- 2. Zona fasciculata** is the middle layer and constitutes approximately 70% of the cortex. It is composed of columns of lipid-rich cells which are precursors of various *steroid hormones* manufactured in the adrenal cortex such as glucocorticoids (e.g. cortisol) and sex steroids (e.g. testosterone).
- 3. Zona reticularis** is the inner layer which makes up the remainder of the adrenal cortex. It consists of cords of more compact cells than those of zona fasciculata but has similar functional characteristics of synthesis and secretion of *glucocorticoids* and *androgens*.

The synthesis of glucocorticoids and adrenal androgens is under the control of ACTH from hypothalamus-anterior pituitary. In turn, ACTH release is under the control of a hypothalamic releasing factor called corticotropin-releasing factor. Release of aldosterone, on the other hand, is independent of ACTH control and is largely regulated by the serum levels of potassium and renin-angiotensin mechanism (page 83).

ADRENAL MEDULLA The adrenal medulla is a component of the dispersed neuroendocrine system derived from primitive neuroectoderm; the other components of this system being *paraganglia* distributed in the vagi, paravertebral and visceral autonomic ganglia. The cells comprising this system are neuroendocrine cells, the major function of which is synthesis and secretion of catecholamines (epinephrine and norepinephrine). Various other peptides such as calcitonin, somatostatin and vasoactive intestinal polypeptide (VIP) are also secreted by these cells. The major metabolites of catecholamines are metanephrine, nor-metanephrine, vanillyl mandelic acid (VMA) and homovanillic acid (HVA). In case of damage to the adrenal medulla, its function is taken over by other paraganglia.

Diseases affecting the two parts of adrenal glands are quite distinctive in view of distinct morphology and function of the adrenal cortex and medulla. While the disorders of the *adrenal cortex* include adrenocortical hyperfunction (hyperadrenalism), adrenocortical insufficiency (hypoadrenalism) and adrenocortical tumours, the main lesions affecting the *adrenal medulla* are the medullary tumours.

ADRENOCORTICAL HYPERFUNCTION (HYPERADRENALISM)

Hypersecretion of each of the three types of corticosteroids elaborated by the adrenal cortex causes distinct corresponding hyperadrenal clinical syndromes:

1. *Cushing's syndrome* caused by excess of glucocorticoids (i.e. cortisol); also called *chronic hypercortisolism*.
2. *Conn's syndrome* caused by oversecretion of mineralocorticoids (i.e. aldosterone); also called *primary hyperaldosteronism*.
3. *Adrenogenital syndrome* characterised by excessive production of adrenal sex steroids (i.e. androgens); also called *adrenal virilism*.

Mixed forms of these clinical syndromes may also occur.

CUSHING'S SYNDROME (CHRONIC HYPERCORTISOLISM)

Cushing's syndrome is caused by excessive production of cortisol of whatever cause. The full clinical expression of the syndrome, however, includes contribution of the secondary derangements.

ETIOPATHOGENESIS There are 4 major etiologic types of Cushing's syndrome which should be distinguished for effective treatment.

1. Pituitary Cushing's syndrome About 60-70% cases of Cushing's syndrome are caused by excessive secretion of ACTH due to a lesion in the pituitary gland, most commonly a corticotroph adenoma or multiple corticotroph microadenomas. This group of cases was first described by Harvey Cushing, an American neurosurgeon, who termed the condition as Cushing's disease. Also included in this group are cases with hypothalamic origin of excessive ACTH levels without apparent pituitary lesion. All cases with pituitary Cushing's syndrome are characterised by bilateral adrenal cortical hyperplasia and elevated ACTH levels. These cases show therapeutic response on administration of high doses of dexamethasone which suppresses ACTH secretion and causes fall in plasma cortisol level.

2. Adrenal Cushing's syndrome Approximately 20-25% cases of Cushing's syndrome are caused by disease in one or both the adrenal glands. These include adrenal cortical adenoma, carcinoma, and less often, cortical hyperplasia. This group of cases is characterised by low serum ACTH levels and absence of therapeutic response to administration of high doses of glucocorticoid.

3. Ectopic Cushing's syndrome About 10-15% cases of Cushing's syndrome have an origin in ectopic ACTH elaboration by non-endocrine tumours. Most often, the tumour is small cell carcinoma of the lung but other lung cancers, malignant thymoma and pancreatic tumours have also been implicated. The plasma ACTH level is high in these cases and cortisol secretion is not suppressed by dexamethasone administration.

4. Iatrogenic Cushing's syndrome Prolonged therapeutic administration of high doses of glucocorticoids or ACTH may result in Cushing's syndrome e.g. in organ transplant recipients and in autoimmune diseases. These cases are generally associated with bilateral adrenocortical insufficiency.

CLINICAL FEATURES Cushing's syndrome occurs more often in patients between the age of 20-40 years with three times higher frequency in women than in men. The severity of the syndrome varies considerably, but in general the following features characterise a case of Cushing's syndrome:

1. Central or truncal *obesity* contrasted with relatively thin arms and legs, buffalo hump due to prominence of fat over the shoulders, and rounded oedematous moon-face.
2. Increased *protein breakdown* resulting in wasting and thinning of the skeletal muscles, atrophy of the skin and subcutaneous tissue with formation of purple striae on the abdominal wall, osteoporosis and easy bruising of the thin skin from minor trauma.
3. *Systemic hypertension* is present in 80% of cases because of associated retention of sodium and water.
4. *Impaired glucose tolerance* and diabetes mellitus are found in about 20% cases.
5. Amenorrhoea, hirsutism and infertility in many women.
6. Insomnia, depression, confusion and psychosis.

CONN'S SYNDROME (PRIMARY HYPERALDOSTERONISM)

This is an uncommon syndrome occurring due to overproduction of aldosterone, the potent salt-retaining hormone.

ETIOPATHOGENESIS The condition results primarily due to adrenocortical diseases as follows:

1. Adrenocortical adenoma, producing aldosterone.
2. Bilateral adrenal hyperplasia, especially in children (congenital hyperaldosteronism).
3. Rarely, adrenal carcinoma.

◆ *Primary hyperaldosteronism* from any of the above causes is associated with low plasma renin levels.

◆ *Secondary hyperaldosteronism*, on the contrary, occurs in response to high plasma renin level due to overproduction of renin by the kidneys such as in renal ischaemia, reninoma or oedema.

CLINICAL FEATURES Conn's syndrome is more frequent in adult females. Its principal features are as under:

1. *Hypertension*, usually mild to moderate diastolic hypertension.
2. *Hypokalaemia* and associated muscular weakness, peripheral neuropathy and cardiac arrhythmias.
3. *Retention of sodium and water*.
4. *Polyuria* and *polydipsia* due to reduced concentrating power of the renal tubules.

ADRENOGENITAL SYNDROME (ADRENAL VIRILISM)

Adrenal cortex secretes a smaller amount of sex steroids than the gonads. However, adrenocortical hyperfunction may occasionally cause sexual disturbances.

ETIOPATHOGENESIS Hypersecretion of sex steroids, mainly androgens, may occur in children or in adults:

◆ *In children*, it is due to congenital adrenal hyperplasia in which there is congenital deficiency of a specific enzyme.

◆ *In adults*, it is caused by an adrenocortical adenoma or a carcinoma. Cushing's syndrome is often present as well.

CLINICAL FEATURES The clinical features depend upon the age and sex of the patient.

◆ *In children*, there is distortion of the external genitalia in girls, and precocious puberty in boys.

◆ *In adults*, the features in females show virilisation (e.g. hirsutism, oligomenorrhoea, deepening of voice, hypertrophy of the clitoris); and in males may rarely cause feminisation.

There is generally increased excretion of 17-ketosteroids in the urine.

ADRENOCORTICAL INSUFFICIENCY (HYPOADRENALISM)

Adrenocortical insufficiency may result from deficient synthesis of cortical steroids from the adrenal cortex or may be secondary to ACTH deficiency. Three types of adrenocortical hypofunction are distinguished:

1. *Primary adrenocortical insufficiency* caused primarily by the disease of the adrenal glands. Two forms are described: acute or 'adrenal crisis', and chronic or 'Addison's disease'.
2. *Secondary adrenocortical insufficiency* resulting from diminished secretion of ACTH.
3. *Hypoadosteronism* characterised by deficient secretion of aldosterone.

PRIMARY ADRENOCORTICAL INSUFFICIENCY

Primary adrenal hypofunction occurs due to defect in the adrenal glands and normal pituitary function. It may develop in 2 ways:

- A. Acute primary adrenocortical insufficiency or 'adrenal crisis'.
- B. Chronic primary adrenocortical insufficiency or 'Addison's disease'.

A. Primary Acute Adrenocortical Insufficiency (Adrenal Crisis)

Sudden loss of adrenocortical function may result in an acute condition called *adrenal crisis*.

ETIOPATHOGENESIS Causes of acute insufficiency are as under:

1. Bilateral adrenalectomy e.g. in the treatment of cortical hyperfunction, hypertension and in selected cases of breast cancer.
2. Septicaemia e.g. in endotoxic shock and meningococcal infection producing grossly haemorrhagic and necrotic adrenal cortex termed adrenal apoplexy. The acute condition so produced is called *Waterhouse-Friderichsen's syndrome*.
3. Rapid withdrawal of steroids.
4. Any form of acute stress in a case of chronic insufficiency i.e. in Addison's disease.

CLINICAL FEATURES Clinical features of acute adrenocortical insufficiency are due to deficiency of mineralocorticoids and glucocorticoids. These are as follows:

1. Deficiency of mineralocorticoids (i.e. aldosterone deficiency) result in salt deficiency, hyperkalaemia and dehydration.

2. Deficiency of glucocorticoids (i.e. cortisol deficiency) leads to hypoglycaemia, increased insulin sensitivity and vomitings.

B. Primary Chronic Adrenocortical Insufficiency (Addison's Disease)

Progressive chronic destruction of more than 90% of adrenal cortex on both sides results in an uncommon clinical condition called Addison's disease.

ETIOPATHOGENESIS Any condition which causes marked chronic adrenal destruction may produce Addison's disease. These include: tuberculosis, autoimmune or idiopathic adrenalitis, histoplasmosis, amyloidosis, metastatic cancer, sarcoidosis and haemochromatosis. However, currently the first two causes—tuberculosis and autoimmune chronic destruction of adrenal glands, are implicated in majority of cases of Addison's disease. Irrespective of the cause, the adrenal glands are bilaterally small and irregularly shrunken. Histologic changes, depending upon the cause, may reveal specific features as in tuberculosis and histoplasmosis, or the changes may be in the form of nonspecific lymphocytic infiltrate as in idiopathic (autoimmune) adrenalitis.

CLINICAL FEATURES Clinical manifestations develop slowly and insidiously. The usual features are as under:

1. Asthenia i.e. progressive weakness, weight loss and lethargy as the cardinal symptoms.
2. Hyperpigmentation, initially most marked on exposed areas, but later involves unexposed parts and mucous membranes as well.
3. Arterial hypotension.
4. Vague upper gastrointestinal symptoms such as mild loss of appetite, nausea, vomiting and upper abdominal pain.
5. Lack of androgen causing loss of hair in women.
6. Episodes of hypoglycaemia.
7. Biochemical changes include reduced GFR, acidosis, hyperkalaemia and low levels of serum sodium, chloride and bicarbonate.

SECONDARY ADRENOCORTICAL INSUFFICIENCY

Adrenocortical insufficiency resulting from deficiency of ACTH is called secondary adrenocortical insufficiency.

ETIOPATHOGENESIS ACTH deficiency may appear in 2 settings:

1. *Selective ACTH deficiency* due to prolonged administration of high doses of glucocorticoids. This leads to suppression of ACTH release from the pituitary gland and selective deficiency.
2. *Panhypopituitarism* due to hypothalamus-pituitary diseases is associated with deficiency of multiple trophic hormones (page 785).

CLINICAL FEATURES The clinical features of secondary adrenocortical insufficiency are like those of Addison's disease except the following:

1. These cases lack hyperpigmentation because of suppressed production of melanocyte-stimulating hormone (MSH) from the pituitary.
2. Plasma ACTH levels are low-to-absent in secondary insufficiency but are elevated in Addison's disease.
3. Aldosterone levels are normal due to stimulation by renin.

HYPOALDOSTERONISM

Isolated deficiency of aldosterone with normal cortisol level may occur in association with reduced renin secretion.

ETIOPATHOGENESIS The causes of such hyporeninism are as follows:

1. Congenital defect due to deficiency of an enzyme required for its synthesis.
2. Prolonged administration of heparin.
3. Certain diseases of the brain.
4. Excision of an aldosterone-secreting tumour.

CLINICAL FEATURES The patients of isolated hypoaldosteronism are adults with mild renal failure and diabetes mellitus. The predominant features are hyperkalaemia and metabolic acidosis.

TUMOURS OF ADRENAL GLANDS

Primary tumours of the adrenal glands are uncommon and include distinct adrenocortical tumours and medullary tumours. However, adrenal gland is a more common site for metastatic carcinoma.

ADRENOCORTICAL TUMOURS

Cortical Adenoma

The commonest cortical tumour is adenoma. They are indistinguishable from hyperplastic nodules except that lesions smaller than 2 cm diameter are labelled *hyperplastic nodules*. A cortical adenoma is a benign and slow-growing tumour. It is usually small and nonfunctional. A few large adenomas may, however, produce excess of cortisol, aldosterone or androgen. Association of cortical adenomas with systemic hypertension has been suggested by some workers. Occasionally, a cortical adenoma may be a part of multiple endocrine neoplasia type I (MEN-I) in which patients have associated adenomas of parathyroid, islet cells and anterior pituitary (page 819).

MORPHOLOGIC FEATURES *Grossly*, an adenoma is usually a small (2–5 cm), solitary, spherical and encapsulated tumour which is well-delineated from the surrounding normal adrenal gland. Cut section is typically bright yellow. *Microscopically*, the tumour cells are arranged in trabeculae and generally resemble the cells of zona fasciculata. Less frequently, the cells of adenoma are like those of zona glomerulosa or zona reticularis.

Cortical Carcinoma

Carcinoma of the adrenal cortex is an uncommon tumour occurring mostly in adults. It invades locally as well as spreads to distant sites. Most cortical carcinomas secrete one of the adrenocortical hormones excessively.

MORPHOLOGIC FEATURES *Grossly*, an adrenal carcinoma is generally large, spherical and well-demarcated tumour. On cut section, it is predominantly yellow with intermixed areas of haemorrhages, necrosis and calcification.

Microscopically, the cortical carcinoma may vary from well-differentiated to anaplastic growth. Well-differentiated carcinoma consists of foci of atypia in an adenoma, while

anaplastic carcinoma shows large, pleomorphic and bizarre cells with high mitotic activity.

MEDULLARY TUMOURS

The most significant lesions of the adrenal medulla are neoplasms. These include the following:

1. *Benign tumours*: These are less common and include pheochromocytoma and myelolipoma.
2. *Tumours arising from embryonic nerve cells*: These are more common and include neuroblastoma and ganglioneuroma.

These tumours together with extra-adrenal paraganglioma are described below.

Pheochromocytoma (Chromaffin Tumour)

Pheochromocytoma is a tumour arising from pheochromocytes (i.e. chromaffin cells) of the adrenal medulla. Its name is derived from its characteristic *dark brown black* appearance of this tumour caused by chromaffin oxidation of catecholamines. The extra-adrenal pheochromocytomas arising from other paraganglia are preferably called *paragangliomas*, named along with the anatomic site of origin, as described later. The etiology of these tumours remains unknown but a quarter of cases have inherited germline mutation in *RET*, *VHL*, *NFI*, *SDHD*, *SDHC* or *SDHS* genes.

Pheochromocytoma may occur at any age but most patients are 20–60 years old. Most pheochromocytomas are slow-growing and benign but about 10% of the tumours are malignant, invasive and metastasising. These tumours are commonly sporadic but 10% are associated with familial syndromes of multiple endocrine neoplasia (MEN) having bilaterality and association with medullary carcinoma of the thyroid, hyperparathyroidism, pituitary adenoma, mucosal neuromas and von Recklinghausen's neurofibromatosis in varying combinations. Thus, the traditional "10% rule" for pheochromocytoma is 10% familial, 10% malignant, 10% extra-adrenal. However, currently, malignant pheochromocytoma is diagnosed by metastasis (most often osseous) rather than by morphology.

The *clinical features* of pheochromocytoma are predominantly due to secretion of catecholamines, both epinephrine and norepinephrine. The most common feature is hypertension. Other manifestations due to sudden release of catecholamines are congestive heart failure, myocardial infarction, pulmonary oedema, cerebral haemorrhage, and even death. The diagnosis is established by measuring 24-hour urinary catecholamines or their metabolites such as metanephrine and VMA.

MORPHOLOGIC FEATURES *Grossly*, the tumour is soft, spherical, may be quite variable in size and weight, and well-demarcated from the adjacent adrenal gland. On cut section, the tumour is grey to dusky brown with areas of haemorrhages, necrosis, calcification and cystic change (**Fig. 25.3**). On immersing the tumour in dichromate fixative, it turns brown-black due to oxidation of catecholamines in the tumour and hence the name chromaffin tumour.

Microscopically, the tumour has the following characteristics (**Fig. 25.4**):

1. The tumour cells are arranged characteristically as well-defined nests (also termed as zellballen pattern) separated by abundant fibrovascular stroma.

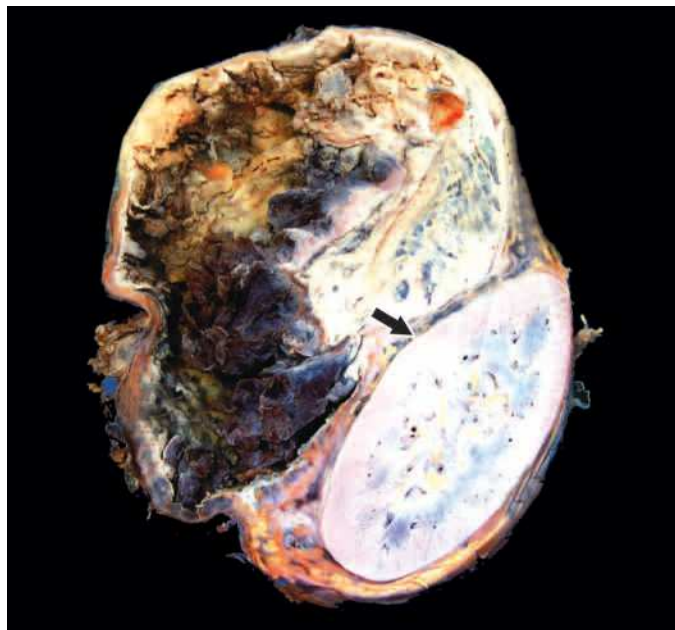

Figure 25.3 Pheochromocytoma of the adrenal medulla. The specimen shows compressed kidney at the lower end (arrow) while the upper end shows a large spherical tumour separate from the kidney. Cut surface of tumour shows cystic change while solid areas show dark brown, necrotic and haemorrhagic tumour.

2. Other arrangements are as solid columns, sheets, trabeculae or clumps.
3. The tumour cells are large, polyhedral and pleomorphic with abundant granular amphophilic or basophilic cytoplasm and vesicular nuclei.
4. The tumour cells of pheochromocytoma stain positively with neuroendocrine substances such as neuron-specific enolase (NSE) and chromogranin.

Myelolipoma

Myelolipoma is an uncommon benign adrenal medullary tumour, sometimes found incidentally at autopsy. Less often, it may produce symptoms due to excessive hormone elaboration.

MORPHOLOGIC FEATURES *Grossly*, a myelolipoma is usually a small tumour, measuring 0.2-2 cm in diameter.

Microscopically, it consists of well-differentiated adipose tissue in which is scattered clumps of haematopoietic cells are seen.

Neuroblastoma

Neuroblastoma, also called as sympathicoblastoma, is a common malignant tumour of neural crest cells, occurring most commonly in children under 5 years of age. Vast majority of cases occur within the abdomen (in the adrenal medulla and paravertebral autonomic ganglia) and rarely in the cerebral hemisphere. Most cases are sporadic but 1-2% cases are familial with autosomal dominant transmission. Familial cases are known to have germline mutation of *ALK* (anaplastic lymphoma kinase) gene.

The *clinical manifestations* of neuroblastoma are related to its rapid local growth, metastatic spread or development of hormonal syndrome. Local symptoms include abdominal distension, fever, weight loss and malaise. Foci of calcification

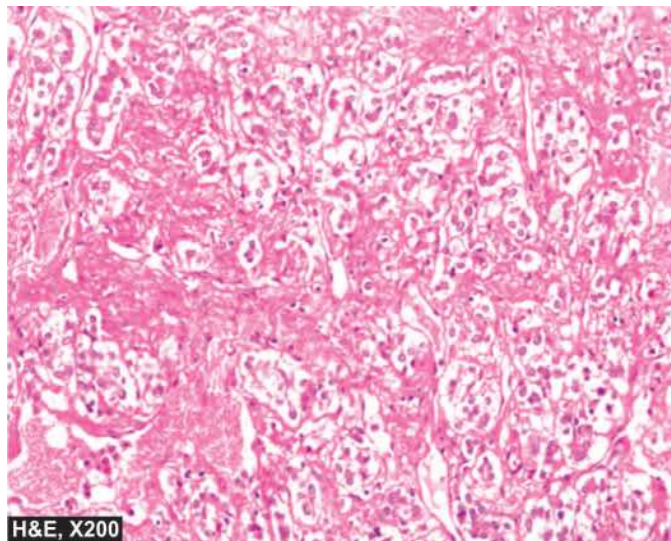

Figure 25.4 Adrenal pheochromocytoma. The tumour has typical zellballen or nested pattern. The tumour cells are large, polyhedral and pleomorphic having abundant granular cytoplasm.

may be observed on radiologic examination of the abdomen. Metastatic spread occurs early and widely through haematogenous as well as lymphatic routes and involves bones (especially skull), liver, lungs and regional lymph nodes. Neuroblastoma produces variable amounts of catecholamines and its metabolites such as vanillyl mandelic acid (VMA) and homovanillic acid (HVA), which can be detected in the 24-hour urine. Less often, the patient develops carcinoid-like syndrome, probably due to production of kinins or prostaglandins by the tumour. The features in such a case include watery diarrhoea, flushing of the skin and hypokalaemia. Rarely, the tumour may produce sufficient catecholamines to cause hypertension.

MORPHOLOGIC FEATURES *Grossly*, the tumour is generally large, soft and lobulated mass with extensive areas of necrosis and haemorrhages. The tumour is usually diffusely infiltrating into the adjacent tissues. Cut surface of the tumour is grey white and may reveal minute foci of calcification.

Microscopically, neuroblastoma has the following characteristics (**Fig. 25.5**):

1. The tumour cells are small, round and oval, slightly larger than lymphocytes, and have scanty and poorly-defined cytoplasm and hyperchromatic nuclei.
2. They are generally arranged in irregular sheets separated by fibrovascular stroma.
3. Classical neuroblastomas show Homer-Wright's rosettes (pseudorosettes) which have a central fibrillar eosinophilic material surrounded by radially arranged tumour cells. The central fibrillar material stains positively by silver impregnation methods indicating their nature as young nerve fibrils.
4. The tumour cells stain positively with immunohistochemical markers such as neuron-specific enolase (NSE), neurofilaments (NF) and chromogranin.

Prognosis of neuroblastoma depends upon a few variables; favourable prognostic features are as under:

- i) Age of child below 2 years.
- ii) Extra-abdominal *location* of the tumour than abdominal masses.

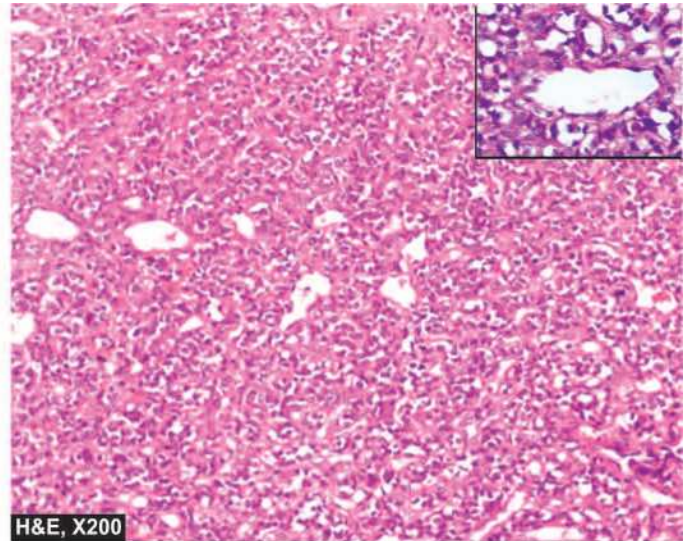

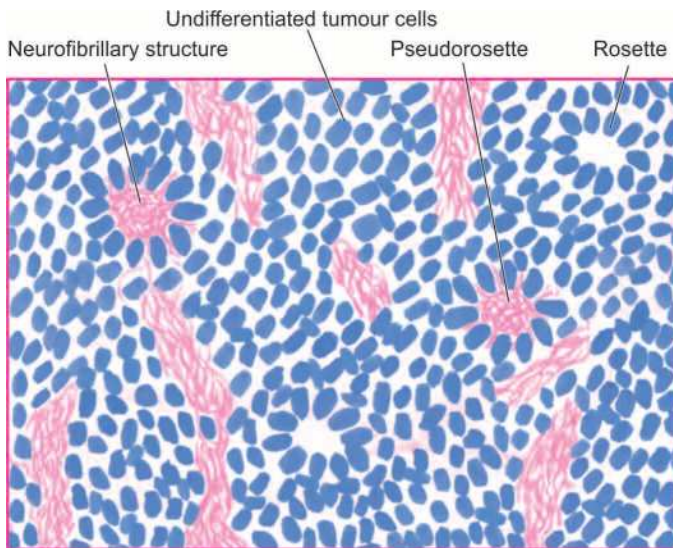

Figure 25.5 Neuroblastoma, It shows small, round to oval cells forming irregular sheets separated by fibrovascular stroma. A few Homer-Wright's pseudorosettes are also present. *Inset* shows a close-up view of pseudorosette.

- iii) *Tumour histology* with schwannian or ganglionic differentiation.
- iv) *Patients in clinical stage I* (confined to the organ of origin) or stage II (tumour extending in continuity beyond the organ of origin but not crossing the midline).
- v) Favourable *genetic features* of hyperdiploidy, lack of amplification of *N-MYC* oncogene and absence of telomerase expression.

Ganglioneuroma

A ganglioneuroma is a mature, benign and uncommon tumour occurring in adults. It is derived from ganglion cells, most often in the posterior mediastinum, and uncommonly in other peripheral ganglia and brain. The tumour produces symptoms because of its size and location. Catecholamines and their metabolites can be detected in large amounts in the 24-hour urine specimen of patients with ganglioneuroma.

MORPHOLOGIC FEATURES *Grossly*, the tumour is spherical, firm and encapsulated.

Microscopically, it contains large number of well-formed ganglionic nerve cells scattered in fibrillar stroma and myelinated and non-myelinated nerve fibres.

Extra-adrenal Paraganglioma (Chemodectoma)

Parasympathetic paraganglia located in extra-adrenal sites such as the carotid bodies, vagus, jugulotympanic and aortic-sympathetic (pre-aortic) paraganglia may produce neoplasms, collectively termed *paragangliomas* with the anatomic site of origin e.g. carotid body paraganglioma, intravagal paraganglioma, jugulotympanic paraganglioma etc. These tumours are also called chemodectomas because of their responsiveness to chemoreceptors. They are uncommon tumours found in adults and rarely secrete excess of catecholamines, except aortic sympathetic paraganglioma (also termed extra-adrenal pheochromocytoma). Paragangliomas are generally benign but recurrent tumours. A small proportion of them may metastasise widely.

GIST BOX 25.3

Diseases of Adrenal Gland

- Hyperadrenal clinical syndromes are Cushing's syndrome caused by excess of glucocorticoids (i.e. cortisol), Conn's syndrome caused by oversecretion of mineralocorticoids (i.e. aldosterone), and adrenogenital syndrome characterised by excessive production of adrenal sex steroids (i.e. androgens).
- Adrenocortical hypofunction may be primary adrenocortical insufficiency caused by the disease of the adrenal glands (acute or 'adrenal crisis', and chronic or 'Addison's disease'), or secondary resulting from diminished secretion of ACTH, and hypoaldosteronism characterised by deficient secretion of aldosterone.
- Adrenocortical tumours are adenomas and rarely cortical adenocarcinoma.
- Medullary tumours include pheochromocytoma, myelolipoma, ganglioneuroma, and neuroblastoma.

THYROID GLAND

NORMAL STRUCTURE

ANATOMY Embryologically, the thyroid gland arises from a midline invagination at the root of the tongue and grows downwards in front of trachea and thyroid cartilage to reach its normal position. Failure to descent may produce *anomalous lingual thyroid*. The thyroglossal duct that connects the gland to the pharyngeal floor normally disappears by 6th week of embryonic life. In adults, its proximal end is represented by foramen caecum at the base of the tongue and distal end by the pyramidal lobe of the thyroid. Persistence of the remnants of thyroglossal duct in the adults may develop into *thyroglossal cyst* (page 502). The C-cells of the thyroid originate from the neuroectoderm.

The thyroid gland in an adult weighs 15-40 gm and is composed of two lateral lobes connected in the midline by a broad isthmus which may have a pyramidal lobe extending

upwards. Cut section of normal thyroid is yellowish and translucent.

HISTOLOGY The thyroid is composed of lobules of colloid-filled spherical follicles or acini. The lobules are enclosed by fibrovascular septa. The follicles are the main functional units of the thyroid. They are lined by cuboidal epithelium with numerous fine microvilli extending into the follicular colloid that contains the glycoprotein, *thyroglobulin*. The follicles are separated from each other by delicate fibrous tissue that contains blood vessels, lymphatics and nerves. Calcitonin-secreting C-cells or parafollicular cells are dispersed within the follicles and can only be identified by silver stains and immunohistochemical methods.

FUNCTIONS The major function of the thyroid gland is to maintain a high rate of metabolism which is done by means of iodine-containing thyroid hormones, thyroxine (T_4) and tri-iodothyronine (T_3).

The thyroid is one of the most labile organs in the body and responds to numerous stimuli such as puberty, pregnancy, physiologic stress and various pathologic states. This functional lability of the thyroid is responsible for transient hyperplasia of the thyroidal epithelium. Under normal conditions, the epithelial lining of the follicles may show changes in various phases of function as under:

- 1. Resting phase** is characterised by large follicles lined by flattened cells and filled with deeply staining homogeneous colloid e.g. in colloid goitre and iodine-treated hyperthyroidism.
- 2. Secretory phase** in which the follicles are lined by cuboidal epithelium and the colloid is moderately dark pink e.g. in normal thyroid.
- 3. Resorptive phase** is characterised by follicles lined by columnar epithelium and containing lightly stained vacuolated and scalloped colloid e.g. in hyperthyroidism.

The *synthesis and release* of the two main circulating thyroid hormones, T_3 and T_4 are regulated by hypophyseal thyroid-stimulating hormone (TSH) and involves the following steps:

- 1. Iodine trapping** by thyroidal cells involves absorbing of iodine from the blood and concentrating it more than twenty-fold.
- 2. Oxidation** of the iodide takes place within the cells by a thyroid peroxidase.
- 3. Iodination** occurs next, at the microvilli level between the oxidised iodine and the tyrosine residues of thyroglobulin so as to form mono-iodotyrosine (MIT) and di-iodotyrosine (DIT).
- 4. Coupling** of MIT and DIT in the presence of thyroid peroxidase forms tri-iodothyronine (T_3) and thyroxine (T_4).

The thyroid hormones so formed are released by endocytosis of colloid and proteolysis of thyroglobulin within the follicular cells resulting in discharge of T_3 and T_4 into circulation where they are bound to thyroxine-binding globulin.

A number of *thyroid function tests* are currently available. These include the following:

- Determination of serum levels of T_3 , T_4 by radio-immunoassay (RIA).
- TSH and TRH determination.
- Determination of calcitonin secreted by parafollicular C cells.
- Estimation of thyroglobulin secreted by thyroid follicular cells.

v) Assessment of thyroid activity by its ability to uptake radioactive iodine (RAIU).

vi) Assessment whether thyroid lesion is a nonfunctioning ('cold nodule') or hyperactive mass ('hot nodule').

Diseases of the thyroid include: functional disorders (hyperthyroidism and hypothyroidism), thyroiditis, Graves' disease, goitre and tumours. The relative frequency of some of these diseases varies in different geographic regions according to the iodine content of the diet consumed. One of the important investigation tools available in current times is the widespread use of FNAC for thyroid lesions which helps in avoiding a large number of unwanted diagnostic biopsies.

FUNCTIONAL DISORDERS

Two significant functional disorders characterised by distinct clinical syndromes are described. These are: *hyperthyroidism (thyrotoxicosis)* and *hypothyroidism*.

HYPERTHYROIDISM (THYROTOXICOSIS)

Hyperthyroidism, also called thyrotoxicosis, is a hypermetabolic clinical and biochemical state caused by excess production of thyroid hormones. The condition is more frequent in females and is associated with rise in both T_3 and T_4 levels in blood, though the increase in T_3 is generally greater than that of T_4 .

ETIOPATHOGENESIS Hyperthyroidism may be caused by many diseases but three most common causes are: Graves' disease (diffuse toxic goitre), toxic multinodular goitre and a toxic adenoma. Less frequent causes are hypersecretion of pituitary TSH by a pituitary tumour, hypersecretion of TRH, thyroiditis, metastatic tumours of the thyroid, struma ovarii, congenital hyperthyroidism in the newborn of mother with Graves' disease, hCG-secreting tumours due to mild thyrotropic effects of hCG (e.g. hydatidiform mole, choriocarcinoma and testicular tumours), and lastly, by excessive doses of thyroid hormones or iodine called *Jod-Basedow disease*.

CLINICAL FEATURES Patients with hyperthyroidism have a slow and insidious onset, varying in severity from case to case. The usual symptoms are emotional instability, nervousness, palpitation, fatigue, weight loss in spite of good appetite, heat intolerance, perspiration, menstrual disturbances and fine tremors of the outstretched hands. Cardiac manifestations in the form of tachycardia, palpitations and cardiomegaly are invariably present in hyperthyroidism. The skin of these patients is warm, moist and flushed. Weakness of skeletal muscles and osteoporosis are common. Typical eye changes in the form of exophthalmos are a common feature in Graves' disease. Serum levels of T_3 and T_4 are elevated but TSH secretion is usually inhibited.

A sudden spurt in the severity of hyperthyroidism termed '*thyroid storm*' or '*thyroid crisis*' may occur in patients who have undergone subtotal thyroidectomy before adequate control of hyperthyroid state, or in a hyperthyroid patient under acute stress, trauma, and with severe infection. These patients develop high grade fever, tachycardia, cardiac arrhythmias and coma and may die of congestive heart failure or hyperpyrexia.

HYPOTHYROIDISM

Hypothyroidism is a hypometabolic clinical state resulting from inadequate production of thyroid hormones for prolonged periods, or rarely, from resistance of the peripheral tissues to

the effects of thyroid hormones. The clinical manifestations of hypothyroidism, depending upon the age at onset of disorder, are divided into 2 forms:

1. *Cretinism* or *congenital hypothyroidism* is the development of severe hypothyroidism during infancy and childhood.
2. *Myxoedema* is the adulthood hypothyroidism.

Cretinism

A cretin is a child with severe hypothyroidism present at birth or developing within first two years of postnatal life. This is the period when brain development is taking place; in the absence of treatment the child is both physically and mentally retarded. The word '*Cretin*' is derived from the French, meaning *Christ-like* because these children are so mentally retarded that they are incapable of committing sins.

ETIOPATHOGENESIS The causes of congenital hypothyroidism are as follows:

1. *Developmental anomalies* e.g. thyroid agenesis and ectopic thyroid.
2. *Genetic defect* in thyroid hormone synthesis e.g. defect in iodine trapping, oxidation, iodination, coupling and thyroglobulin synthesis.
3. *Foetal exposure* to iodides and antithyroid drugs.
4. *Endemic cretinism* in regions with endemic goitre due to dietary lack of iodine (*sporadic cretinism*, on the other hand, is due to developmental anomalies and genetic defects in thyroid hormone synthesis described above).

CLINICAL FEATURES The clinical manifestations usually become evident within a few weeks to months of birth. The presenting features of a cretin are: slow to thrive, poor feeding, constipation, dry scaly skin, hoarse cry and bradycardia. As the child ages, clinical picture of fully-developed cretinism emerges characterised by impaired skeletal growth and consequent dwarfism, round face, narrow forehead, widely-set eyes, flat and broad nose, big protuberant tongue and protuberant abdomen. Neurological features such as deaf-mutism, spasticity and mental deficiency are more evident in sporadic cretinism due to developmental anomalies and dys-hormonogenetic defects.

Characteristic laboratory findings include a rise in TSH level and fall in T_3 and T_4 levels.

Myxoedema

The adult-onset severe hypothyroidism causes myxoedema. The term myxoedema connotes non-pitting oedema due to accumulation of hydrophilic mucopolysaccharides in the ground substance of dermis and other tissues.

ETIOPATHOGENESIS There are several causes of myxoedema listed below but the first two are the most common causes:

1. Ablation of the thyroid by surgery or radiation.
2. Autoimmune (lymphocytic) thyroiditis (termed primary idiopathic myxoedema).
3. Endemic or sporadic goitre.
4. Hypothalamic-pituitary lesions.
5. Thyroid cancer.
6. Prolonged administration of antithyroid drugs.
7. Mild developmental anomalies and dys-hormonogenesis.

CLINICAL FEATURES The onset of myxoedema is slow and a fully-developed clinical syndrome may appear after several years of hypothyroidism. The striking features are cold intolerance, mental and physical lethargy, constipation, slowing of speech and intellectual function, puffiness of face, loss of hair and altered texture of the skin.

The laboratory diagnosis in myxoedema is made by low serum T_3 and T_4 levels and markedly elevated TSH levels as in the case of cretinism but cases with suprathyroid lesions (hypothalamic-pituitary disease) have low TSH levels.

The clinical appearance of these three major forms of functional disorders of the thyroid gland is shown in **Fig. 25.6**.

THYROIDITIS

Inflammation of the thyroid, thyroiditis, is more often due to non-infectious causes and is classified on the basis of onset and duration of disease into acute, subacute and chronic as under:

I. Acute thyroiditis

1. Bacterial infection e.g. *Staphylococcus*, *Streptococcus*.
2. Fungal infection e.g. *Aspergillus*, *Histoplasma*, *Pneumocystis*.
3. Radiation injury.

II. Subacute thyroiditis

1. Subacute granulomatous thyroiditis (de Quervain's thyroiditis, giant cell thyroiditis, viral thyroiditis)

Figure 25.6 Appearance in functional disorders of the thyroid gland.

2. Subacute lymphocytic (postpartum, silent) thyroiditis
3. Tuberculous thyroiditis.

III. Chronic thyroiditis

1. Autoimmune thyroiditis (Hashimoto's thyroiditis or chronic lymphocytic thyroiditis)
2. Riedel's thyroiditis (or invasive fibrous thyroiditis).

While acute infectious thyroiditis is uncommon, some of the morphologically important forms of thyroiditis from the above list are discussed below.

HASHIMOTO'S (AUTOIMMUNE, CHRONIC LYMPHOCYTIC) THYROIDITIS

Hashimoto's thyroiditis, also called diffuse lymphocytic thyroiditis, struma lymphomatosa or goitrous autoimmune thyroiditis, is characterised by 3 principal features:

1. Diffuse goitrous enlargement of the thyroid.
2. Lymphocytic infiltration of the thyroid gland.
3. Occurrence of thyroid autoantibodies.

Hashimoto's thyroiditis occurs more frequently between the age of 30 and 50 years and shows an approximately ten-fold preponderance among females. Though rare in children, about half the cases of adolescent goitre are owing to autoimmune thyroiditis. Hashimoto's thyroiditis is the most common cause of *goitrous hypothyroidism* in regions where iodine supplies are *adequate*. Regions where iodine intake is more have higher incidence of Hashimoto's thyroiditis e.g. in Japan and the United States.

ETIOPATHOGENESIS Hashimoto's thyroiditis is an autoimmune disease is well established. Hashimoto, a Japanese surgeon, described it in 1912 as the first autoimmune disease of any organ. Autoimmune pathogenesis of Hashimoto's thyroiditis is explained by the following observations:

1. Other autoimmune disease association Like in many autoimmune diseases, Hashimoto's disease has been found in association with other autoimmune diseases such as Graves' disease, SLE, Sjögren's syndrome, rheumatoid arthritis, pernicious anaemia and Type 1 diabetes mellitus.

2. Immune destruction of thyroid cells An association of cytotoxic lymphocyte-associated antigen 4 (*CTLA4*), a T cell regulatory gene, with autoimmune phenomenon in Hashimoto's disease has been reported. There is initial activation of CD4+ T helper cells, which then induce infiltration of CD8+ T cytotoxic cells in the thyroid parenchyma. In the process, B cells are also activated to form autoantibodies, which bring about immune destruction of thyroid parenchyma.

3. Detection of autoantibodies The following autoantibodies against different thyroid cell antigens are detectable in the sera of most patients with Hashimoto's thyroiditis:

- i) Thyroid microsomal autoantibodies (against the microsomes of the follicular cells).
- ii) Thyroglobulin autoantibodies.
- iii) TSH receptor autoantibodies.
- iv) Less constantly found are thyroid autoantibodies against follicular cell membranes, thyroid hormones themselves, and colloid component other than thyroglobulin.

4. Inhibitory TSH-receptor antibodies TSH-receptor antibody seen on the surface of thyroid cells in Hashimoto's thyroiditis is inhibitory to TSH, producing hypothyroidism. Similar antibody is observed in Graves' disease where it causes

hyperthyroidism. It appears that TSH-receptor antibody may act both to depress or stimulate the thyroid cells to produce hypo- or hyperthyroidism respectively. Thus, these patients may have alternate episodes of hypo- or hyperthyroidism.

5. Genetic basis The disease has higher incidence in first-degree relatives of affected patients. Hashimoto's thyroiditis is seen more often with HLA-DR3 and HLA-DR5 subtypes.

MORPHOLOGIC FEATURES Pathologically, two varieties of Hashimoto's thyroiditis are seen: *classic form*, the usual and more common, and *fibrosing variant* found in only 10% cases of Hashimoto's thyroiditis.

Grossly, the *classic form* is characterised by diffuse, symmetric, firm and rubbery enlargement of the thyroid which may weigh 100-300 gm. Sectioned surface of the thyroid is fleshy with accentuation of normal lobulations but with retained normal shape of the gland. The *fibrosing variant* has a firm, enlarged thyroid with compression of the surrounding tissues.

Histologically, the *classic form* shows the following features (Fig. 25.7):

1. There is extensive infiltration of the gland by lymphocytes, plasma cells, immunoblasts and macrophages, with formation of lymphoid follicles having germinal centres.
2. There is decreased number of thyroid follicles which are generally atrophic and are often devoid of colloid.
3. The follicular epithelial cells are transformed into their degenerated state termed Hurthle cells (also called Askanazy cells, or oxyphil cells, or oncocytes). These cells have abundant oxyphilic or eosinophilic and granular cytoplasm due to large number of mitochondria and contain large bizarre nuclei.
4. There is slight fibrous thickening of the septa separating the thyroid lobules.

The less common *fibrosing variant* of Hashimoto's thyroiditis shows considerable fibrous replacement of thyroid parenchyma and a less prominent lymphoid infiltrate.

CLINICAL FEATURES The presenting feature of Hashimoto's thyroiditis is a painless, firm and moderate goitrous enlargement of the thyroid gland, usually associated with hypothyroidism, in a middle-aged woman. At this stage, serum T₃ and T₄ levels are decreased and RAIU is also reduced. A few cases, however, develop hyperthyroidism, termed *hashitoxicosis*, further substantiating the similarities in the autoimmune phenomena between Hashimoto's thyroiditis and Graves' thyrotoxicosis. There is no increased risk of developing thyroid carcinoma in Hashimoto's thyroiditis but there is increased frequency of malignant lymphoma in these cases.

A variant of autoimmune thyroiditis is subacute lymphocytic (or painless or silent or postpartum) thyroiditis seen more often 3-6 months after delivery.

SUBACUTE GRANULOMATOUS (DE QUERVAIN'S) THYROIDITIS

Granulomatous thyroiditis, also called de Quervain's or subacute, or giant cell thyroiditis, is a distinctive form of self-limited inflammation of the thyroid gland. Etiology of the condition is not known but clinical features of a prodromal

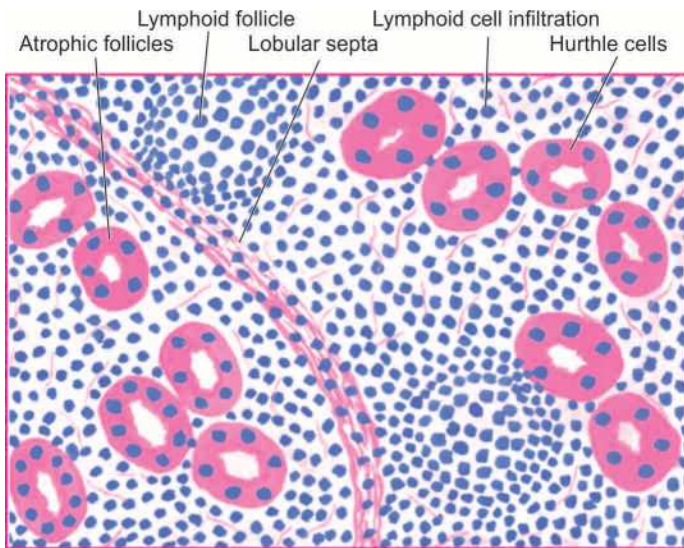

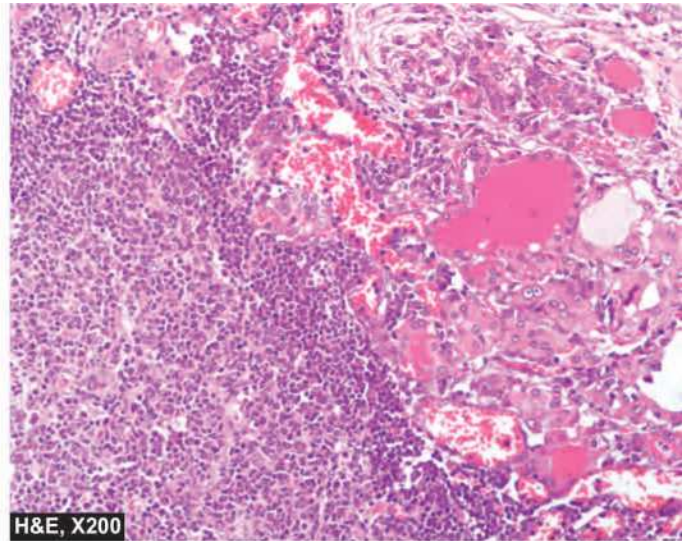

Figure 25.7 Hashimoto's thyroiditis. Histologic features include: lymphoid cell infiltration with formation of lymphoid follicles having germinal centres; small, atrophic and colloid-deficient follicles; presence of Hurthle cells which have granular oxyphil cytoplasm and large irregular nuclei; and slight fibrous thickening of lobular septa.

phase and preceding respiratory infection suggest a possible viral etiology. The disease is more common in young and middle-aged women and may present clinically with painful moderate thyroid enlargement with fever, features of hyperthyroidism in the early phase of the disease, and hypothyroidism if the damage to the thyroid gland is extensive. The condition is self-limiting and shows complete recovery of thyroid function in about 6 months.

MORPHOLOGIC FEATURES *Grossly*, there is moderate enlargement of the gland which is often asymmetric or focal. The cut surface of the involved area is firm and yellowish-white.

Microscopically, the features vary according to the stage of the disease:

- ◆ *Initially*, there is acute inflammatory destruction of the thyroid parenchyma and formation of microabscesses.
- ◆ *Later*, the more characteristic feature of granulomatous appearance is produced. These granulomas consist of central colloid material surrounded by histiocytes and scattered multinucleate giant cells.
- ◆ More *advanced* cases may show fibroblastic proliferation.

Morphologically similar appearance may be produced in cases where vigorous thyroid palpation may initiate mechanical trauma to follicles, so-called *palpation thyroiditis*.

RIEDEL'S THYROIDITIS

Riedel's thyroiditis, also called Riedel's struma or invasive fibrous thyroiditis, is a rare chronic disease characterised by stony-hard thyroid that is densely adherent to the adjacent structures in the neck. The condition is clinically significant due to compressive clinical features (e.g. dysphagia, dyspnoea, recurrent laryngeal nerve paralysis and stridor) and resemblance with thyroid cancer. Riedel's struma is seen more commonly in females in 4th to 7th decades of life. The etiology is unknown but possibly Riedel's thyroiditis is a part of *multifocal idiopathic fibrosclerosis* (page 575). This group of

disorders includes: idiopathic retroperitoneal, mediastinal and retro-orbital fibrosis, and sclerosing cholangitis, all of which may occur simultaneously with Riedel's thyroiditis.

MORPHOLOGIC FEATURES *Grossly*, the thyroid gland is usually contracted, stony-hard, asymmetric and firmly adherent to the adjacent structures. Cut section is hard and devoid of lobulations.

Microscopically, there is extensive fibrocollagenous replacement, marked atrophy of the thyroid parenchyma, focally scattered lymphocytic infiltration and invasion of the adjacent muscle tissue by the process.

GRAVES' DISEASE (DIFFUSE TOXIC GOITRE)

Graves' disease, also known as Basedow's disease, primary hyperplasia, exophthalmic goitre, and diffuse toxic goitre, is characterised by a triad of features:

1. Hyperthyroidism (thyrotoxicosis)
2. Diffuse thyroid enlargement
3. Ophthalmopathy.

The disease is more frequent between the age of 30 and 40 years and has five-fold increased prevalence among females.

ETIOPATHOGENESIS Graves' disease is an autoimmune disease and, as already stated, there are many immunologic similarities between this condition and Hashimoto's thyroiditis. These are as follows:

1. Genetic factor association Like in Hashimoto's thyroiditis. Graves' disease too has genetic predisposition. A familial occurrence has been observed. Susceptibility to develop Graves' disease has been found associated with HLA-DR3 (Hashimoto's thyroiditis has both HLA-DR3 and HLA-DR5 association, page 795), *CTLA-4* and *PTPN22* (a T-cell regulatory gene).

2. Autoimmune disease association Graves' disease may be found in association with other organ-specific autoimmune diseases. Hashimoto's thyroiditis and Graves' disease are frequently present in the same families and the two diseases may coexist in the same patient.

3. Other factors Besides these two factors, Graves' disease has higher prevalence in women (7 to 10 times), and association with emotional stress and smoking.

4. Autoantibodies Autoantibodies against thyroid antigens are detectable in the serum of these patients too but their sites of action are different from that of Hashimoto's thyroiditis. In Graves' disease, TSH-receptor autoantigen is the main antigen against which *autoantibodies* are directed. These are as under:

- i) *Thyroid-stimulating immunoglobulin (TSI)*: It binds to TSH receptor and stimulates increased release of thyroid hormone.
- ii) *Thyroid growth-stimulating immunoglobulins (TGI)*: It stimulates proliferation of follicular epithelium.
- iii) *TSH-binding inhibitor immunoglobulins (TBII)*: It is inhibitory to binding of TSH to its own receptor. Depending upon its action as inhibitory or stimulatory to follicular epithelium, it may result in alternate episodes of hypo- and hyperthyroidism.

However, it is not quite clear what stimulates B cells to form these autoantibodies in Graves' disease. Possibly, intrathyroidal CD4+ helper T cells are responsible for stimulating B cells to secrete autoantibodies.

The pathogenesis of Graves' infiltrative ophthalmopathy is also based on autoimmune origin. The evidence in support is the intense lymphocytic infiltrate around the ocular muscles and detection of circulating autoantibodies against muscle antigen that cross-react with thyroid microsomes.

MORPHOLOGIC FEATURES *Grossly*, the thyroid is moderately, diffusely and symmetrically enlarged and may weigh up to 70-90 gm. On cut section, the thyroid parenchyma is typically homogeneous, red-brown and meaty and lacks the normal translucency.

Histologically, the following features are found (Fig. 25.8):

1. There is considerable epithelial hyperplasia and hypertrophy as seen by increased height of the follicular lining cells and formation of papillary infoldings of piled up epithelium into the lumina of follicles which are small.
2. The colloid is markedly diminished and is lightly staining, watery and finely vacuolated.
3. The stroma shows increased vascularity and accumulation of lymphoid cells.

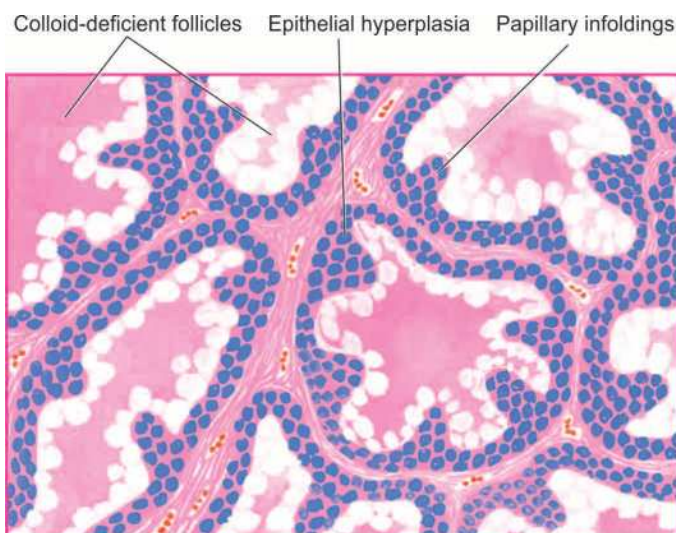

Figure 25.8 Graves' disease. The follicles are small and are lined by tall columnar epithelium, which is piled up at places forming papillary infoldings. Colloid is nearly absent and appears lightly staining, watery and finely vacuolated.

However, the pathologic changes in gross specimen as well as on histologic examination are considerably altered if preoperative medication has been administered. Iodine administration results in accumulation of colloid in the follicles and decrease in vascularity and height of follicular cells, while antithyroid drugs such as thiouracil cause marked hyperplasia.

CLINICAL FEATURES Graves' disease generally develops slowly and insidiously.

◆ Patients are usually young women who present with symmetric, moderate *enlargement of the thyroid gland* with features of thyrotoxicosis (page 793), ophthalmopathy and dermatopathy.

◆ *Ocular abnormalities* are lid lag, upper lid retraction, stare, weakness of eye muscles and proptosis. In extreme cases, the lids can no longer close and may produce corneal injuries and ulcerations.

◆ *Dermatopathy* in Graves' disease most often consists of pretibial (localised) myxoedema in the form of firm plaques.

Like in Hashimoto's thyroiditis, there is no increased risk of development of thyroid cancer in Graves' disease.

GOITRE

The term goitre is defined as thyroid enlargement caused by compensatory hyperplasia and hypertrophy of the follicular epithelium in response to thyroid hormone deficiency. The end-result of this hyperplasia is generally a *euthyroid state* (in contrast to thyrotoxicosis occurring in diffuse toxic goitre or Graves' disease) though at some stages there may be hypo- or hyperthyroidism. Two morphologic forms of goitre are distinguished:

- A. Diffuse goitre (simple nontoxic goitre or colloid goitre).
- B. Nodular goitre (multinodular goitre or adenomatous goitre).

PATHOGENESIS OF GOITRE

The pathogenetic mechanisms of both forms of goitre can be considered together since nodular goitre is generally regarded as the end-stage of long-standing simple goitre (Fig. 25.9). The fundamental defect is deficient production of thyroid hormones due to various etiologic factors described below, but most common is *dietary lack of iodine*. Deficient thyroid hormone production causes excessive TSH stimulation which leads to hyperplasia of follicular epithelium as well as formation of new thyroid follicles. Cyclical hyperplastic stage followed by involution stage completes the picture of *simple goitre*. Repeated and prolonged changes of hyperplasia result in continued growth of thyroid tissue while involuted areas undergo fibrosis, thus completing the picture of *nodular goitre*.

DIFFUSE GOITRE (SIMPLE NON-TOXIC GOITRE, COLLOID GOITRE)

Diffuse, nontoxic simple or colloid goitre is the name given to diffuse enlargement of the thyroid gland, unaccompanied by hyperthyroidism. Most cases are in a state of euthyroid though they may have passed through preceding stage of hypothyroidism due to inadequate supply of iodine. TSH levels are invariably elevated. In general, goitre is more common in females. Simple goitre often appears at puberty or in adolescence, following which it may either regress or may progress to nodular goitre.

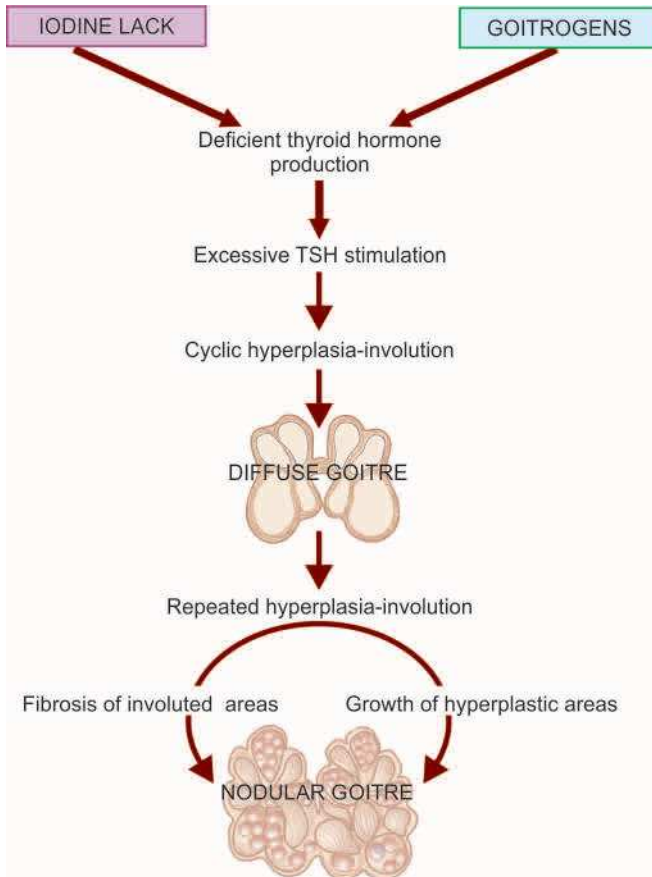

Figure 25.9 Pathogenesis of simple and nodular goitre.

ETIOLOGY Epidemiologically, goitre occurs in 2 forms: endemic, and non-endemic or sporadic.

Endemic goitre Prevalence of goitre in a geographic area in more than 10% of the population is termed endemic goitre. Such endemic areas are several high mountainous regions far from the sea where iodine content of drinking water and food is low such as in the regions of the Himalayas, the Alps and the Andes. Of late, however, the prevalence in these areas has declined due to prophylactic use of iodised salt.

Though most endemic goitres are caused by dietary lack of iodine, some cases occur due to goitrogens and genetic factors.

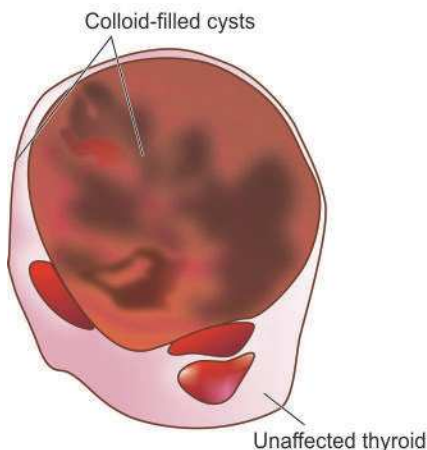

Figure 25.10 Simple (diffuse nontoxic or colloid) goitre. The thyroid gland is enlarged diffusely. Cut section shows lobules of translucent gelatinous light brown parenchyma and areas of haemorrhage.

Goitrogens are substances which interfere with the synthesis of thyroid hormones. These substances are drugs used in the treatment of hyperthyroidism and certain items of food such as cabbage, cauliflower, turnips and cassava roots.

Sporadic (non-endemic) goitre Non-endemic or sporadic simple goitre is less common than the endemic variety. In most cases, the etiology of sporadic goitre is unknown. A number of causal influences have been attributed. These include the following:

- i) Suboptimal iodine intake in conditions of increased demand as in puberty and pregnancy.
- ii) Genetic factors.
- iii) Dietary goitrogens.
- iv) Hereditary defect in thyroid hormone synthesis and transport (dyshormonogenesis).
- v) Inborn errors of iodine metabolism.

MORPHOLOGIC FEATURES *Grossly*, the enlargement of the thyroid gland in simple goitre is moderate (weighing up to 100-150 gm), symmetric and diffuse. Cut surface is gelatinous and translucent brown (**Fig. 25.10**).

Histologically, two stages are distinguished:

1. *Hyperplastic stage* is the early stage and is characterised by tall columnar follicular epithelium showing papillary infoldings and formation of small new follicles.
2. *Involution stage* generally follows hyperplastic stage after variable period of time. This stage is characterised by large follicles distended by colloid and lined by flattened follicular epithelium (**Fig. 25.11**).

NODULAR GOITRE (MULTINODULAR GOITRE, ADENOMATOUS GOITRE)

As already stated, nodular goitre is regarded as the end-stage of long-standing simple goitre. It is characterised by most extreme degree of tumour-like enlargement of the thyroid gland and characteristic nodularity. The enlargement of the gland may be sufficient to not only cause cosmetic disfigurement, but in many cases may cause dysphagia and choking due to compression of oesophagus and trachea. Most cases are in a euthyroid state but about 10% cases may develop thyrotoxicosis resulting in toxic nodular goitre or Plummer's disease. However, thyrotoxicosis of *Plummer's disease* (toxic nodular goitre) differs from that

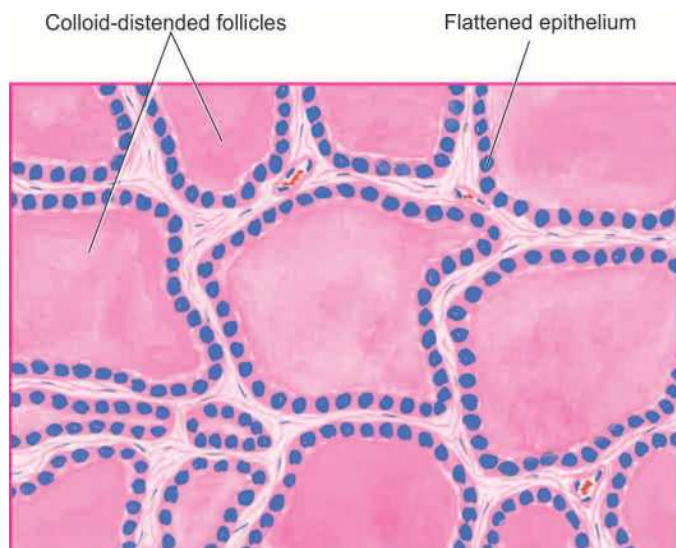

Figure 25.11 Simple goitre. Microscopy shows large follicles distended by colloid and lined by flattened follicular epithelium.

of Graves' disease (diffuse toxic goitre) in lacking features of ophthalmopathy and dermatopathy. Such 'hot nodules' may be picked up by CT scan or by RAIU studies. Since nodular goitre is derived from simple goitre, it has the same female preponderance but affects older individuals because it is a late complication of simple goitre.

ETIOLOGY Etiologic factors implicated in endemic and non-endemic or sporadic variety of simple goitre are involved in the etiology of nodular goitre too. However, how nodular pattern is produced is not clearly understood. Possibly, epithelial hyperplasia, generation of new follicles, and irregular accumulation of colloid in the follicles—all contribute to produce increased tension and stress in the thyroid gland causing rupture of follicles and vessels. This is followed by haemorrhages, cystic change, scarring and sometimes calcification, resulting in development of nodular pattern.

MORPHOLOGIC FEATURES *Grossly*, the thyroid in nodular goitre shows asymmetric and extreme enlargement, weighing 100-500 gm or even more. The *five* cardinal macroscopic features are as under (**Fig. 25.12**):

1. Nodularity with poor encapsulation
2. Fibrous scarring
3. Haemorrhages
4. Focal calcification
5. Cystic degeneration.

Cut surface generally shows multinodularity but occasionally there may be only one or two nodules which are poorly-circumscribed (unlike complete encapsulation of thyroid adenoma, described below).

Histologically, the same heterogeneity as seen on gross appearance is seen. Corresponding microscopic features are as follows (**Fig. 25.13**):

1. Partial or incomplete encapsulation of nodules.
2. The follicles varying from small to large and lined by flat to high epithelium. A few may show macropapillary formation.
3. Areas of haemorrhages, haemosiderin-laden macrophages and cholesterol crystals.
4. Fibrous scarring with foci of calcification.
5. Micro-macrocytic change.

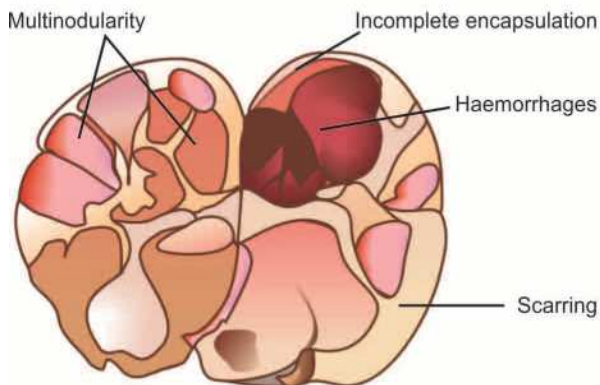

Figure 25.12 Nodular goitre. The thyroid gland is enlarged and nodular. Cut surface shows multiple nodules separated from each other by incomplete fibrous septa. Areas of haemorrhage and cystic change are also seen.

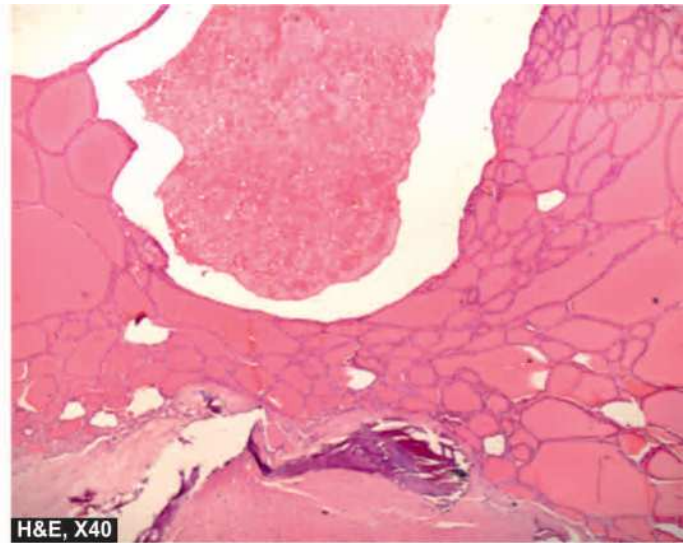

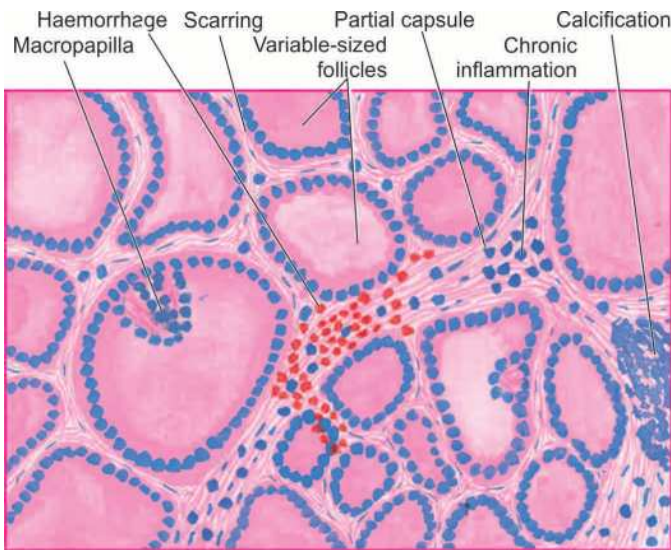

Figure 25.13 Nodular goitre. The predominant histologic features are: nodularity, extensive scarring with foci of calcification, areas of haemorrhages and variable-sized follicles lined by flat to high epithelium and containing abundant colloid.

The contrasting features of diffuse and nodular goitre are summarised in [Table 25.2](#).

THYROID TUMOURS

Most primary tumours of the thyroid are of follicular epithelial origin; a few arise from parafollicular C-cells. The most common benign thyroid neoplasm is a follicular adenoma. Malignant tumours of the thyroid are less common but thyroid carcinoma is the most common type, though rarely lymphomas and sarcomas also occur.

FOLLICULAR ADENOMA

Follicular adenoma is the most common benign thyroid tumour occurring more frequently in adult women. Clinically, it appears as a solitary nodule which can be found in approximately 1% of the population. Besides the follicular adenoma, other conditions which may produce clinically apparent solitary nodule in the thyroid are a dominant nodule of nodular goitre and thyroid carcinoma. It is thus important to distinguish adenomas from these two conditions. Though most adenomas cause no clinical problem and behave as a 'cold nodule', rarely they may produce mild hyperthyroidism and appear as 'hot nodule' on RAIU studies. Adenoma, however, rarely ever becomes malignant.

MORPHOLOGIC FEATURES *Grossly*, the follicular adenoma is characterised by *four* features so as to distinguish it from a nodule of nodular goitre ([Fig. 25.14](#)):

1. solitary nodule;
2. complete encapsulation;
3. clearly distinct architecture inside and outside the capsule; and
4. compression of the thyroid parenchyma outside the capsule.

Usually, an adenoma is small (up to 3 cm in diameter) and spherical. On cut section, the adenoma is grey-white to red-brown, less colloidal than the surrounding thyroid parenchyma and may have degenerative changes such as fibrous scarring, focal calcification, haemorrhages and cyst formation.

Histologically, the tumour shows complete fibrous encapsulation. The tumour cells are benign follicular epithelial cells lining follicles of various sizes. These cells may also form trabecular, solid and cord patterns with little follicle formation. Accordingly, the following 6 types of growth patterns are distinguished, though more than one pattern may be present in a single tumour:

1. *Microfollicular (foetal) adenoma* consists of small follicles containing little or no colloid and separated by abundant loose stroma ([Fig. 25.15](#)).

Table 25.2 Contrasting features of simple and nodular goitre.

| FEATURE | DIFFUSE GOITRE | NODULAR GOITRE |
|-----------------------------|---|---|
| 1. <i>Nomenclature</i> | Simple goitre, hyperplastic goitre, nontoxic goitre | Multinodular, adenomatous goitre |
| 2. <i>Etiology</i> | Graves' disease, thyroiditis, puberty | Endemic thyroiditis, cancer |
| 3. <i>Pathogenesis</i> | Hyperplasia-involution | Repeated cycles of hyperplasia with growth and involution with fibrosis |
| 4. <i>Composition</i> | Cellular-rich | Colloid-rich |
| 5. <i>Gross</i> | Moderate, symmetric, diffuse enlargement, colloid-filled follicles, gelatinous | Nodular asymmetric, haemorrhages, scarring, cystic change, calcification |
| 6. <i>Microscopy</i> | Hyperplastic phase: papillary infoldings, Involution stage: large colloid filled follicles with flat epithelium | Incomplete encapsulation, nodularity, variable-sized follicles, fibrous scarring, haemorrhages, calcification, cyst formation |
| 7. <i>Functional status</i> | Hyperthyroidism, euthyroid | Hypothyroidism, euthyroid |

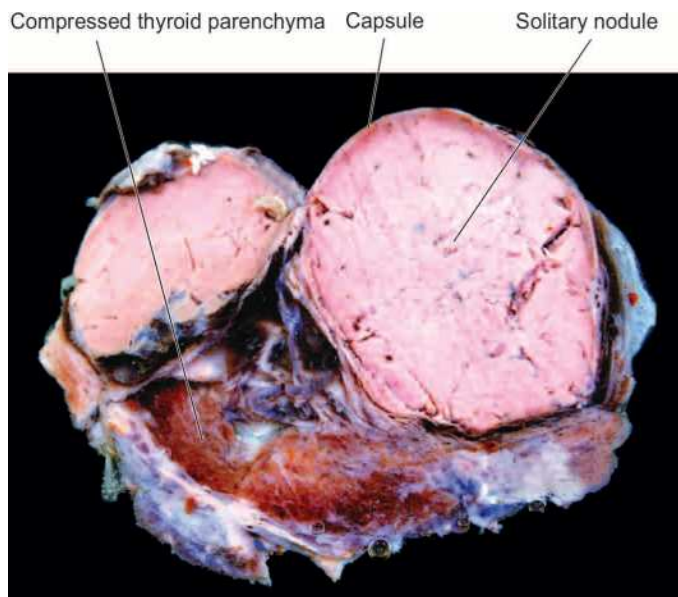

Figure 25.14 Follicular adenoma thyroid. Sectioned surface of the thyroid shows a solitary nodule having capsule. The nodule is grey-white and is distinct from the adjoining thyroid parenchyma.

2. *Normofollicular (simple) adenoma* has closely packed follicles like that of normal thyroid gland.
3. *Macrofollicular (colloid) adenoma* contains large follicles of varying size and distended with colloid.
4. *Trabecular (embryonal) adenoma* resembles embryonal thyroid and consists of closely packed solid or trabecular pattern of epithelial cells with an occasional small abortive follicle.
5. *Hurthle cell (oxyphilic) adenoma* is an uncommon variant composed of solid trabeculae of large cells having abundant granular oxyphilic cytoplasm and vesicular nuclei. The tumour cells do not form follicles and contain little stroma.
6. *Atypical adenoma* is the term used for a follicular adenoma which has more pronounced cellular proliferation so that features may be considered indicative of malignancy such as pleomorphism, increased mitoses and nuclear

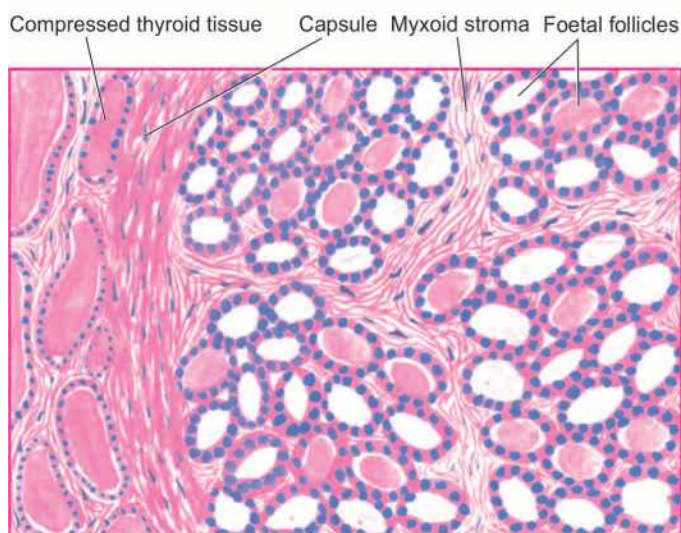

Figure 25.15 Follicular adenoma, foetal (microfollicular) type. The tumour is well-encapsulated with compression of surrounding thyroid parenchyma. The tumour consists of small follicles lined by cuboidal epithelium and contain little or no colloid and separated by abundant loose stroma.

atypia. These tumours, however, do not show capsular and vascular invasion—features which distinguish it from follicular carcinoma.

THYROID CANCER

Approximately 95% of all primary thyroid cancers are carcinomas. Primary lymphomas of the thyroid comprise less than 5% of thyroid cancers and majority of them possibly evolve from autoimmune (lymphocytic) thyroiditis (page 795). Sarcomas of the thyroid are extremely rare. About 20% of patients dying of metastasising malignancy have metastatic deposits in the thyroid gland, most commonly from malignant melanoma, renal cell carcinoma and bronchogenic carcinoma.

In line with most other thyroid lesions, most carcinomas of the thyroid too have female preponderance and are twice more common in women.

Carcinoma of the thyroid gland has 4 major morphologic types with distinctly different clinical behaviour and variable prevalence. These are: papillary, follicular, medullary and undifferentiated (anaplastic) carcinoma; their contrasting features are summed up in **Table 25.3**.

ETIOPATHOGENESIS Most important environmental factor implicated in the etiology of thyroid cancer is external radiation, and to some extent, there is role of TSH receptors and iodine excess. Pathogenesis of thyroid cancer is explained on combination of these environmental etiologic factors and distinct genetic alterations in different microscopic types.

1. External radiation The single most important environmental factor associated with increased risk of developing thyroid carcinoma after many years of exposure to external radiation of high dose. Evidences in support include: high incidence of thyroid cancer in individuals irradiated in early age for enlarged thymus and for skin disorders, in Japanese atomic bomb survivors, and in individuals living in the vicinity of nuclear accident sites. In particular, exposure to radiation to children and young adults has been found to be associated with higher incidence of development of papillary carcinoma later.

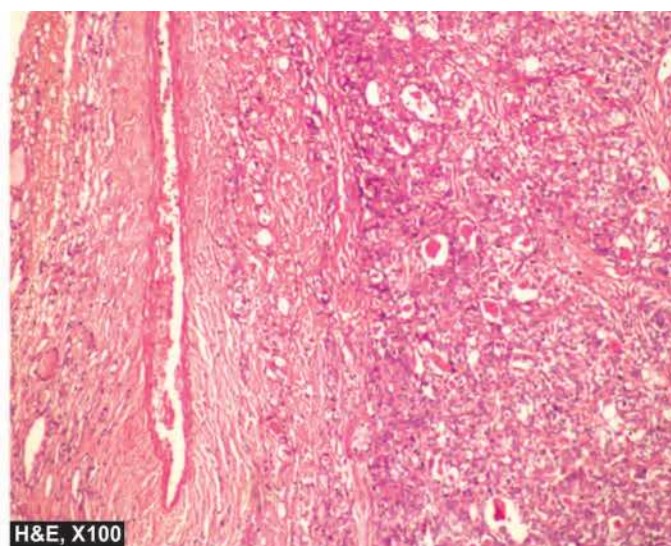

Table 25.3 Contrasting features of main histologic types of thyroid carcinoma.

| FEATURE | PAPILLARY CARCINOMA | FOLLICULAR CARCINOMA | MEDULLARY CARCINOMA | ANAPLASTIC CARCINOMA |
|-----------------------------|---|--|---------------------------------|---|
| 1. Frequency | 75-80% | 10-20% | 5% | 5% |
| 2. Age | All ages | Middle to old age | Middle to old age; familial too | Old age |
| 3. Female/male ratio | 3:1 | 2.5:1 | 1:1 | 1.5:1 |
| 4. Relation to radiation | Maximum | Present | None | Present |
| 5. Genetic alterations | <i>RET</i> gene over-expression, <i>NTRK</i> gene rearrangement | <i>RAS</i> mutation, <i>PAX-PPAR γ1</i> fusion | <i>RET</i> point mutation | <i>p53</i> loss, β -catenin mutation |
| 6. Cell of origin | Follicular | Follicular | Parafollicular | Follicular |
| 7. Gross | Small, multifocal | Moderate size, nodular | Moderate size | Invasive growth |
| 8. Pathognomonic microscopy | Nuclear features, papillary pattern | Vascular and capsular invasion | Solid nests, amyloid stroma | Undifferentiated, spindle-shaped, giant cells |
| 9. Regional metastases | Common | Rare | Common | Common |
| 10. Distant metastases | Rare | Common | Rare | Common |
| 11. 10-year survival | 80-95% | 50-70% | 60-70% | 5-10% (median survival about 2 months) |

2. Iodine excess and TSH In regions where endemic goitre is widespread, addition of iodine to diet has resulted in increase in incidence of papillary cancer. Many well-differentiated thyroid cancers express TSH receptors and thus respond to T₄ suppression of TSH.

3. Genetic basis Familial clustering of thyroid cancer has been observed, especially in medullary carcinoma. Molecular studies reveal that thyroid carcinoma is a multistep process involving genetic alterations but distinct mutations are seen in different histologic types:

i) *Papillary thyroid carcinoma*: Mutation in *RET* gene (gene overexpression) located on chromosome 10q is seen in about 20% cases of papillary thyroid carcinoma. This mutation renders the tyrosine kinase receptor under the target of other tumour-promoting factors such as radiation exposure in papillary carcinoma. Another genetic abnormality seen in 5-10% cases of papillary thyroid carcinoma is gene rearrangement in *NTRK1* (neurotrophic tyrosine kinase receptor 1 located on chromosome 1q) gene.

ii) *Follicular thyroid carcinoma*: About 50% cases of follicular thyroid carcinoma have mutation in *RAS* family of oncogenes that includes *HRAS*, *NRAS* and *KRAS*. Besides, fusion-translocation between 2 genes—*PAX-8* (paired domain transcription factor) and *PPAR γ -1* (gene coding for peroxisome proliferator-activator receptor γ -1), has also been described in a proportion of cases of follicular thyroid neoplasms, both adenoma and carcinoma.

iii) *Medullary thyroid carcinoma*: Medullary thyroid carcinoma arises from parafollicular C-cells in the thyroid. Point mutation in *RET*-protooncogene is seen in both familial (MEN2) as well as sporadic cases of medullary thyroid carcinoma.

iv) *Anaplastic thyroid carcinoma*: This tumour either arises from further dedifferentiation of differentiated papillary or follicular thyroid carcinoma, or by inactivating point mutation in *p53* tumour suppressor gene or by mutation in gene coding for β -catenin pathway.

Papillary Thyroid Carcinoma

Papillary carcinoma is the most common type of thyroid carcinoma, comprising 75-85% of cases. It can occur at all ages including children and young adults but the incidence is higher with advancing age. The tumour is found about three times more frequently in females than in males.

Papillary carcinoma is typically a slow-growing malignant tumour, most often presenting as an asymptomatic solitary nodule. Involvement of the regional lymph nodes is common but distant metastases to organs are rare. Some cases first come to attention by spread to regional lymph nodes and cause cervical lymphadenopathy. '*Lateral aberrant thyroid*' is the term used for occurrence of thyroid tissue in the lateral cervical lymph node, which in most patients represents a well-differentiated metastasis of an occult papillary carcinoma of the thyroid.

MORPHOLOGIC FEATURES *Grossly*, papillary carcinoma may range from microscopic foci to nodules upto 10 cm in diameter and is generally poorly delineated. Cut surface of the tumour is greyish-white, hard and scar-like (Fig. 25.16). Sometimes the tumour is transformed into a cyst, into which numerous papillae project and is termed *papillary cystadenocarcinoma*.

Histologically, the following features are present (Fig. 25.17):

1. Papillary pattern Papillae composed of fibrovascular stalk and covered by single layer of tumour cells is the predominant feature. Papillae are often accompanied by follicles.

2. Tumour cells The tumour cells have characteristic nuclear features due to dispersed nuclear chromatin imparting it *ground glass or optically clear appearance* and clear or oxyphilic cytoplasm. These tumour cells, besides covering the papillae, may form follicles and solid sheets.

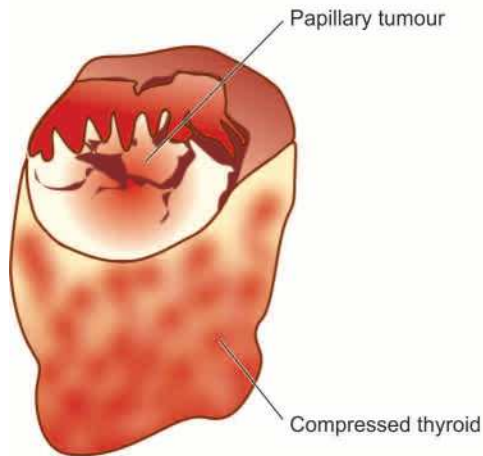

Figure 25.16 Papillary carcinoma of the thyroid. Cut surface of the enlarged thyroid gland shows a single nodule separated from the rest of thyroid parenchyma by incomplete fibrous septa (arrow). The nodule is grey-white soft and shows grossly visible papillary pattern.

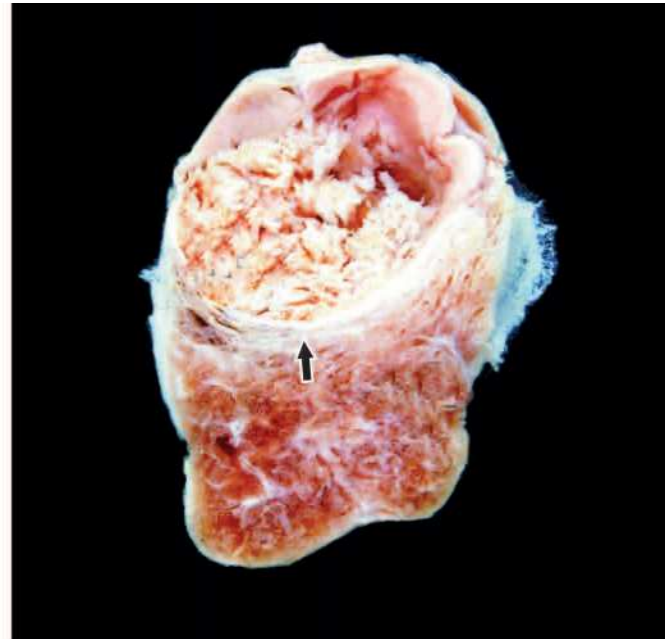

3. Invasion The tumour cells invade the capsule and intrathyroid lymphatics but invasion of blood vessels is rare.

4. Psammoma bodies Half of papillary carcinomas show typical small, concentric, calcified spherules called psammoma bodies in the stroma.

The prognosis of papillary carcinoma is good: 10-year survival rate is 80-95%, irrespective of whether the tumour is pure papillary or mixed papillary-follicular carcinoma.

Follicular Thyroid Carcinoma

Follicular carcinoma is the other common type of thyroid cancer, next only to papillary carcinoma and comprises about 10-20% of all thyroid carcinomas. It is more common in middle and old age and has preponderance in females (female-male ratio 2.5:1). In contrast to papillary carcinoma, follicular carcinoma has a positive correlation with endemic goitre but the role of external radiation in its etiology is unclear.

Follicular carcinoma presents clinically either as a solitary nodule or as an irregular, firm and nodular thyroid enlargement. The tumour is slow-growing but more rapid than the papillary carcinoma. In contrast to papillary carcinoma, regional lymph node metastases are rare but distant metastases by haematogenous route are common, especially to the lungs and bones, and sometimes this may be the presenting feature.

MORPHOLOGIC FEATURES *Grossly*, follicular carcinoma may be either in the form of a solitary adenoma-like circumscribed nodule or as an obvious cancerous irregular thyroid enlargement. The cut surface of the tumour is grey-white with areas of haemorrhages, necrosis and cyst formation and may extend to involve adjacent structures.

Microscopically, the features are as under (**Fig. 25.18**):

1. Follicular pattern Follicular carcinoma, like follicular adenoma, is composed of follicles of various sizes and may show trabecular or solid pattern. The tumour cells have hyperchromatic nuclei and the cytoplasm resembles that

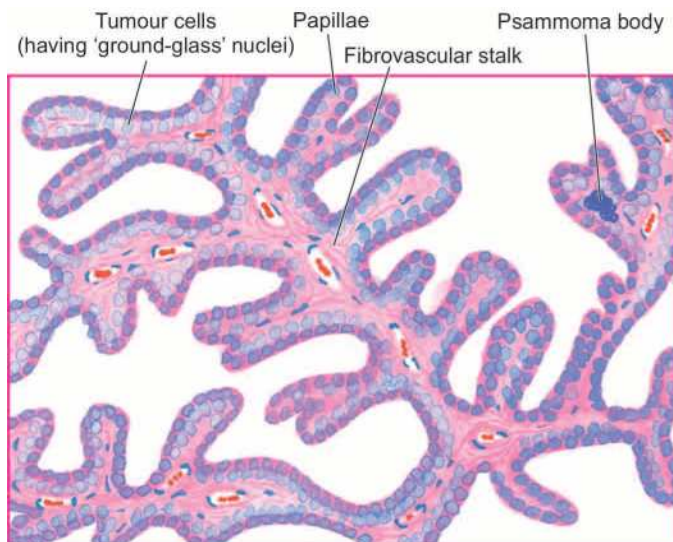

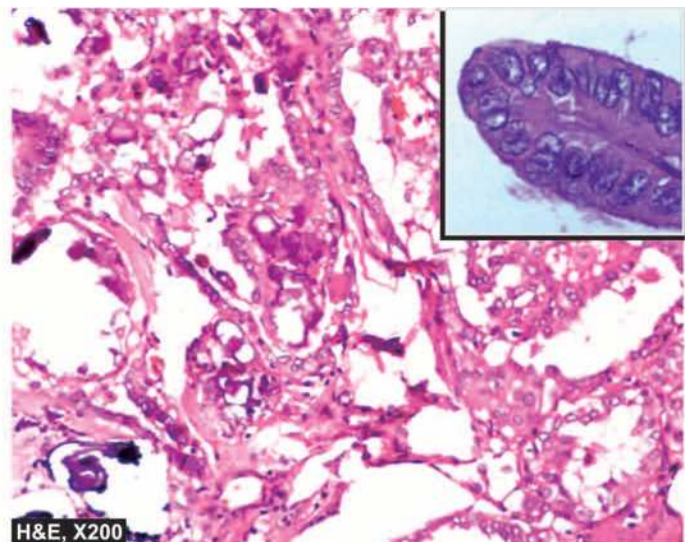

Figure 25.17 Papillary carcinoma thyroid. Microscopy shows branching papillae having fibrovascular stalk covered by a single layer of cuboidal cells having ground-glass nuclei (inbox). Colloid-filled follicles and solid sheets of tumour cells are also present.

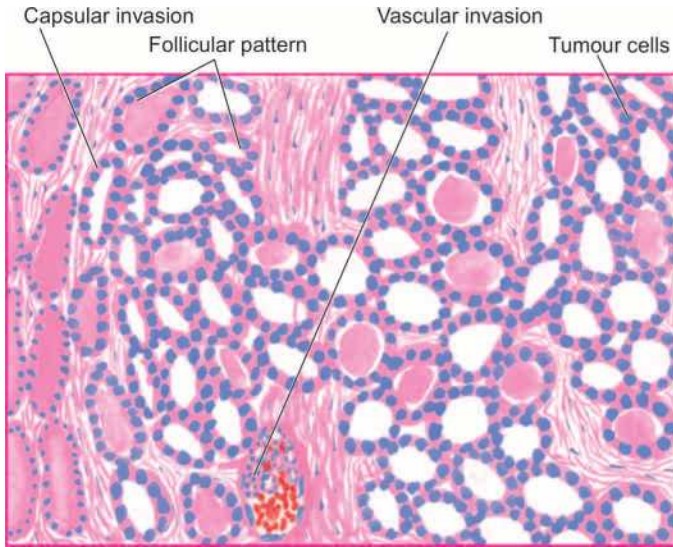

Figure 25.18 Follicular carcinoma, showing encapsulated tumour with invasion of a capsular vessel. The follicles lined by tumour cells are of various sizes and there is mild pleomorphism.

of normal follicular cells. However, variants like *clear cell type* and *Hurthle cell (oxyphilic) type* of follicular carcinoma may occur. The tumour differs from papillary carcinoma in lacking: papillae, ground-glass nuclei of tumour cells and psammoma bodies.

2. Vascular invasion and direct extension Vascular invasion and direct extension to involve the adjacent structures (e.g. into the capsule) are significant features but lymphatic invasion is rare.

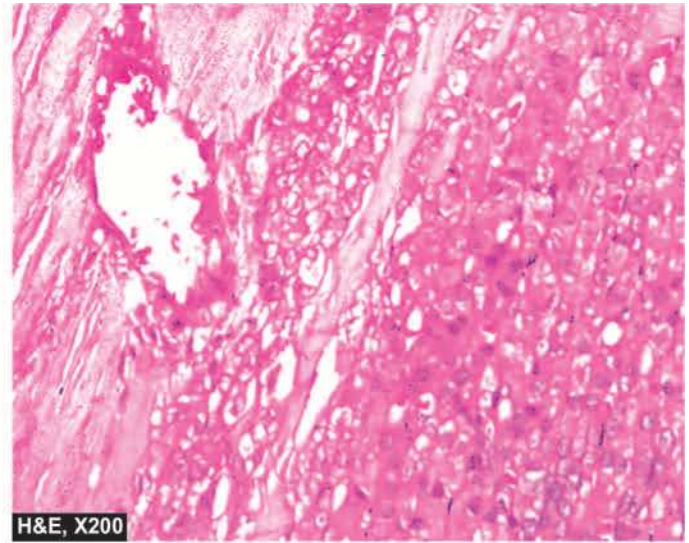

The prognosis of follicular carcinoma is between that of papillary and undifferentiated carcinoma: 10-year survival rate is 50-70%.

Medullary Thyroid Carcinoma

Medullary carcinoma is a less frequent type derived from parafollicular or C-cells present in the thyroid and comprises about 5% of thyroid carcinomas. It is equally common in men and women. There are 3 distinctive features which distinguish medullary carcinoma from the other thyroid carcinomas. These are: its familial occurrence, secretion of calcitonin and other peptides, and amyloid stroma.

1. Familial occurrence Most cases of medullary carcinoma occur sporadically, but about 10% have a genetic background with point mutation in *RET*-protooncogene located on chromosome 10q. The familial form of medullary carcinoma has association with pheochromocytoma and parathyroid adenoma (multiple endocrine neoplasia, MEN II A), or with pheochromocytoma and multiple mucosal neuromas (MEN II B). The sporadic cases occur in the middle and old age (5th-6th decades) and are generally unilateral, while the familial cases are found at younger age (2nd-3rd decades) and are usually bilateral and multicentric.

2. Secretion of calcitonin and other peptides Like normal C-cells, tumour cells of medullary carcinoma secrete calcitonin, the hypocalcaemic hormone. In addition, the tumour may also elaborate prostaglandins, histaminase,

somatostatin, vasoactive intestinal peptide (VIP) and ACTH. These hormone elaborations are responsible for a number of clinical syndromes such as carcinoid syndrome, Cushing's syndrome and diarrhoea.

3. Amyloid stroma Most medullary carcinomas have amyloid deposits in the stroma which stains positively with usual amyloid stains such as Congo red. The amyloid deposits are believed to represent stored calcitonin derived from neoplastic C-cells in the form of prohormone.

Most cases of medullary carcinoma present as solitary thyroid nodule but sometimes an enlarged cervical lymph node may be the first manifestation.

MORPHOLOGIC FEATURES *Grossly*, the tumour may either appear as a unilateral solitary nodule (*sporadic form*), or have bilateral and multicentric involvement (*familial form*). However, sporadic neoplasms also eventually spread to the contralateral lobe. Cut surface of tumour in both forms shows well-defined tumour areas which are firm to hard, grey-white to yellow-brown with areas of haemorrhages and necrosis.

Histologically, the features are as under (**Fig. 25.19**):

1. Tumour cells Like other neuroendocrine tumours (e.g. carcinoid, islet cell tumour, paraganglioma etc.), medullary carcinoma of the thyroid too has a well-defined organoid pattern, forming nests of tumour cells separated by fibrovascular septa. Sometimes, the tumour cells may be arranged in sheets, ribbons pseudopapillae or small follicles. The tumour cells are uniform and have the structural and functional characteristics of C-cells. Less often, the neoplastic cells are spindle-shaped.

2. Amyloid stroma The tumour cells are separated by amyloid stroma derived from altered calcitonin which can be demonstrated by immunostain for calcitonin. The staining properties of amyloid are similar to that seen in systemic amyloidosis and may have areas of irregular calcification but without regular laminations seen in psammoma bodies.

3. C-cell hyperplasia Familial cases generally have C-cell hyperplasia as a precursor lesion but not in sporadic cases.

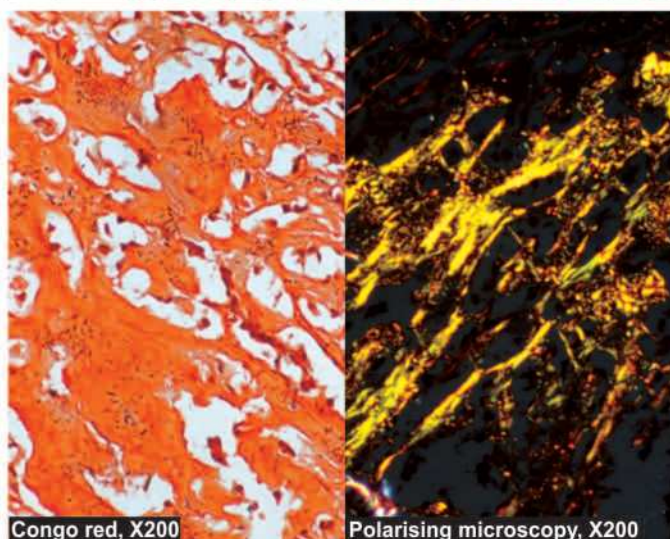

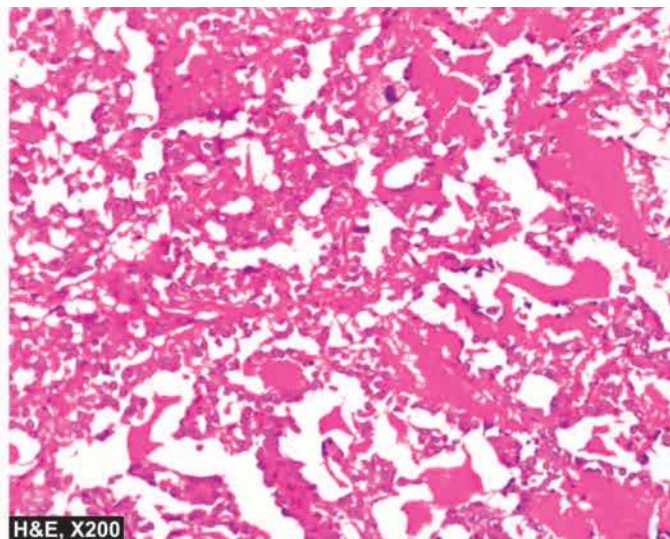

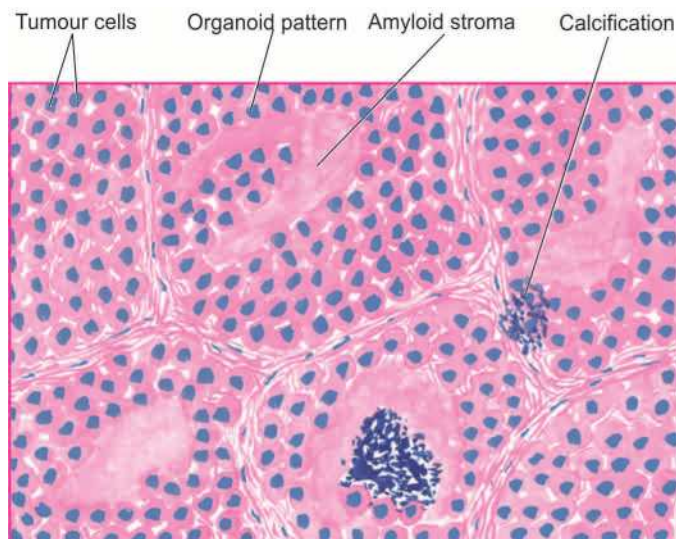

Figure 25.19 Medullary carcinoma thyroid. Microscopy shows organoid pattern of oval tumour cells and abundant amyloid stroma. Amyloid shows congophilia which depicts apple-green birefringence under polarising microscopy.

Most medullary carcinomas are slow-growing. Regional lymph node metastases may occur but distant organ metastases are infrequent. The prognosis is better in familial form than in the sporadic form: overall 10-year survival rate is 60-70%.

Anaplastic Carcinoma

Undifferentiated or anaplastic carcinoma of the thyroid comprises less than 5% of all thyroid cancers and is one of the most malignant tumour in humans. The tumour is predominantly found in old age (7th-8th decades) and is slightly more common in females than in males (female-male ratio 1.5:1). The tumour is widely aggressive and rapidly growing. The features at presentation are usually those of extensive invasion of adjacent soft tissue, trachea and oesophagus. These features include: dyspnoea, dysphagia and hoarseness, in association with rapidly-growing tumour in the neck. The tumour metastasises both to regional lymph nodes and to distant organs such as the lungs.

MORPHOLOGIC FEATURES *Grossly*, the tumour is generally large and irregular, often invading the adjacent strap muscles of the neck and other structures in the vicinity of the thyroid. Cut surface of the tumour is white and firm with areas of necrosis and haemorrhages.

Histologically, the tumour is too poorly-differentiated to be placed in any other histologic type of thyroid cancer, but usually shows a component of either papillary or follicular carcinoma in better differentiated areas. The tumour is generally composed of 3 types of cells occurring in varying proportions: small cells, spindle cells and giant cells. When one of these cell types is predominant, the histologic variant of undifferentiated carcinoma is named accordingly. Thus, there are 3 histologic variants:

- 1. Small cell carcinoma** This type of tumour is composed of closely packed small cells having hyperchromatic nuclei and numerous mitoses. This variant closely resembles malignant lymphoma.
- 2. Spindle cell carcinoma** These tumours are composed of spindle cells resembling sarcoma. Some tumours may contain obvious sarcomatous component such as areas of osteosarcoma, chondrosarcoma or rhabdomyosarcoma.
- 3. Giant cell carcinoma** This type is composed of highly anaplastic giant cells showing numerous atypical mitoses, bizarre and lobed nuclei and some assuming spindle shapes.

The prognosis is poor: 5-year survival rate is less than 10% and median survival after the diagnosis is about 2 months.

- ▣ Hyperthyroidism or thyrotoxicosis is a hypermetabolic clinical and biochemical state caused by excess production of thyroid hormones.
- ▣ Hypothyroidism is a hypometabolic state resulting from inadequate production of thyroid hormones for prolonged periods and has 2 forms. Cretinism or congenital hypothyroidism is the development of severe hypothyroidism during infancy and childhood, and myxoedema is the adulthood hypothyroidism.
- ▣ Thyroiditis may be due to infections but is more often non-infectious. It includes acute (bacterial or fungal infection and radiation injury), subacute (granulomatous thyroiditis) and chronic (e.g. autoimmune thyroiditis or Hashimoto's thyroiditis, Riedel's thyroiditis).
- ▣ Graves' disease is a combination of diffuse thyroid enlargement with hyperthyroidism and ophthalmopathy. It has autoimmune pathogenesis.
- ▣ Goitre is enlargement of thyroid due to compensatory hyperplasia in response to thyroid hormone deficiency. It may be diffuse or nodular.
- ▣ The most common benign thyroid neoplasm is a follicular adenoma.
- ▣ Carcinoma of the thyroid gland has 4 major morphologic types with distinctly different clinical behaviour and variable prevalence: papillary (most frequent, best prognosis), follicular, medullary and undifferentiated (anaplastic) carcinoma (less common, most malignant).

PARATHYROID GLANDS

NORMAL STRUCTURE

ANATOMY The parathyroid glands are usually 4 in number: the *superior pair* derived from the 4th branchial pouch and *inferior pair* from the 3rd branchial pouch of primitive foregut. Both pairs are usually embedded in the posterior aspect of the thyroid substance but separated from it by a connective tissue capsule. In the adults, each gland is an oval, yellowish-brown, flattened body, weighing 35-45 mg. There may, however, be variation in the number, location and size of parathyroid glands.

HISTOLOGY AND FUNCTIONS *Microscopically*, parathyroid glands are composed of solid sheets and cords of parenchymal cells and variable amount of stromal fat. The parenchymal cells are of 3 types: *chief cells*, *oxyphil cells* and *water-clear cells*. The chief cells are most numerous and are the major source of parathyroid hormone. The latter two types of cells appear to be derived from the chief cells and have sparse secretory granules but are potentially capable of secreting parathyroid hormone.

The major *function* of the parathyroid hormone, in conjunction with calcitonin and vitamin D, is to regulate serum calcium levels and metabolism of bone. Parathyroid hormone tends to elevate serum calcium level and reduce serum phosphate level. Secretion of parathyroid hormone takes place in response to serum level of calcium by a feedback mechanism—lowered serum calcium stimulates secretion of parathyroid hormone, while elevated serum calcium causes decreased secretion of the hormone. The role of parathyroid

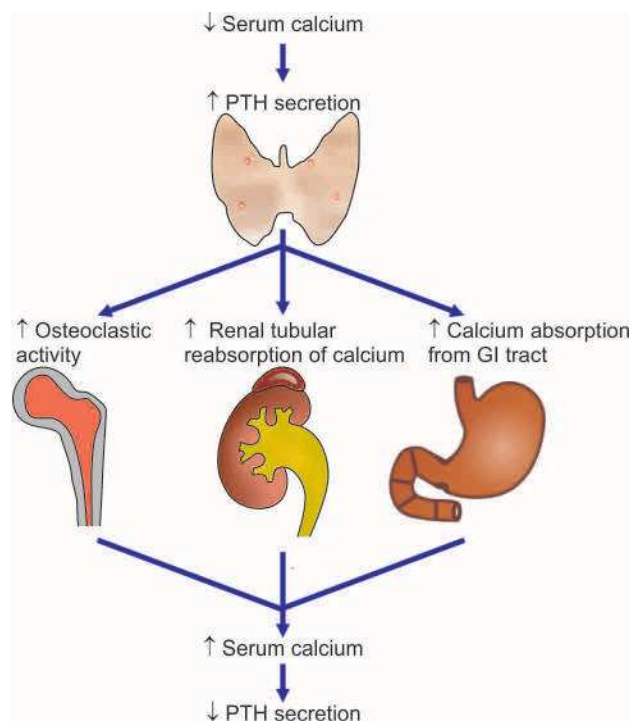

Figure 25.20 Role of parathormone in regulating calcium metabolism in the body.

hormone in regulating calcium metabolism in the body is at the following 3 levels (**Fig. 25.20**):

1. Parathyroid hormone *stimulates osteoclastic activity* and results in resorption of bone and release of calcium. Calcitonin released by C-cells, on the other hand, opposes parathyroid hormone by preventing resorption of bone and lowering serum calcium level.
2. Parathyroid hormone acts *directly on renal tubular epithelial cells* and increases renal reabsorption of calcium and inhibits reabsorption of phosphate; calcitonin enhances renal excretion of phosphate.
3. Parathyroid hormone increases renal production of the *most active metabolite of vitamin D*, i.e. 1, 25-dihydrocholecalciferol, which in turn increases calcium absorption from the small intestine.

The major parathyroid disorders are its functional disorders (hyper- and hypoparathyroidism) and neoplasms.

HYPERPARATHYROIDISM

Hyperfunction of the parathyroid glands occurs due to excessive production of parathyroid hormone. It is classified into 3 types—primary, secondary and tertiary.

1. *Primary hyperparathyroidism* occurs from oversecretion of parathyroid hormone due to disease of the parathyroid glands.
2. *Secondary hyperparathyroidism* is caused by diseases in other parts of the body.
3. *Tertiary hyperparathyroidism* develops from secondary hyperplasia after removal of the cause of secondary hyperplasia.

PRIMARY HYPERPARATHYROIDISM

Primary hyperparathyroidism is not uncommon and occurs more commonly with increasing age. It is especially likely to occur in women near the time of menopause.

ETIOLOGY Common causes of primary hyperparathyroidism are as follows:

1. Most commonly, parathyroid adenomas in approximately 80% cases.
2. Carcinoma of the parathyroid glands in 2-3% patients.
3. Primary hyperplasia in about 15% cases (usually chief cell hyperplasia).

Also included above are the familial cases of multiple endocrine neoplasia (MEN) syndromes where parathyroid adenoma or primary hyperplasia is one of the components.

CLINICAL FEATURES The patients with primary hyperparathyroidism have the following characteristic biochemical abnormalities:

- i) Elevated levels of parathyroid hormone
- ii) Hypercalcaemia
- iii) Hypophosphataemia
- iv) Hypercalciuria

Clinical presentation of individuals with primary hyperparathyroidism may be in a variety of ways:

1. Most commonly, *nephrolithiasis* and or/*nephrocalcinosis* (page 672). These dysfunctions result from excessive excretion of calcium in the urine due to hypercalcaemia induced by increased parathyroid hormone level.
2. *Metastatic calcification*, especially in the blood vessels, kidneys, lungs, stomach, eyes and other tissues (page 36).
3. *Generalised osteitis fibrosa cystica* due to osteoclastic resorption of bone and its replacement by connective tissue (page 826).
4. *Neuropsychiatric disturbances* such as depression, anxiety, psychosis and coma.
5. *Hypertension* is found in about half the cases.
6. *Other changes* such as pancreatitis, cholelithiasis and peptic ulcers due to hypercalcaemia and high parathyroid hormone level are less constant features.

SECONDARY HYPERPARATHYROIDISM

Secondary hyperparathyroidism occurs due to increased parathyroid hormone elaboration secondary to a disease elsewhere in the body. Hypocalcaemia stimulates compensatory hyperplasia of the parathyroid glands and causes secondary hyperparathyroidism.

ETIOLOGY Though any condition that causes hypocalcaemia stimulates excessive secretion of parathyroid hormone, the important causes of secondary hyperparathyroidism are as under:

1. *Chronic renal insufficiency* resulting in retention of phosphate and impaired intestinal absorption of calcium.
2. *Vitamin D deficiency* and consequent rickets and osteomalacia may cause parathyroid hyperfunction.
3. *Intestinal malabsorption syndromes* causing deficiency of calcium and vitamin D.

CLINICAL FEATURES The main biochemical abnormality in secondary hyperparathyroidism is mild hypocalcaemia, in striking contrast to hypercalcaemia in primary hyperparathyroidism. The patients with secondary hyperparathyroidism have signs and symptoms of the disease which caused it. Usually, secondary hyperparathyroidism is a beneficial compensatory mechanism, but more severe cases may be associated with renal osteodystrophy (i.e. features of

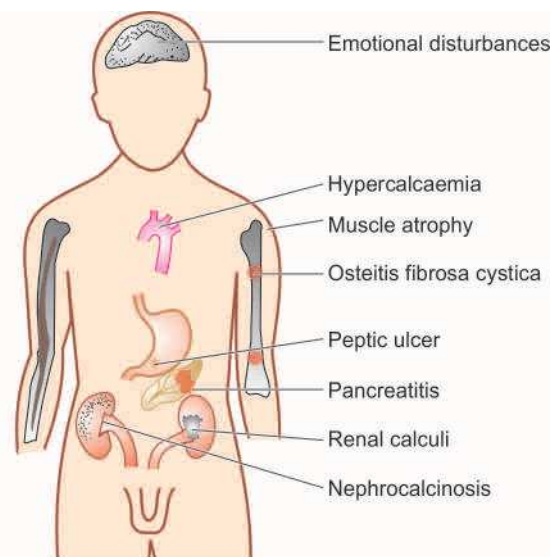

Figure 25.21 Major clinical manifestations of hyperparathyroidism.

varying degree of osteitis fibrosa, osteomalacia, osteoporosis and osteosclerosis in cases of chronic renal insufficiency) and soft tissue calcification (**Fig. 25.21**).

TERTIARY HYPERPARATHYROIDISM

Tertiary hyperparathyroidism is a complication of secondary hyperparathyroidism in which the hyperfunction persists in spite of removal of the cause of secondary hyperplasia. Possibly, a hyperplastic nodule in the parathyroid gland develops which becomes partially autonomous and continues to secrete large quantities of parathyroid hormone without regard to the needs of the body.

HYPOPARATHYROIDISM

Deficiency or absence of parathyroid hormone secretion causes hypoparathyroidism. Hypoparathyroidism is of 3 types—*primary*, *pseudo*- and *pseudopseudo-hypoparathyroidism*.

PRIMARY HYPOPARATHYROIDISM

Primary hypoparathyroidism is caused by disease of the parathyroid glands. Most common causes of primary hypoparathyroidism are: surgical procedures involving thyroid, parathyroid, or radical neck dissection for cancer. Other causes are uncommon and include idiopathic hypoparathyroidism of autoimmune origin in children and may occur as sporadic or familial cases. These cases are generally associated with other autoimmune diseases.

CLINICAL FEATURES The main biochemical dysfunctions in primary hypoparathyroidism are hypocalcaemia, hypophosphataemia and hypocalciuria. The clinical manifestations of these abnormalities are as under:

1. Increased neuromuscular irritability and tetany
2. Calcification of the lens and cataract formation
3. Abnormalities in cardiac conduction
4. Disorders of the CNS due to intracranial calcification
5. Abnormalities of the teeth.

PSEUDO-HYPOPARATHYROIDISM

In pseudo-hypoparathyroidism, the tissues fail to respond to parathyroid hormone though parathyroid glands are usually normal. It is a rare inherited condition with an autosomal dominant character. The patients are generally females and are characterised by signs and symptoms of hypoparathyroidism and other clinical features like short stature, short metacarpals and metatarsals, flat nose, round face and multiple exostoses. Since renal tubules cannot adequately respond to parathyroid hormone, there is hypercalciuria, hypocalcaemia and hyperphosphataemia.

PSEUDOPSEUDO-HYPOPARATHYROIDISM

Pseudopseudo-hypoparathyroidism is another rare familial disorder in which all the clinical features of pseudo-hypoparathyroidism are present except that these patients have no hypocalcaemia or hyperphosphataemia and the tissues respond normally to parathyroid hormone. Pseudopseudo-hypoparathyroidism has been considered an incomplete form of pseudo-hypoparathyroidism.

PARATHYROID TUMOURS

Parathyroid adenoma and carcinoma are the neoplasms found in parathyroid glands, the former being much more common than the latter.

PARATHYROID ADENOMA

The commonest tumour of the parathyroid glands is an adenoma. It may occur at any age and in either sex but is found more frequently in adult life. Most adenomas are first brought to attention because of excessive secretion of parathyroid hormone causing features of hyperparathyroidism as described above.

MORPHOLOGIC FEATURES *Grossly*, a parathyroid adenoma is small (less than 5 cm diameter) encapsulated, yellowish-brown, ovoid nodule and weighing up to 5 gm or more.

Microscopically, majority of adenomas are predominantly composed of chief cells arranged in sheets or cords. Oxyphil cells and water-clear cells may be found intermingled in varying proportions. Usually, a rim of normal parathyroid parenchyma and fat are present external to the capsule which help to distinguish an adenoma from diffuse hyperplasia.

PARATHYROID CARCINOMA

Carcinoma of the parathyroid is rare and produces manifestations of hyperparathyroidism which is often more pronounced. Carcinoma tends to be irregular in shape and is adherent to the adjacent tissues. Most parathyroid carcinomas are well-differentiated. It may be difficult to distinguish carcinoma of parathyroid gland from an adenoma but local invasion of adjacent tissues and distant metastases are helpful criteria of malignancy in such cases.

GIST BOX 25.5

Diseases of Parathyroid Gland

- Hyperparathyroidism occurs due to excessive production of parathyroid hormone and may be primary (due to disease of the parathyroid glands), secondary (caused by

diseases in other parts of the body) and tertiary (developing after removal of the cause of secondary hyperplasia).

- Hypoparathyroidism is of 3 types—primary, pseudo- and pseudopseudo-hypoparathyroidism.
- The commonest tumour of the parathyroid glands is an adenoma; carcinoma of the parathyroid is rare and most often is well-differentiated.

ENDOCRINE PANCREAS

The human pancreas, though anatomically a single organ, histologically and functionally, has 2 distinct parts—the exocrine and endocrine. The exocrine part of the gland and its disorders have already been discussed in Chapter 19. The discussion here is focused on the endocrine pancreas and its two main disorders: *diabetes mellitus* and *islet cell tumours*.

NORMAL STRUCTURE

The endocrine pancreas consists of microscopic collections of cells called islets of Langerhans found scattered within the pancreatic lobules, as well as individual endocrine cells found in duct epithelium and among the acini. The total weight of endocrine pancreas in the adult, however, does not exceed 1-1.5 gm (total weight of pancreas 60-100 gm). The islet cell tissue is greatly concentrated in the tail than in the head or body of the pancreas. Islets possess no ductal system and they drain their secretory products directly into the circulation. Ultrastructurally and immunohistochemically, 4 *major* and 2 *minor* types of islet cells are distinguished, each type having its distinct secretory product and function. These are as follows:

A. Major cell types:

- Beta (β) or B cells* comprise about 70% of islet cells and secrete insulin, the defective response or deficient synthesis of which causes diabetes mellitus.
- Alpha (α) or A cells* comprise 20% of islet cells and secrete glucagon which induces hyperglycaemia.
- Delta (δ) or D cells* comprise 5-10% of islet cells and secrete somatostatin which suppresses both insulin and glucagon release.
- Pancreatic polypeptide (PP) cells or F cells* comprise 1-2% of islet cells and secrete pancreatic polypeptide having some gastrointestinal effects.

B. Minor cell types:

- D1 cells* elaborate vasoactive intestinal peptide (VIP) which induces glycogenolysis and hyperglycaemia and causes secretory diarrhoea by stimulation of gastrointestinal fluid secretion.
- Enterochromaffin cells* synthesise serotonin which in pancreatic tumours may induce carcinoid syndrome.

Major disease of endocrine pancreas is diabetes mellitus; others are uncommon islet cell tumours.

DIABETES MELLITUS

DEFINITION AND EPIDEMIOLOGY

As per the WHO, diabetes mellitus (DM) is defined as a heterogeneous metabolic disorder characterised by common feature of chronic hyperglycaemia with disturbance of carbohydrate,

fat and protein metabolism. At this point, it is also important to understand another related term, *metabolic syndrome* (also called syndrome X or insulin resistance syndrome), consisting of a combination of metabolic abnormalities which increase the risk to develop diabetes mellitus and cardiovascular disease. Major features of metabolic syndrome are central obesity, hypertriglyceridaemia, low LDL cholesterol, hyperglycaemia and hypertension.

DM is a leading cause of morbidity and mortality world over. It is expected to continue as a major health problem owing to its serious complications, especially end-stage renal disease, IHD, gangrene of the lower extremities, and blindness in the adults. Top 5 countries with highest prevalence of DM are India, China, US, Indonesia and Japan. In India, its incidence is estimated at 7% of adult population (approximately 65 million affected people), largely due to genetic susceptibility combined with changing life style of low-activity high-calorie diet in the growing Indian middle class. The incidence is somewhat low in Africa. But prevalence of DM is expected to rise in developing countries of Asia and Africa due to urbanisation and associated obesity and increased body weight. The rise in prevalence is more for type 2 diabetes than for type 1. It is anticipated that by the year 2030 the number of diabetics globally will double from the present figure of 250 million.

CLASSIFICATION AND ETIOLOGY

The older classification systems dividing DM into primary (idiopathic) and secondary types, juvenile-onset and maturity onset types, and insulin-dependent (IDDM) and non-insulin dependent (NIDDM) types, have become obsolete and undergone major revision due to extensive understanding of etiology and pathogenesis of DM in recent times.

As outlined in **Table 25.4**, current classification of DM based on etiology divides it into two broad categories—type 1 and type 2; besides there are a few uncommon specific etiologic types, and gestational DM. American Diabetes Association (2007) has identified risk factors for type 2 DM listed in **Table 25.5**.

Brief comments on etiologic terminologies as contrasted with former nomenclatures of DM are as under:

TYPE 1 DM It constitutes about 10% cases of DM. It was previously termed as juvenile-onset diabetes (JOD) due to its occurrence in younger age, and was called insulin-dependent DM (IDDM) because it was known that these patients have absolute requirement for insulin replacement as treatment. However, in the new classification, neither age nor insulin-dependence are considered as absolute criteria. Instead, based on underlying etiology, type 1 DM is further divided into 2 subtypes:

Subtype 1A (immune-mediated) DM characterised by auto-immune destruction of β -cells which usually leads to insulin deficiency.

Subtype 1B (idiopathic) DM characterised by insulin deficiency with tendency to develop ketosis but these patients are negative for autoimmune markers.

Though type 1 DM occurs commonly in patients under 30 years of age, autoimmune destruction of β -cells can occur at any age. In fact, 5-10% patients who develop DM above 30 years of age are of type 1A DM and hence the term JOD has become obsolete.

Table 25.4 Etiologic classification of diabetes mellitus (as per American Diabetes Association, 2007).

| | |
|------|---|
| I. | TYPE 1 DIABETES MELLITUS (10%) (earlier called Insulin-dependent, or juvenile-onset diabetes) <i>Type 1A DM:</i> Immune-mediated <i>Type 1B DM:</i> Idiopathic |
| II. | TYPE 2 DIABETES MELLITUS (80%) (earlier called non-insulin-dependent, or maturity-onset diabetes) |
| III. | OTHER SPECIFIC TYPES OF DIABETES (10%) <ol style="list-style-type: none"> Genetic defect of β-cell function due to mutations in various enzymes (earlier called maturity-onset diabetes of the young or MODY) (e.g. hepatocyte nuclear transcription factor—HNF, glucokinase) Genetic defect in insulin action (e.g. type A insulin resistance) Diseases of exocrine pancreas (e.g. chronic pancreatitis, pancreatic tumours, post-pancreatectomy) Endocrinopathies (e.g. acromegaly, Cushing's syndrome, pheochromocytoma) Drug- or chemical-induced (e.g. steroids, thyroid hormone, thiazides, β-blockers etc) Infections (e.g. congenital rubella, cytomegalovirus) Uncommon forms of immune-mediated DM (stiff man syndrome, anti-insulin receptor antibodies) Other genetic syndromes (e.g. Down's syndrome, Klinefelter's syndrome, Turner's syndrome) |
| IV. | GESTATIONAL DIABETES MELLITUS (4%) |

TYPE 2 DM This type comprises about 80% cases of DM. It was previously called maturity-onset diabetes, or non-insulin dependent diabetes mellitus (NIDDM) of obese and non-obese type.

Although type 2 DM predominantly affects older individuals, it is now known that it also occurs in obese adolescent children; hence the term MOD for it is inappropriate. Moreover, many type 2 DM patients also require insulin therapy to control hyperglycaemia or to prevent ketosis and thus are not truly non-insulin dependent contrary to its older nomenclature.

OTHER SPECIFIC ETIOLOGIC TYPES OF DM Besides the two main types, about 10% cases of DM have a known specific etiologic defect listed in **Table 25.4**. One important subtype

Table 25.5 Major risk factors for type 2 diabetes mellitus (ADA Recommendations, 2007).

| | |
|-----|---|
| 1. | Family history of type 2 DM |
| 2. | Obesity |
| 3. | Habitual physical inactivity |
| 4. | Race and ethnicity (Blacks, Asians, Pacific Islanders) |
| 5. | Previous identification of impaired fasting glucose or impaired glucose tolerance |
| 6. | History of gestational DM or delivery of baby heavier than 4 kg |
| 7. | Hypertension |
| 8. | Dyslipidaemia (HDL level < 35 mg/dl or triglycerides > 250 mg/dl) |
| 9. | Polycystic ovary disease and acanthosis nigricans |
| 10. | History of vascular disease |

in this group is *maturity-onset diabetes of the young (MODY)* which has autosomal dominant inheritance, early onset of hyperglycaemia and impaired insulin secretion.

GESTATIONAL DM About 4% pregnant women develop DM due to metabolic changes during pregnancy. Although they revert back to normal glycaemia after delivery, these women are prone to develop DM later in their life.

PATHOGENESIS

Depending upon etiology of DM, hyperglycaemia may result from the following:

- ◆ Reduced insulin secretion
- ◆ Decreased glucose use by the body
- ◆ Increased glucose production.

Pathogenesis of two main types of DM and its complications is distinct. In order to understand it properly, it is essential to first recall physiology of normal insulin synthesis and secretion.

NORMAL INSULIN METABOLISM *The major stimulus for both synthesis and release of insulin is glucose.* The steps involved in biosynthesis, release and actions of insulin are as follows (Fig. 25.22):

Synthesis Insulin is synthesised in the β -cells of pancreatic islets of Langerhans:

- i) It is initially formed as *pre-proinsulin* which is single-chain 86-amino acid precursor polypeptide.
- ii) Subsequent proteolysis removes the amino terminal signal peptide, forming *proinsulin*.
- iii) Further cleavage of proinsulin gives rise to A (21 amino acids) and B (30 amino acids) chains of insulin, linked together by connecting segment called *C-peptide*, all of which are stored in the secretory granules in the β -cells. As compared to A and B chains of insulin, C-peptide is less susceptible to degradation in the liver and is therefore used as a marker to distinguish endogenously synthesised and exogenously administered insulin.

For therapeutic purposes, *human insulin* is now produced by recombinant DNA technology.

Release Glucose is the key regulator of insulin secretion from β -cells by a series of steps:

- i) Hyperglycaemia (glucose level more than 70 mg/dl or above 3.9 mmol/L) stimulates transport into β -cells of a *glucose transporter, GLUT2*. Other stimuli influencing insulin release include nutrients in the meal, ketones, amino acids etc.
- ii) An islet transcription factor, *glucokinase*, causes glucose phosphorylation, and thus acts as a step for controlled release of glucose-regulated insulin secretion.
- iii) Metabolism of glucose to glucose-6-phosphate by glycolysis generates *ATP*.
- iv) Generation of *ATP alters the ion channel activity* on the membrane. It causes inhibition of ATP-sensitive K^+ channel on the cell membrane and opening up of calcium channel with resultant influx of calcium, which stimulates insulin release.

Action Half of insulin secreted from β -cells into portal vein is degraded in the liver while the remaining half enters the systemic circulation for action on the target cells:

- i) Insulin from circulation binds to its receptor on the target cells. *Insulin receptor* has intrinsic tyrosine kinase activity.
- ii) This, in turn, activates post-receptor intracellular signalling pathway molecules, *insulin receptor substrates (IRS) 1 and 2 proteins*, which initiate sequence of phosphorylation and dephosphorylation reactions.
- iii) These reactions on the target cells are responsible for the main *mitogenic and anabolic actions of insulin*—glycogen synthesis, glucose transport, protein synthesis, lipogenesis.
- iv) Besides the role of glucose in maintaining equilibrium of insulin release, *low insulin level in the fasting state* promotes hepatic gluconeogenesis and glycogenolysis, reduced glucose uptake by insulin-sensitive tissues and promotes mobilisation of stored precursors, so as to prevent hypoglycaemia.

PATHOGENESIS OF TYPE 1 DM *The basic phenomenon in type 1 DM is destruction of β -cell mass, usually leading to absolute insulin deficiency.* While type 1B DM remains idiopathic, pathogenesis of type 1A DM is immune-mediated and has been extensively studied. Currently, pathogenesis of

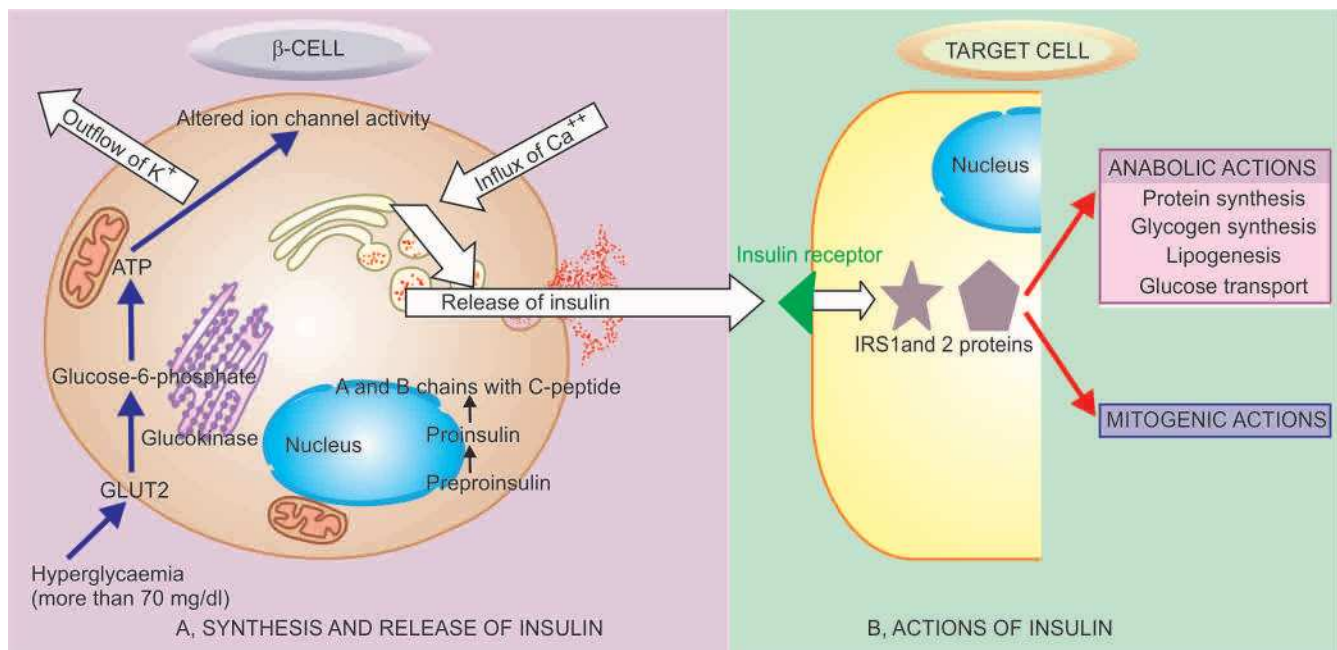

Figure 25.22 A, Pathway of normal insulin synthesis and release in β -cells of pancreatic islets. B, Chain of events in action of insulin on target cell.

type 1A DM is explained on the basis of 3 mutually-interlinked mechanisms: genetic susceptibility, autoimmunity, and certain environmental factors (Fig. 25.23,A).

1. Genetic susceptibility Type 1A DM involves inheritance of multiple genes to confer susceptibility to the disorder:

i) It has been observed in *identical twins* that if one twin has type 1A DM, there is about 50% chance of the second twin developing it, but not all. This means that some additional modifying factors are involved in development of DM in these cases.

ii) About half the cases with genetic predisposition to type 1A DM have the *susceptibility gene* located in the HLA region of chromosome 6 (MHC class II region), particularly HLA DR3, HLA DR4 and HLA DQ locus.

2. Autoimmunity Studies on humans and animal models on type 1ADM have shown several immunologic abnormalities:

i) Presence of *islet cell antibodies* against GAD (glutamic acid decarboxylase), insulin etc, though their assay largely remains a research tool due to tedious method.

ii) Occurrence of lymphocytic infiltrate in and around the pancreatic islets termed *insulinitis*. It chiefly consists of CD8+ T lymphocytes with variable number of CD4+ T lymphocytes and macrophages.

iii) *Selective destruction of β -cells* while other islet cell types (glucagon-producing alpha cells, somatostatin-producing delta cells, or polypeptide-forming PP cells) remain unaffected. This is mediated by T-cell mediated cytotoxicity or by apoptosis.

iv) Role of *T cell-mediated autoimmunity* is further supported by transfer of type 1A DM from diseased animal by infusing T lymphocytes to a healthy animal.

v) Association of type 1A DM with *other autoimmune diseases* in about 10-20% cases such as Graves' disease, Addison's disease, Hashimoto's thyroiditis, pernicious anaemia.

vi) Remission of type 1A DM in response to immunosuppressive therapy such as administration of cyclosporin A.

3. Environmental factors Epidemiologic studies in type 1A DM suggest the involvement of certain environmental factors in its pathogenesis, though role of none of them has been conclusively proved. In fact, the trigger may precede the occurrence of the disease by several years. It appears that certain viral and dietary proteins share antigenic properties with human cell surface proteins and trigger the immune attack on β -cells by a process of molecular mimicry. These factors include the following:

i) *Certain viral infections* preceding the onset of disease e.g. mumps, measles, coxsackie B virus, cytomegalovirus and infectious mononucleosis.

ii) *Experimental induction* of type 1A DM with certain chemicals has been possible e.g. alloxan, streptozotocin and pentamidine.

iii) *Geographic and seasonal variations* in its incidence suggest some common environmental factors.

iv) Possible relationship of early exposure to *bovine milk proteins* and occurrence of autoimmune process in type 1A DM is being studied.

KEY POINTS Pathogenesis of type 1A DM can be summed up by interlinking the above three factors as under:

- At birth, individuals with *genetic susceptibility* to this disorder have normal β -cell mass.
- β -cells act as autoantigens and activate CD4+ T lymphocytes, bringing about immune destruction of pancreatic

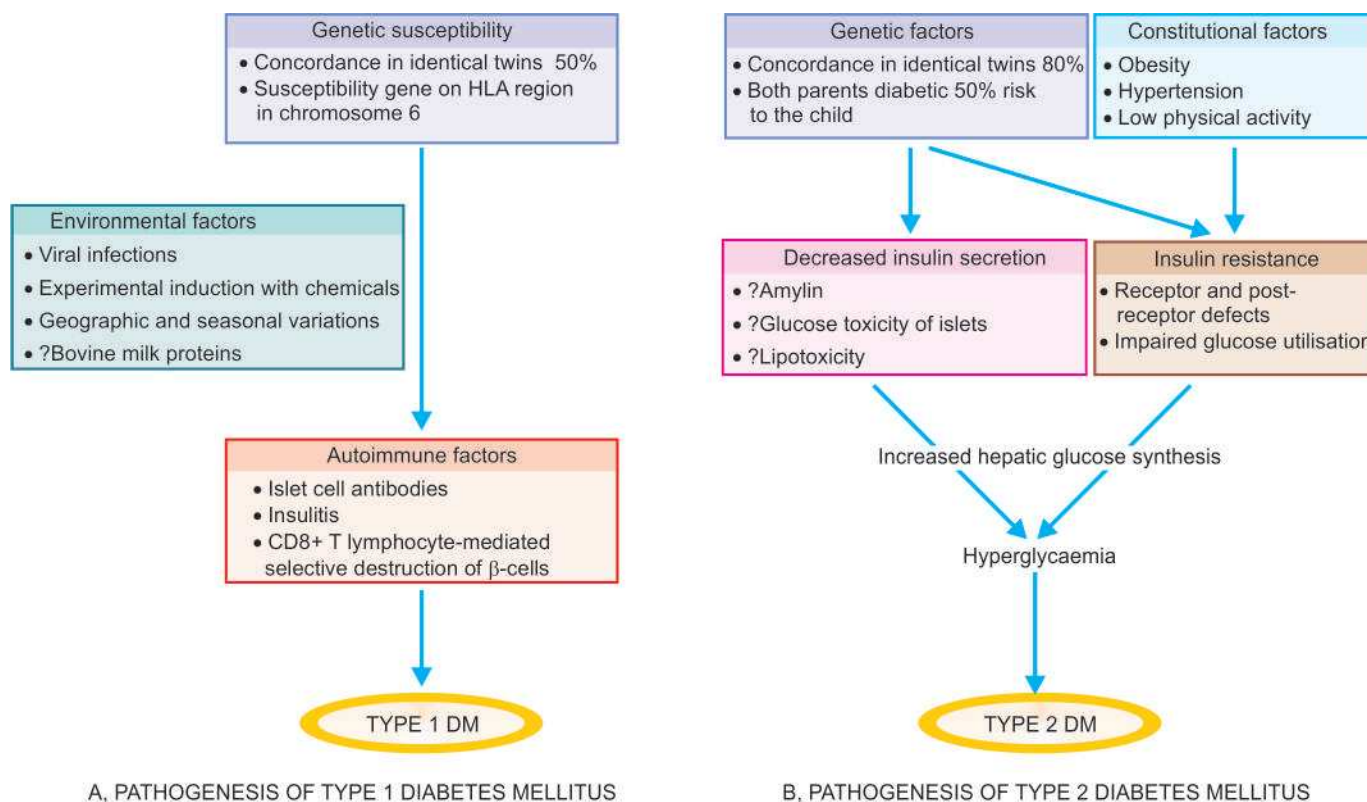

Figure 25.23 Schematic mechanisms involved in pathogenesis of two main types of diabetes mellitus.

β -cells by *autoimmune phenomena* and takes months to years. Clinical features of diabetes manifest after more than 80% of β -cell mass has been destroyed.

3. The trigger for autoimmune process appears to be some *infectious or environmental factor* which specifically targets β -cells.

PATHOGENESIS OF TYPE 2 DM The basic metabolic defect in type 2 DM is either a delayed insulin secretion relative to glucose load (*impaired insulin secretion*), or the peripheral tissues are unable to respond to insulin (*insulin resistance*).

Type 2 DM is a heterogeneous disorder with a more complex etiology and is far more common than type 1, but much less is known about its pathogenesis. A number of factors have been implicated though, but HLA association and autoimmune phenomena are not implicated. These factors are as under (**Fig. 25.23,B**):

1. Genetic factors Genetic component has a stronger basis for type 2 DM than type 1A DM. Although no definite and consistent genes have been identified, multifactorial inheritance is the most important factor in development of type 2 DM:

- i) There is approximately 80% chance of developing diabetes in the other *identical twin* if one twin has the disease.
- ii) A person with one parent having type 2 DM is at an increased risk of getting diabetes, but if *both parents* have type 2 DM the risk in the offspring rises to 40%.

2. Constitutional factors Certain environmental factors such as obesity, hypertension, and level of physical activity play contributory role and modulate the phenotyping of the disease.

3. Insulin resistance One of the most prominent metabolic features of type 2 DM is the lack of responsiveness of peripheral tissues to insulin, especially of the skeletal muscle and liver. Obesity, in particular, is strongly associated with insulin resistance and hence type 2 DM. Mechanism of hyperglycaemia in these cases is explained as under:

- i) Resistance to action of insulin *impairs glucose utilisation* and hence hyperglycaemia.
- ii) There is *increased hepatic synthesis* of glucose.
- iii) *Hyperglycaemia in obesity* is related to high levels of free fatty acids and cytokines (e.g. TNF- α and adiponectin) affect peripheral tissue sensitivity to respond to insulin.

The precise underlying molecular defect responsible for insulin resistance in type 2 DM has yet not been fully identified. Currently, it is proposed that insulin resistance may be possibly due to one of the following defects:

- a) Polymorphism in various *post-receptor intracellular signal pathway molecules*.
- b) *Elevated free fatty acids* seen in obesity may contribute e.g. by impaired glucose utilisation in the skeletal muscle, by increased hepatic synthesis of glucose, and by impaired β -cell function.

c) *Insulin resistance syndrome* is a complex of clinical features occurring from insulin resistance and its resultant metabolic derangements that includes hyperglycaemia and compensatory hyperinsulinaemia. The clinical features are in the form of accelerated cardiovascular disease and may occur in both obese as well as non-obese type 2 DM patients. The features include: mild hypertension (related to endothelial

dysfunction) and dyslipidaemia (characterised by reduced HDL level, increased triglycerides and LDL level).

4. Impaired insulin secretion In type 2 DM, insulin resistance and insulin secretion are interlinked:

i) Early in the course of disease, in response to insulin resistance there is compensatory increased secretion of insulin (*hyperinsulinaemia*) in an attempt to maintain normal blood glucose level.

ii) Eventually, however, there is *failure of β -cell function* to secrete adequate insulin, although there is some secretion of insulin i.e. cases of type 2 DM have mild to moderate deficiency of insulin (which is much less severe than that in type 1 DM) but not its total absence.

The exact genetic mechanism why there is a fall in insulin secretion in these cases is unclear. However, following possibilities are proposed:

- a) Islet amyloid polypeptide (*amylin*) which forms fibrillar protein deposits in pancreatic islets in longstanding cases of type 2 DM may be responsible for impaired function of β -cells of islet cells.
- b) Metabolic environment of chronic hyperglycaemia surrounding the islets (*glucose toxicity*) may paradoxically impair islet cell function.
- c) Elevated free fatty acid levels (*lipotoxicity*) in these cases may worsen islet cell function.

5. Increased hepatic glucose synthesis One of the normal roles played by insulin is to promote hepatic storage of glucose as glycogen and suppress gluconeogenesis. In type 2 DM, as a part of insulin resistance by peripheral tissues, the liver also shows insulin resistance i.e. in spite of hyperinsulinaemia in the early stage of disease, gluconeogenesis in the liver is not suppressed. This results in increased hepatic synthesis of glucose which contributes to hyperglycaemia in these cases.

KEY POINTS In essence, hyperglycaemia in type 2 DM is not due to destruction of β -cells but is instead a failure of β -cells to meet the requirement of insulin in the body. Its pathogenesis can be summed up by interlinking the above factors as under:

1. Type 2 DM is a more *complex multifactorial disease*.
2. There is greater role of *genetic defect and heredity*.
3. Two main mechanisms for hyperglycaemia in type 2 DM—*insulin resistance and impaired insulin secretion*, are interlinked.
4. While *obesity* plays a role in pathogenesis of insulin resistance, impaired insulin secretion may be from many constitutional factors.
5. *Increased hepatic synthesis of glucose* in initial period of disease contributes to hyperglycaemia.

MORPHOLOGIC FEATURES IN PANCREATIC ISLETS

Morphologic changes in islets have been demonstrated in both types of diabetes, though the changes are more distinctive in type 1 DM:

1. Insulinitis:

In type 1 DM, characteristically, in early stage there is lymphocytic infiltrate, mainly by T cells, in the islets which may be accompanied by a few macrophages and polymorphs. Diabetic infants born to diabetic mothers, however, have eosinophilic infiltrate in the islets.

In type 2 DM, there is no significant leucocytic infiltrate in the islets but there is variable degree of fibrous tissue in the islets.

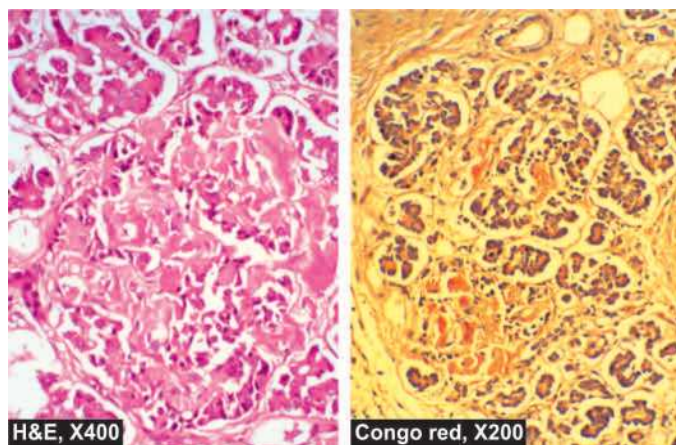

Figure 25.24 Amyloidosis of the pancreatic islet tissue. The islets are mostly replaced by structureless eosinophilic material which stains positively with Congo red.

2. Islet cell mass:

In type 1 DM, as the disease becomes chronic there is progressive depletion of β -cell mass, eventually resulting in total loss of pancreatic β -cells and its hyalinisation.

In type 2 DM, β -cell mass is either normal or mildly reduced. Infants of diabetic mothers, however, have hyperplasia and hypertrophy of islets as a compensatory response to maternal hyperglycaemia.

3. Amyloidosis:

In type 1 DM, deposits of amyloid around islets are absent.

In type 2 DM, characteristically chronic long-standing cases show deposition of amyloid material, amylin, around the capillaries of the islets causing compression and atrophy of islet tissue (**Fig. 25.24**).

β -cell degranulation:

In type 1 DM, EM shows degranulation of remaining β -cells of islets.

In type 2 DM, no such change is observed.

CLINICAL FEATURES

It can be appreciated that hyperglycaemia in DM does not cause a single disease but is associated with numerous diseases and symptoms, especially due to complications. Two main types of DM can be distinguished clinically to the extent shown in **Table 25.6**. However, overlapping of clinical features occurs as regards the age of onset, duration of symptoms and family history. Pathophysiology in evolution of clinical features is schematically shown in **Fig. 25.25**.

Type 1 DM:

- i) Patients of type 1 DM usually manifest at early age, generally below the age of 35.
- ii) The onset of symptoms is often abrupt.
- iii) At presentation, these patients have polyuria, polydipsia and polyphagia.
- iv) The patients are not obese but have generally progressive loss of weight.
- v) These patients are prone to develop metabolic complications such as ketoacidosis and hypoglycaemic episodes.

Type 2 DM:

- i) This form of diabetes generally manifests in middle life or beyond, usually above the age of 40.
- ii) The onset of symptoms in type 2 DM is slow and insidious.
- iii) Generally, the patient is asymptomatic when the diagnosis is made on the basis of glucosuria or hyperglycaemia during physical examination, or may present with polyuria and polydipsia.
- iv) The patients are frequently obese and have unexplained weakness and loss of weight.
- v) Metabolic complications such as ketoacidosis are infrequent.

PATHOGENESIS OF COMPLICATIONS

It is now known that in both type 1 and 2 DM, *severity and chronicity of hyperglycaemia* forms the main pathogenetic mechanism for 'microvascular complications' (e.g. retinopathy, nephropathy, neuropathy); therefore control of blood glucose level constitutes the mainstay of treatment for minimising

Table 25.6 Contrasting features of type 1 and type 2 diabetes mellitus.

| FEATURE | TYPE 1 DM | TYPE 2 DM |
|--------------------------------|--|--|
| 1. Frequency | 10-20% | 80-90% |
| 2. Age at onset | Early (below 35 years) | Late (after 40 years) |
| 3. Type of onset | Abrupt and severe | Gradual and insidious |
| 4. Weight | Normal | Obese/non-obese |
| 5. HLA | Linked to HLA DR3, HLA DR4, HLA DQ | No HLA association |
| 6. Family history | < 20% | About 60% |
| 7. Genetic locus | Unknown | Chromosome 6 |
| 8. Diabetes in identical twins | 50% concordance | 80% concordance |
| 9. Pathogenesis | Autoimmune destruction of β -cells | Insulin resistance, impaired insulin secretion |
| 10. Islet cell antibodies | Yes | No |
| 11. Blood insulin level | Decreased insulin | Normal or increased insulin |
| 12. Islet cell changes | Insulinitis, β -cell depletion | No insulinitis, later fibrosis of islets |
| 13. Amyloidosis | Infrequent | Common in chronic cases |
| 14. Clinical management | Insulin and diet | Diet, exercise, oral drugs, insulin |
| 15. Acute complications | Ketoacidosis | Hyperosmolar coma |

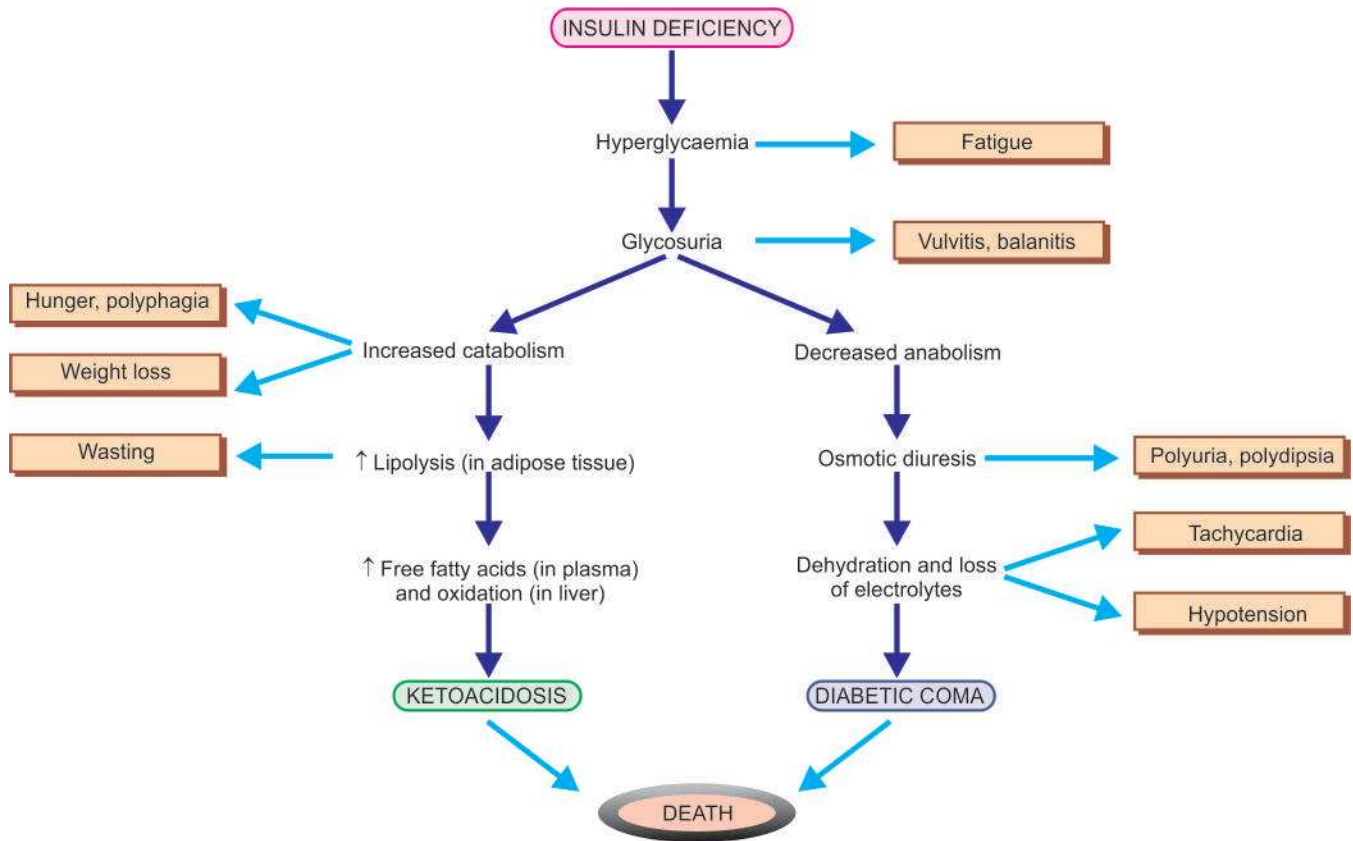

Figure 25.25 Pathophysiological basis of common signs and symptoms due to uncontrolled hyperglycaemia in diabetes mellitus.

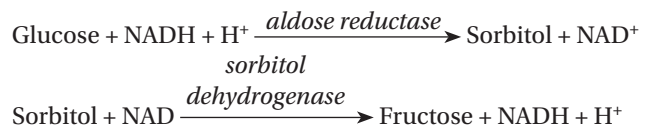

development of these complications. Longstanding cases of type 2 DM, however, in addition, frequently develop 'macrovascular complications' (e.g. atherosclerosis, coronary artery disease, peripheral vascular disease, cerebrovascular disease) which are more difficult to explain on the basis of hyperglycaemia alone.

The following biochemical mechanisms have been proposed to explain the development of complications of diabetes mellitus (Fig. 25.26,A):

1. Non-enzymatic protein glycosylation The free amino group of various body proteins binds by non-enzymatic mechanism to glucose; this process is called *glycosylation* and is directly proportionate to the severity of hyperglycaemia. Various body proteins undergoing chemical alterations in this way include haemoglobin, lens crystalline protein, and basement membrane of body cells. An example is the measurement of a fraction of haemoglobin called glycosylated haemoglobin (HbA_{1c}) as a test for monitoring glycaemic control in a diabetic patient during the preceding 90 to 120 days which is lifespan of red cells (page 265). Similarly, there is accumulation of labile and reversible glycosylation products on collagen and other tissues of the blood vessel wall which subsequently become stable and irreversible by chemical changes and form advanced glycosylation end-products (AGE). The AGEs bind to receptors on different cells and produce a variety of biologic and chemical changes e.g. thickening of vascular basement membrane in diabetes.

2. Polyol pathway mechanism This mechanism is responsible for producing lesions in the aorta, lens of the eye, kidney and peripheral nerves. These tissues have an enzyme,

aldose reductase, that reacts with glucose to form sorbitol and fructose in the cells of the hyperglycaemic patient as under:

Intracellular accumulation of sorbitol and fructose so produced results in entry of water inside the cell and consequent cellular swelling and cell damage. Also, intracellular accumulation of sorbitol causes intracellular deficiency of myoinositol which promotes injury to Schwann cells and retinal pericytes. These polyols result in disturbed processing of normal intermediary metabolites leading to complications of diabetes.

3. Excessive oxygen free radicals In hyperglycaemia, there is increased production of reactive oxygen free radicals from mitochondrial oxidative phosphorylation which may damage various target cells in diabetes.

COMPLICATIONS OF DIABETES

As a consequence of hyperglycaemia of diabetes, every tissue and organ of the body undergoes biochemical and structural alterations which account for the major complications in diabetics which may be *acute metabolic* or *chronic systemic*.

Both types of diabetes mellitus may develop complications which are broadly divided into 2 major groups:

I. *Acute metabolic complications*: These include diabetic ketoacidosis, hyperosmolar nonketotic coma, and hypoglycaemia.

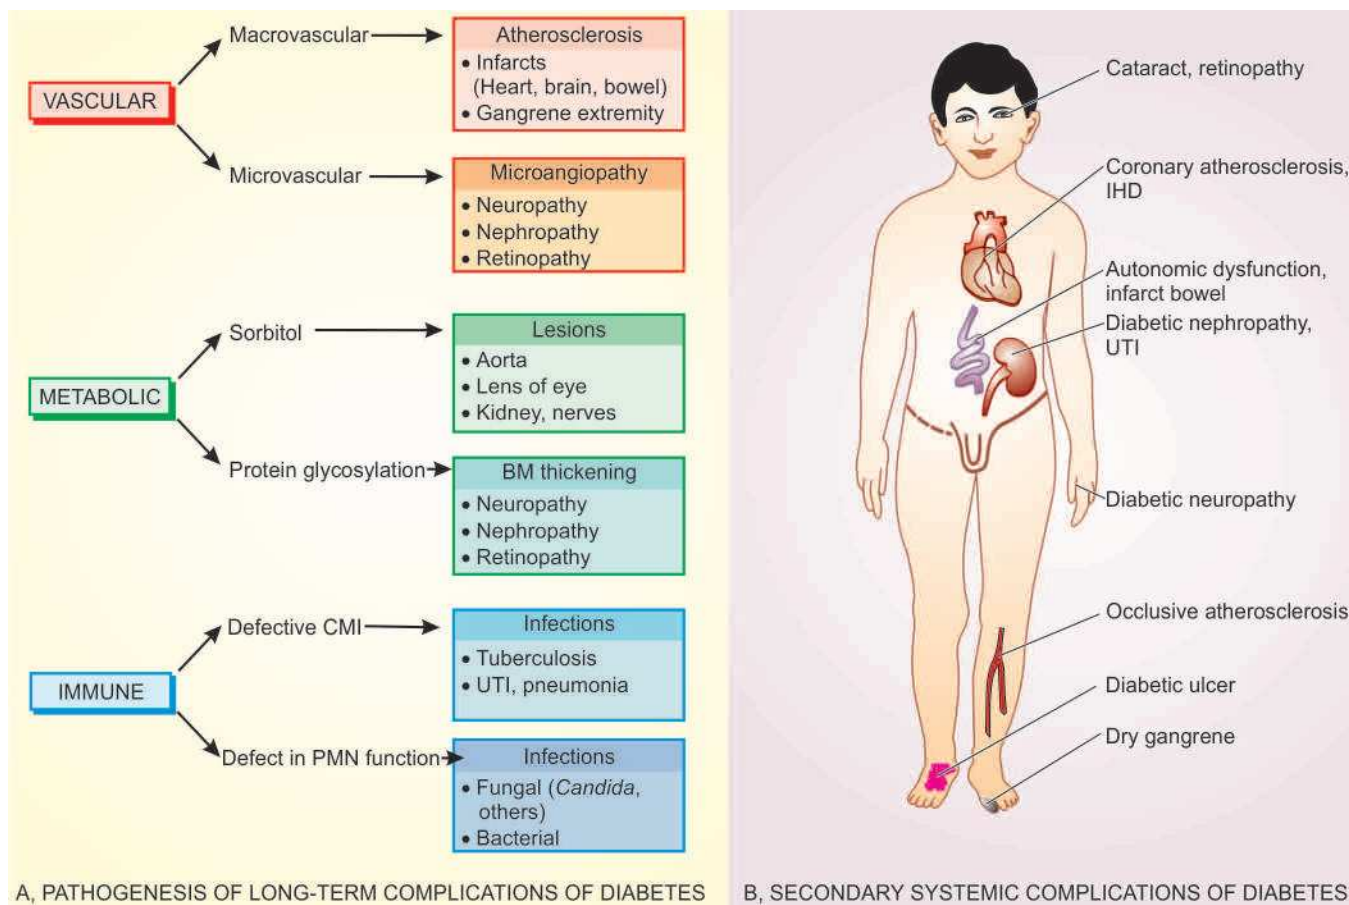

Figure 25.26 Long-term complications of diabetes mellitus. A, Pathogenesis. B, Secondary systemic complications.

II. *Late systemic complications:* These are atherosclerosis, diabetic microangiopathy, diabetic nephropathy, diabetic neuropathy, diabetic retinopathy and infections.

I. ACUTE METABOLIC COMPLICATIONS Metabolic complications develop acutely. While ketoacidosis and hypoglycaemic episodes are primarily complications of type 1 DM, hyperosmolar nonketotic coma is chiefly a complication of type 2 DM (also see **Fig. 25.25**).

1. Diabetic ketoacidosis (DKA) Ketoacidosis is almost exclusively a complication of type 1 DM. It can develop in patients with severe insulin deficiency combined with glucagon excess. Failure to take insulin and exposure to stress are the usual precipitating causes. Severe lack of insulin causes lipolysis in the adipose tissues, resulting in release of free fatty acids into the plasma. These free fatty acids are taken up by the liver where they are oxidised through acetyl coenzyme-A to ketone bodies, principally acetoacetic acid and β -hydroxybutyric acid. Such free fatty acid oxidation to ketone bodies is accelerated in the presence of elevated level of glucagon. Once the rate of ketogenesis exceeds the rate at which the ketone bodies can be utilised by the muscles and other tissues, ketonaemia and ketonuria occur. If urinary excretion of ketone bodies is prevented due to dehydration, systemic metabolic ketoacidosis occurs. Clinically, the condition is characterised by anorexia, nausea, vomitings, deep and fast breathing, mental confusion and coma. Most patients of ketoacidosis recover.

2. Hyperosmolar hyperglycaemic nonketotic coma (HHS) Hyperosmolar hyperglycaemic nonketotic coma is usually a

complication of type 2 DM. It is caused by severe dehydration resulting from sustained hyperglycaemic diuresis. The loss of glucose in urine is so intense that the patient is unable to drink sufficient water to maintain urinary fluid loss. The usual clinical features of ketoacidosis are absent but prominent central nervous signs are present. Blood sugar is extremely high and plasma osmolality is high. Thrombotic and bleeding complications are frequent due to high viscosity of blood. The mortality rate in hyperosmolar nonketotic coma is high.

The contrasting features of diabetic ketoacidosis and hyperosmolar non-ketotic coma are summarised in **Table 25.7**.

3. Hypoglycaemia Hypoglycaemic episode may develop in patients of type 1 DM. It may result from excessive administration of insulin, missing a meal, or due to stress. Hypoglycaemic episodes are harmful as they produce permanent brain damage, or may result in worsening of diabetic control and rebound hyperglycaemia, so called *Somogyi's effect*.

II. LATE SYSTEMIC COMPLICATIONS A number of systemic complications may develop after a period of 15-20 years in either type of diabetes. Late complications are largely responsible for morbidity and premature mortality in diabetes mellitus. These complications are briefly outlined below and have been discussed in detail in relevant chapters (**Fig. 25.26,B**).

1. Atherosclerosis Diabetes mellitus of both type 1 and type 2 accelerates the development of atherosclerosis. Consequently, atherosclerotic lesions appear earlier than in the general population, are more extensive, and are more often associated with complicated plaques such as ulceration,

Table 25.7 Contrasting features of diabetic ketoacidosis (DKA) and hyperosmolar hyperglycaemic non-ketotic coma (HHS).

| LAB FINDINGS | DKA | HHS |
|---------------------------------|-------------|-------------|
| i. Plasma glucose (mg/dL) | 250-600 | > 600 |
| ii. Plasma acetone | + | Less + |
| iii. S. Na ⁺ (mEq/L) | Usually low | N, ↑ or low |
| iv. S. K ⁺ (mEq/L) | N, ↑ or low | N or ↑ |
| v. S. phosphorus (mEq/L) | N or ↑ | N or ↑ |
| vi. S. Mg ⁺⁺ | N or ↑ | N or ↑ |
| vii. S. bicarbonate (mEq/L) | Usually <15 | Usually >20 |
| viii. Blood pH | <7.30 | > 7.30 |
| ix. S. osmolarity (mOsm/L) | <320 | > 330 |
| x. S. lactate (mmol/L) | 2-3 | 1-2 |
| xi. S. BUN (mg/dL) | Less ↑ | Greater ↑ |
| xii. Plasma insulin | Low to 0 | Some |

calcification and thrombosis (page 378). The cause for this accelerated atherosclerotic process is not known but possible contributory factors are hyperlipidaemia, reduced HDL levels (see metabolic syndrome on page 809), nonenzymatic glycosylation, increased platelet adhesiveness, obesity and associated hypertension in diabetes.

The possible ill-effects of accelerated atherosclerosis in diabetes are early onset of coronary artery disease, silent myocardial infarction, cerebral stroke and gangrene of the toes and feet. Gangrene of the lower extremities is 100 times more common in diabetics than in non-diabetics.

2. Diabetic microangiopathy Microangiopathy of diabetes is characterised by basement membrane thickening of small blood vessels and capillaries of different organs and tissues such as the skin, skeletal muscle, eye and kidney. Similar type of basement membrane-like material is also deposited in nonvascular tissues such as peripheral nerves, renal tubules and Bowman's capsule. The pathogenesis of diabetic microangiopathy as well as of peripheral neuropathy in diabetics is believed to be due to recurrent hyperglycaemia that causes *increased glycosylation* of haemoglobin and other proteins (e.g. collagen and basement membrane material) resulting in thickening of basement membrane.

3. Diabetic nephropathy Renal involvement is a common complication and a leading cause of death in diabetes. Four types of lesions are described in diabetic nephropathy (page 664):

- Diabetic glomerulosclerosis* which includes diffuse and nodular lesions of glomerulosclerosis.
- Vascular lesions* that include hyaline arteriosclerosis of afferent and efferent arterioles and atheromas of renal arteries.
- Diabetic pyelonephritis* and *necrotising renal papillitis*.
- Tubular lesions or Armani-Ebstein lesion*.

4. Diabetic neuropathy Diabetic neuropathy may affect all parts of the nervous system but symmetric peripheral neuropathy is most characteristic. The basic pathological changes are segmental demyelination, Schwann cell injury and axonal damage (page 884). The pathogenesis of neuropathy is not clear but it may be related to diffuse microangiopathy as already explained, or may be due to accumulation of sorbitol

and fructose as a result of hyperglycaemia, leading to deficiency of myoinositol.

5. Diabetic retinopathy Diabetic retinopathy is a leading cause of blindness. There are 2 types of lesions involving retinal vessels: *background* and *proliferative* (page 489). Besides retinopathy, diabetes also predisposes the patients to early development of cataract and glaucoma.

6. Infections Diabetics have enhanced susceptibility to various infections such as tuberculosis, pneumonias, pyelonephritis, otitis, carbuncles and diabetic ulcers. This could be due to various factors such as impaired leucocyte functions, reduced cellular immunity, poor blood supply due to vascular involvement and hyperglycaemia *per se*.

DIAGNOSIS OF DIABETES

Hyperglycaemia remains the fundamental basis for the diagnosis of diabetes mellitus. In *symptomatic cases*, the diagnosis is not a problem and can be confirmed by finding glucosuria and a random plasma glucose concentration above 200 mg/dl.

◆ The severity of clinical symptoms of polyuria and polydipsia is directly related to the degree of hyperglycaemia.

◆ In *asymptomatic cases*, when there is persistently elevated fasting plasma glucose level, diagnosis again poses no difficulty.

◆ The problem arises in asymptomatic patients who have normal fasting glucose level in the plasma but are suspected to have diabetes on other grounds and are thus subjected to oral glucose tolerance test (GTT). If abnormal GTT values are found, these subjects are said to have '*chemical diabetes*' (Fig. 25.27). The American Diabetes Association (2007) has recommended definite diagnostic criteria for early diagnosis of diabetes mellitus (Table 25.8).

The following investigations are helpful in establishing the diagnosis of diabetes mellitus:

I. URINE TESTING Urine tests are cheap and convenient but the diagnosis of diabetes cannot be based on urine testing alone since there may be false-positives and false-negatives.

Table 25.8 Revised criteria for diagnosis of diabetes by oral GTT (as per American Diabetes Association, 2007).

| PLASMA GLUCOSE VALUE* | DIAGNOSIS |
|---|--|
| FASTING (FOR > 8 HOURS) VALUE | |
| <i>Below 100 mg/dl (< 5.6 mmol/L)</i> | Normal fasting value |
| <i>100-125 mg/dl (5.6-6.9 mmol/L)</i> | Impaired fasting glucose (IFG)** |
| <i>126 mg/dl (7.0 mmol/L) or more</i> | Diabetes mellitus |
| TWO-HOUR AFTER 75 GM ORAL GLUCOSE LOAD | |
| <i>< 140 mg/dl (< 7.8 mmol/L)</i> | Normal post-prandial GTT |
| <i>140-199 mg/dl (7.8-11.1 mmol/L)</i> | Impaired post-prandial glucose tolerance (IGT)** |
| <i>200 mg/dl (11.1 mmol/L) or more</i> | Diabetes mellitus |
| RANDOM VALUE | |
| <i>200 mg/dl (11.1 mmol/L) or more in a symptomatic patient</i> | Diabetes mellitus |

Note: * Plasma glucose values are 15% higher than whole blood glucose value.
** Individuals with IFG and IGT are at increased risk for development of type 2 DM later.

They can be used in population screening surveys. Urine is tested for the presence of glucose and ketones.

1. Glucosuria *Benedict's qualitative test* detects any reducing substance in the urine and is not specific for glucose. More sensitive and glucose specific test is *dipstick* method based on enzyme-coated paper strip which turns purple when dipped in urine containing glucose.

The main disadvantage of relying on urinary glucose test alone is the individual variation in renal threshold. Thus, a diabetic patient may have a negative urinary glucose test and a nondiabetic individual with low renal threshold may have a positive urine test.

Besides diabetes mellitus, *glucosuria* may also occur in certain other conditions such as: renal glycosuria, alimentary (lag storage) glucosuria, many metabolic disorders, starvation and intracranial lesions (e.g. cerebral tumour, haemorrhage and head injury). However, two of these conditions—renal glycosuria and alimentary glucosuria, require further elaboration here.

◆ *Renal glycosuria* (Fig. 25.27,B): After diabetes, the next most common cause of glucosuria is the reduced renal threshold for glucose. In such cases although the blood glucose level is below 180 mg/dl (i.e. below normal renal threshold for glucose) but glucose still appears regularly and consistently in the urine due to lowered renal threshold.

Renal glycosuria is a benign condition unrelated to diabetes and runs in families and may occur temporarily in pregnancy without symptoms of diabetes.

◆ *Alimentary (lag storage) glucosuria* (Fig. 25.27,C): A rapid and transitory rise in blood glucose level above the normal renal threshold may occur in some individuals after a meal. During this period, glucosuria is present. This type of response to meal is called 'lag storage curve' or more appropriately 'alimentary glucosuria'. A characteristic feature is that unusually high blood glucose level returns to normal 2 hours after meal.

2. Ketonuria Tests for ketone bodies in the urine are required for assessing the severity of diabetes and not for diagnosis of diabetes. However, if both glucosuria and ketonuria are present, diagnosis of diabetes is almost certain. *Rothera's test* (nitroprusside reaction) and *strip test* are conveniently performed for detection of ketonuria.

Besides uncontrolled diabetes, ketonuria may appear in individuals with prolonged vomitings, fasting state or exercising for long periods.

II. SINGLE BLOOD SUGAR ESTIMATION For diagnosis of diabetes, blood sugar determinations are absolutely necessary. *Folin-Wu method* of measurement of all reducing substances in the blood including glucose is now obsolete. Currently used are *O-toluidine*, *Somogyi-Nelson* and *glucose oxidase* methods. Whole blood or plasma may be used but *whole blood values are 15% lower than plasma values*.

A grossly elevated single determination of plasma glucose may be sufficient to make the diagnosis of diabetes. A *fasting plasma glucose value above 126 mg/dl (≥ 7 mmol/L) is certainly indicative of diabetes*. In other cases, oral GTT is performed.

III. SCREENING BY FASTING GLUCOSE TEST Fasting plasma glucose determination is a screening test for DM type 2. It is recommended that all individuals above 45 years of age must undergo screening fasting glucose test every 3-years, and relatively earlier if the person is overweight or at risk because of the following reasons:

- Many of the cases meeting the current criteria of DM are asymptomatic and do not know that they have the disorder.
- Studies have shown that type 2 DM may be present for about 10 years before symptomatic disease appears.
- About half the cases of type 2 DM have some diabetes-related complication at the time of diagnosis.
- Course of the disease is favourably altered with treatment.

IV. ORAL GLUCOSE TOLERANCE TEST Oral GTT is performed principally for patients with borderline fasting plasma glucose value (i.e. between 100 and 140 mg/dl). The patient who is scheduled for oral GTT is instructed to eat a high carbohydrate diet for at least 3 days prior to the test and come after an overnight fast on the day of the test (for at least 8 hours). A fasting blood sugar sample is first drawn. Then 75 gm of glucose dissolved in 300 ml of water is given. Blood and urine specimen are collected at half-hourly intervals for at least 2 hours. Blood or plasma glucose content is measured and urine is tested for glucosuria to determine the approximate renal threshold for glucose. Venous whole blood concentrations are 15% lower than plasma glucose values.

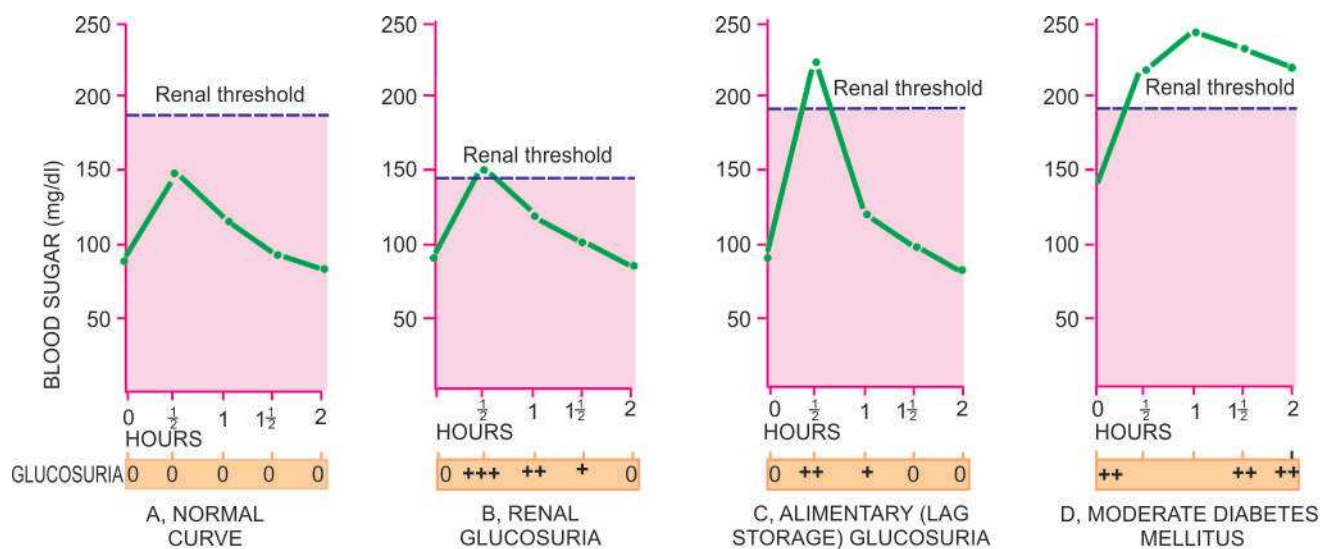

Figure 25.27 The glucose tolerance test, showing blood glucose curves (venous blood glucose) and glucosuria after 75 gm of oral glucose.

Currently accepted criteria for diagnosis of DM (as per American Diabetes Association, 2007) are given in **Table 25.8**:

- ◆ Normal cut off value for fasting blood glucose level is considered as 100 mg/dl.
- ◆ Cases with fasting blood glucose value in range of 100-125 mg/dl are considered as *impaired fasting glucose tolerance (IGT)*; these cases are at increased risk of developing diabetes later and therefore kept under observation for repeating the test. During pregnancy, however, a case of IGT is treated as a diabetic.
- ◆ Individuals with fasting value of plasma glucose higher than 126 mg/dl and 2-hour value after 75 gm oral glucose higher than 200 mg/dl are labelled as *diabetics* (**Fig. 25.27,D**).
- ◆ In symptomatic case, the random blood glucose value above 200 mg/dl is diagnosed as diabetes mellitus.

V. OTHER TESTS A few other tests are sometimes performed in specific conditions in diabetics and for research purposes:

1. Glycosylated haemoglobin (HbA_{1C}) Measurement of blood glucose level in diabetics suffers from variation due to dietary intake of the previous day. Long-term objective assessment of degree of glycaemic control is better monitored by measurement of glycosylated haemoglobin (HbA_{1C}), a minor haemoglobin component present in normal persons. This is because the non-enzymatic glycosylation of haemoglobin takes place over 90-120 days, lifespan of red blood cells. HbA_{1C} assay, therefore, gives an estimate of diabetic control and compliance for the preceding 3-4 months. This assay has the advantage over traditional blood glucose test that no dietary preparation or fasting is required. Increased HbA_{1C} value almost certainly means DM but normal value does not rule out IGT; thus the test is not used for making the diagnosis of DM. Moreover, since HbA_{1C} assay has a direct relation between poor control and development of complications, it is also a good measure of prediction of microvascular complications. Care must be taken in interpretation of the HbA_{1C} value because it varies with the assay method used and is affected by presence of haemoglobinopathies, anaemia, reticulocytosis, transfusions and uraemia.

2. Glycated albumin This is used to monitor degree of hyperglycaemia during previous 1-2 weeks when HbA_{1C} can not be used.

3. Extended GTT The oral GTT is extended to 3-4 hours for appearance of symptoms of hyperglycaemia. It is a useful test in cases of reactive hypoglycaemia of early diabetes.

4. Intravenous GTT This test is performed in persons who have intestinal malabsorption or in postgastrectomy cases.

5. Cortisone-primed GTT This provocative test is a useful investigative aid in cases of potential diabetics.

6. Insulin assay Plasma insulin can be measured by radio-immunoassay and ELISA technique. Plasma insulin deficiency is crucial for type 1 DM but is not essential for making the diagnosis of DM.

7. Proinsulin assay Proinsulin is included in immunoassay of insulin; normally it is $\leq 20\%$ of total insulin.

8. C-peptide assay C-peptide is released in circulation during conversion of proinsulin to insulin in equimolar quantities to insulin; thus its levels correlate with insulin level

in blood except in islet cell tumours and in obesity. This test is even more sensitive than insulin assay because its levels are not affected by insulin therapy.

9. Islet autoantibodies Glutamic acid decarboxylase and islet cell cytoplasmic antibodies may be used as a marker for type 1 DM.

10. Screening for diabetes-associated complications Besides making the diagnosis of DM based on the defined criteria, screening tests are done for DM-associated complications e.g. microalbuminuria, dyslipidaemia, thyroid dysfunction etc.

ISLET CELL TUMOURS

Islet cell tumours are rare as compared with tumours of the exocrine pancreas. Islet cell tumours are generally small and may be hormonally inactive or may produce hyperfunction. They may be benign or malignant, single or multiple. They are named according to their histogenesis such as: β -cell tumour (insulinoma), G-cell tumour (gastrinoma), A-cell tumour (glucagonoma) D-cell tumour (somatostatinoma), vipoma (diarrhoeagenic tumour from D₁ cells which elaborate VIP), pancreatic polypeptide (PP)-secreting tumour, and carcinoid tumour. However, except insulinoma and gastrinoma, all others are extremely rare and require no further comments.

INSULINOMA (β -CELL TUMOUR)

Insulinomas or beta (β)-cell tumours are the most common islet cell tumours. The neoplastic β -cells secrete insulin into the blood stream which remains unaffected by normal regulatory mechanisms. This results in characteristic attacks of hypoglycaemia with blood glucose level falling to 50 mg/dl or below, high plasma insulin level (hyperinsulinism) and high insulin-glucose ratio. The central nervous manifestations are conspicuous which are promptly relieved by intake of glucose. Besides insulinoma, however, there are other causes of hypoglycaemia such as: in starvation, partial gastrectomy, diffuse liver disease, hypopituitarism and hypofunction of adrenal cortex.

MORPHOLOGIC FEATURES *Grossly*, insulinoma is usually solitary and well-encapsulated tumour which may vary in size from 0.5 to 10 cm. Rarely, they are multiple.

Microscopically, the tumour is composed of cords and sheets of well-differentiated β -cells which do not differ from normal cells. Electron microscopy reveals typical crystalline rectangular granules in the neoplastic cells. It is extremely difficult to assess the degree of anaplasia to distinguish benign from malignant β -cell tumour.

GASTRINOMA (G-CELL TUMOUR, ZOLLINGER-ELLISON SYNDROME)

Zollinger and Ellison described diagnostic triad consisting of the following:

- i) Fulminant peptic ulcer disease
- ii) Gastric acid hypersecretion
- iii) Presence of non- β pancreatic islet cell tumour.

Such non- β pancreatic islet cell tumour is the source of gastrin, producing hypergastrinaemia and hence named gastrinoma. Definite G cells similar to intestinal and gastric

G cells which are normally the source of gastrin in the body, have not been identified in the normal human pancreas but neoplastic cells of certain islet cell tumours have ultrastructural similarities.

MORPHOLOGIC FEATURES Majority of gastrinomas occur in the wall of the duodenum. They may be benign or malignant. Gastrinomas are associated with peptic ulcers at usual sites such as the stomach, first and second part of the duodenum, or sometimes at unusual sites such as in the oesophagus and jejunum. About one-third of patients have multiple endocrine neoplasia—multiple adenomas of the islet cells, pituitary, adrenal and parathyroid glands.

GIST BOX 25.6 Tumours and Tumour-like Lesions

- ☐ Diabetes mellitus is a heterogeneous metabolic disorder characterised by common feature of chronic hyperglycaemia with disturbance of carbohydrate, fat and protein metabolism.
- ☐ Based on etiology, DM is classified into type 1 and type 2.
- ☐ Type 1 occurs commonly in patients under 30 years of age and has autoimmune pathogenesis. Type 2 comprises about 80% cases of DM and predominantly affects older individuals and is complex multifactorial disease with greater role of genetic defect and heredity.
- ☐ Both types of DM may develop complications. These may be acute metabolic complications (e.g. diabetic ketoacidosis, hyperosmolar nonketotic coma, and hypoglycaemia) and late systemic complications (e.g. atherosclerosis, diabetic microangiopathy, diabetic nephropathy, diabetic neuropathy, diabetic retinopathy and infections).
- ☐ Diagnostic criteria have been developed, most important of which is blood glucose level: fasting value of plasma glucose higher than 126 mg/dl and 2-hour value after 75 gm oral glucose higher than 200 mg/dl are labelled as diabetics.
- ☐ Islet cell tumours are rare; examples are insulinoma and gastrinoma.

MISCELLANEOUS ENDOCRINE TUMOURS

MULTIPLE ENDOCRINE NEOPLASIA (MEN) SYNDROMES

Multiple adenomas and hyperplasias of different endocrine organs are a group of genetic disorders which produce heterogeneous clinical features called multiple endocrine neoplasia (MEN) syndromes. These are MEN type 1 and type 2 and mixed type:

1. MEN type 1 syndrome (Wermer's syndrome) includes adenomas of the parathyroid glands, pancreatic islets and pituitary. The syndrome is inherited as an autosomal dominant trait. There is 50% chance of transmitting the predisposing gene, *MEN 1* (or *menin*) gene, to the child of an affected person. MEN 1 is characterised by the following features:

1. **Parathyroid:** Hyperplasia or adenoma; hyperparathyroidism is the most common (90%) clinical manifestation.
2. **Pancreatic islet cells:** Hyperplasia or adenoma seen in 80% cases; frequently with Zollinger-Ellison syndrome.
3. **Pituitary:** Hyperplasia or adenoma in 65% cases; manifest as acromegaly or hypopituitarism.
4. **Adrenal cortex:** Uncommonly involved by adenoma or pheochromocytoma.
5. **Thyroid:** Less commonly involved by adenoma or hyperplasia.

2. MEN type 2 syndrome (Sipple's syndrome) is characterised by medullary carcinoma thyroid and pheochromocytoma. Genetic abnormality in these cases is mutation in *RET* gene in almost all cases. MEN 2 has two major syndromes:

◆ **MEN type 2A** is the combination of medullary carcinoma thyroid, pheochromocytoma and hyperparathyroidism. MEN type 2A has further *three subvariants*:

- i) MEN 2A with familial medullary carcinoma thyroid
- ii) MEN 2A with cutaneous lichen amyloidosis
- iii) MEN 2A with Hirschsprung's disease.

◆ **MEN type 2B** the combination of medullary carcinoma thyroid, pheochromocytoma, mucosal neuromas, intestinal ganglioneuromatosis, and marfanoid features.

3. Mixed syndromes include a variety of endocrine neoplastic combinations which are distinct from those in MEN type 1 and type 2. A few examples are as under:

- i) von Hippel-Lindau syndrome from mutation in *VHL* gene is association of CNS tumours, renal cell carcinoma, pheochromocytoma and islet cell tumours.
- ii) Type 1 neurofibromatosis from inactivation of neurofibromin protein and activation of *RAS* gene, is associated with MEN type 1 or type 2 features.

POLYGLANDULAR AUTOIMMUNE (PGA) SYNDROMES

Immunologic syndromes affecting two or more endocrine glands and some non-endocrine immune disturbances produce syndromic presentation termed polyglandular autoimmune (PGA) syndromes. PGA syndromes are of two types:

- ◆ PGA type I occurring in children is characterised by mucocutaneous candidiasis, hypoparathyroidism, and adrenal insufficiency.
- ◆ PGA type II (Schmidt syndrome) presents in adults and commonly comprises of adrenal insufficiency, autoimmune thyroiditis, and type 1 diabetes mellitus.

GIST BOX 25.7 Miscellaneous Endocrine Tumours

- ☐ Multiple adenomas and hyperplasias of different endocrine organs are a group of genetic disorders which produce heterogeneous clinical features called multiple endocrine neoplasia (MEN) syndromes. These are MEN type 1, MEN type 2, and mixed syndromes.
- ☐ Polyglandular autoimmune syndromes (PGA) affect two or more endocrine glands and some non-endocrine immune disturbances and has 2 types PGA type I and II.

✿ CLINICAL CASE 26

A 25 years old female presents with gradually progressive painless swelling in the midline of her neck for 6 months. She also complains of irregular and heavy periods, weight loss, intermittent headache, nervousness, palpitation, excessive sweating and tremors in both hands. Of late, her both eyes have also become prominent.

On physical examination, the thyroid gland is diffusely enlarged, non-tender and prominent but there is no nodularity. Her blood pressure is 140/90 mmHg and pulse rate is 100 per minute.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 913 (Appendix II)

✿ CLINICAL CASE 27

A 57 years old male, reports to his physician with complaints of intermittent fever for 3-4 months and pain in both legs and darkening of right great toe. He is a known case of diabetes for 7 years and hypertension for the last 10 years and has been on irregular treatment and intermittent follow up. He gives history of myocardial infarction 4 years back. He is not alcoholic or smoker.

On examination, the blood pressure is 130/94 mmHg, pulse rate 86 per minute. On auscultation, pericardial rub and bilateral crepts are heard.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 913 (Appendix II)

26

The Musculoskeletal System

SKELETAL SYSTEM

The skeleton consists of cartilage and bone. Cartilage has a role in growth and repair of bone, and in the adults forms the articular skeleton responsible for movement of joints. Bone is a specialised form of connective tissue which performs the function of providing mechanical support and is also a mineral reservoir for calcium homeostasis. There are 206 bones in the human body, and depending upon their size and shape may be long, flat, tubular etc.

NORMAL STRUCTURE OF BONE

Bone is divided into 2 components (Fig. 26.1):

◆ **Cortical or compact bone** comprises 80% of the skeleton and is the dense outer shell responsible for structural rigidity. It consists of Haversian canals with blood vessels surrounded by concentric layers of mineralised collagen forming osteons which are joined together by cement lines.

◆ **Trabecular or cancellous bone** composes 20% of the skeleton and has trabeculae traversing the marrow space. Its main role is in mineral homeostasis.

HISTOLOGY Bone consists of large quantities of extracellular osteoid matrix which is loaded with calcium hydroxyapatite and relatively small number of bone cells which are of 3 main types: osteoblasts, osteocytes and osteoclasts.

1. Osteoblasts Osteoblasts are uninucleate cells found abundantly along the new bone-forming surfaces. They synthesise bone matrix. The serum levels of bone-related *alkaline phosphatase* (other being hepatic alkaline phosphatase) is a marker for osteoblastic activity. Its levels are raised at

puberty during period of active bone growth and in pathologic conditions associated with high osteoblastic activity such as in fracture repair and Paget's disease of the bone.

2. Osteocytes Osteocytes are those osteoblasts which get incorporated into the bone matrix during its synthesis. Osteocytes are found within small spaces called lacunae lying in the bone matrix. The distribution of the osteocytic lacunae is a reliable parameter for distinguishing between woven and lamellar bone.

◆ *Woven bone* is immature and is rapidly deposited. It contains large number of closely-packed osteocytes and consists of irregular interlacing pattern of collagen fibre bundles in bone matrix. Woven bone is seen in foetal life and in children under 4 years of age.

◆ *Lamellar bone* differs from woven bone in having smaller and less numerous osteocytes and fine and parallel or lamellar sheets of collagen fibres. Lamellar bone usually replaces woven bone or pre-existing cartilage.

3. Osteoclasts Osteoclasts are large multinucleate cells of mononuclear-macrophage origin and are responsible for bone resorption. The osteoclastic activity is determined by bone-related serum *acid phosphatase* levels (other being prostatic acid phosphatase). Osteoclasts are found along the endosteal surface of the cortical (compact) bone and the trabeculae of trabecular (cancellous) bone.

4. Osteoid matrix The osteoid matrix of bone consists of 90-95% of collagen type I and comprises nearly half of total body's collagen. Virtually whole of body's hydroxyproline and hydroxylysine reside in the bone. The architecture of bone collagen reflects the rate of its synthesis and may be woven or lamellar, as described above.

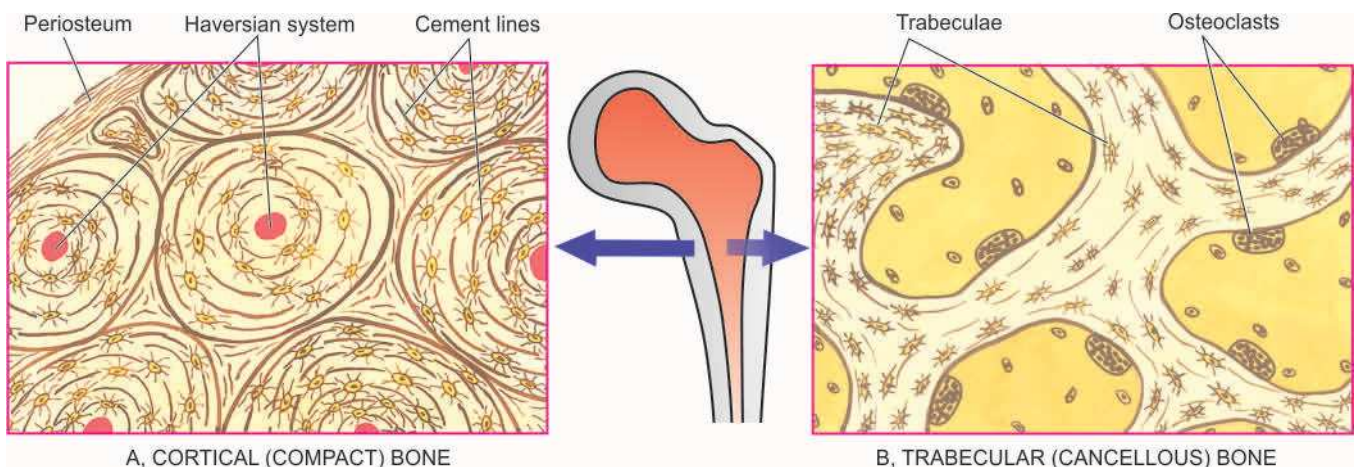

Figure 26.1 The normal structure of cortical (compact) bone (A) and trabecular (cancellous) bone (B) in transverse section. The cortical bone forming the outer shell shows concentric lamellae along with osteocytic lacunae surrounding central blood vessels, while the trabecular bone forming the marrow space shows trabeculae with osteoclastic activity at the margins.

BONE FORMATION AND RESORPTION Bone is not a static tissue but its formation and resorption are taking place during period of growth as well as in adult life. Bone deposition is the result of osteoblasts while bone resorption is the function of osteoclasts. Bone formation may take place directly from collagen called *membranous ossification* seen in certain flat bones, or may occur through an intermediate stage of cartilage termed *endochondral ossification* found in metaphysis of long bones. In either case, firstly an uncalcified osteoid matrix is formed by osteoblasts which is then mineralised in 12-15 days. This delay in mineralisation results in formation of about 15 µm thick osteoid seams at calcification fronts (About > 1 µm of matrix osteoid is formed daily). Uncalcified osteoid appears eosinophilic in H & E stains and does not stain with von Kossa reaction, while mineralised osteoid is basophilic in appearance and stains black with von Kossa reaction (a stain for calcium). Areas of active bone resorption have scalloped edges of bone surface called Howship's lacunae and contain multinucleated osteoclasts. In this way, osteoblastic formation and osteoclastic resorption continue to take place into adult life in a balanced way termed *bone modelling*. The important role of vitamin D₁, parathyroid hormone and calcitonin in calcium metabolism has already been discussed on page 806.

NORMAL STRUCTURE OF CARTILAGE

Unlike bone, the cartilage lacks blood vessels, lymphatics and nerves. It may have focal areas of calcification. Cartilage consists of 2 components: cartilage matrix and chondrocytes.

Cartilage matrix Like bone, cartilage too consists of organic and inorganic material. Inorganic material of cartilage is calcium hydroxyapatite similar to that in bone matrix but the organic material of the cartilage is distinct from the bone. It consists of very high content of water (80%) and remaining 20% consists of type II collagen and proteoglycans. High water content of cartilage matrix is responsible for function of articular cartilage and lubrication. Proteoglycans are macromolecules having proteins complexed with polysaccharides termed glycosaminoglycans. Cartilage glycosaminoglycans consist of chondroitin sulfate and keratan sulfate, the former being most abundant comprising 55-90% of cartilage matrix varying on the age of the cartilage.

Chondrocytes Primitive mesenchymal cells which form bone cells from chondroblasts which give rise to chondrocytes. However, calcified cartilage is removed by the osteoclasts.

Depending upon location and structural composition, cartilage is of 3 types:

1. *Hyaline cartilage* is the basic cartilaginous tissue comprising articular cartilage of joints, cartilage in the growth plates of developing bones, costochondral cartilage, cartilage in the trachea, bronchi and larynx and the nasal cartilage. Hyaline cartilage is the type found in most cartilage-forming tumours and in the fracture callus.
2. *Fibrocartilage* is a hyaline cartilage that contains more abundant type II collagen fibres. It is found in annulus fibrosus of intervertebral disc, menisci, insertions of joint capsules, ligament and tendons. Fibrocartilage may also be found in some cartilage-forming tumours and in the fracture callus.
3. *Elastic cartilage* is hyaline cartilage that contains abundant elastin. Elastic cartilage is found in the pinna of ears, epiglottis and arytenoid cartilage of the larynx.

Diseases of skeletal system include infection (osteomyelitis), disordered growth and development (skeletal dysplasias), metabolic and endocrine derangements, and tumours and tumour-like conditions.

GIST BOX 26.1

Normal Structure of Bone and Cartilage

- ☐ Bone is composed of cortical or compact bone (80%) which is the dense outer shell, and trabecular or cancellous bone (20%) which has trabeculae traversing the marrow space.
- ☐ Bone consists of extracellular osteoid matrix and bone cells (osteoblasts, osteocytes and osteoclasts).
- ☐ Cartilage consists of cartilage matrix and chondrocytes and lacks blood vessels, lymphatics and nerves. It may have focal areas of calcification.

INFECTION, NECROSIS, FRACTURE HEALING

OSTEOMYELITIS

An infection of the bone is termed osteomyelitis (myelo = marrow). A number of systemic infectious diseases may spread to the bone such as enteric fever, actinomycosis, mycetoma (madura foot), syphilis, tuberculosis and brucellosis. However, two of the conditions which produce significant pathologic lesions in the bone, namely pyogenic osteomyelitis and tuberculous osteomyelitis, are described below.

Pyogenic Osteomyelitis

Pyogenic or suppurative osteomyelitis is usually caused by bacterial infection and rarely by fungi. The profile of patients in developing and developed countries is different:

- ◆ In the developing countries of the world, it may occur by haematogenous route, most commonly in the long bones of infants and young children (5-15 years of age) (called haematogenous osteomyelitis).
- ◆ On the other hand, in the developed world, where institution of antibiotics is early and prompt, haematogenous spread of infection to the bone is uncommon; instead, direct extension of infection from the adjacent area, frequently involving the jaws and skull, is more common mode of spread.
- ◆ Bacterial osteomyelitis may be a complication at all ages in patients with compound fractures, surgical procedures involving prosthesis or implants, gangrene of a limb in diabetics, debilitation and immunosuppression.

Though any etiologic agent may cause osteomyelitis, *Staphylococcus aureus* is implicated in a vast majority of cases. Less frequently, other organisms such as streptococci, *Escherichia coli*, *Pseudomonas*, *Klebsiella* and anaerobes are involved. Mixed infections are common in post-traumatic cases of osteomyelitis. There may be transient bacteraemia preceding the development of osteomyelitis so that blood cultures may be positive.

Clinically, the child with acute haematogenous osteomyelitis has painful and tender limb. Fever, malaise and leucocytosis generally accompany the bony lesion. Radiologic examination confirms the bony destruction.

Occasionally, osteomyelitis remains undiscovered until it becomes chronic. Draining sinus tracts may form which may occasionally be the site for development of squamous carcinoma. Persistence, neglect and chronicity of osteomyelitis

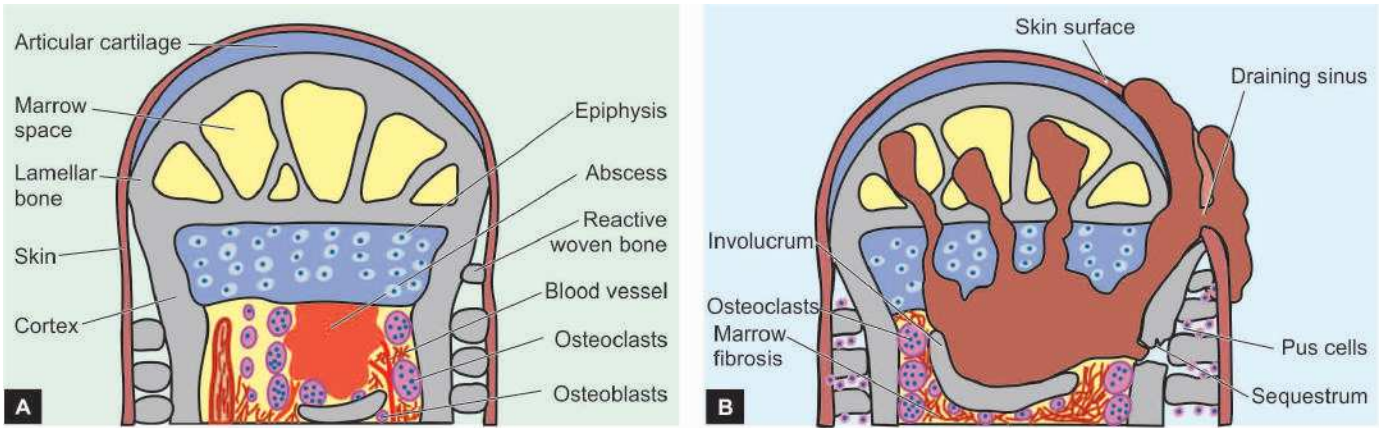

Figure 26.2 Pathogenesis of pyogenic osteomyelitis. A, The process begins as a focus of microabscess in a vascular loop in the marrow which expands to stimulate resorption of adjacent bony trabeculae. Simultaneously, there is beginning of reactive woven bone formation by the periosteum. B, The abscess expands further causing necrosis of the cortex called sequestrum. The formation of viable new reactive bone surrounding the sequestrum is called involucrum. The extension of infection into the joint space, epiphysis and the skin produces a draining sinus.

over a longer period of time may lead to development of amyloidosis.

MORPHOLOGIC FEATURES Depending upon the duration, osteomyelitis may be *acute*, *subacute* or *chronic*. The basic pathologic changes in any stage of osteomyelitis are: suppuration, ischaemic necrosis, healing by fibrosis and bony repair. The **sequence of pathologic changes** is as under (**Fig. 26.2**):

1. The infection begins in the metaphyseal end of the *marrow cavity* which is largely occupied by *pus*. At this stage, microscopy reveals congestion, oedema and an exudate of neutrophils.
2. The tension in the marrow cavity is increased due to pus and results in spread of infection along the marrow cavity, into the endosteum, and into the haversian and Volkmann's canal, causing *periosteitis*.
3. The infection may reach the subperiosteal space forming *subperiosteal abscesses*. It may penetrate through the cortex creating draining skin sinus tracts (**Fig. 26.3**).
4. Combination of suppuration and impaired blood supply to the cortical bone results in erosion, thinning and infarction necrosis of the cortex called *sequestrum*.

5. With passage of time, there is formation of new bone beneath the periosteum present over the infected bone. This forms an encasing sheath around the necrosed bone and is known as *involucrum*. Involucrum has irregular surface and has perforations through which discharging sinus tracts pass.

6. Long continued neo-osteogenesis gives rise to dense sclerotic pattern of osteomyelitis called *chronic sclerosing nonsuppurative osteomyelitis of Garré*.

7. Occasionally, acute osteomyelitis may be contained to a localised area and walled off by fibrous tissue and granulation tissue. This is termed *Brodie's abscess*.

8. In *vertebral pyogenic osteomyelitis*, infection begins from the disc (*discitis*) and spreads to involve the vertebral bodies (**Fig. 26.4,A**).

COMPLICATIONS Osteomyelitis may result in the following complications:

1. Septicaemia.
2. Acute bacterial arthritis.
3. Pathologic fractures.
4. Development of squamous cell carcinoma in long-standing cases.

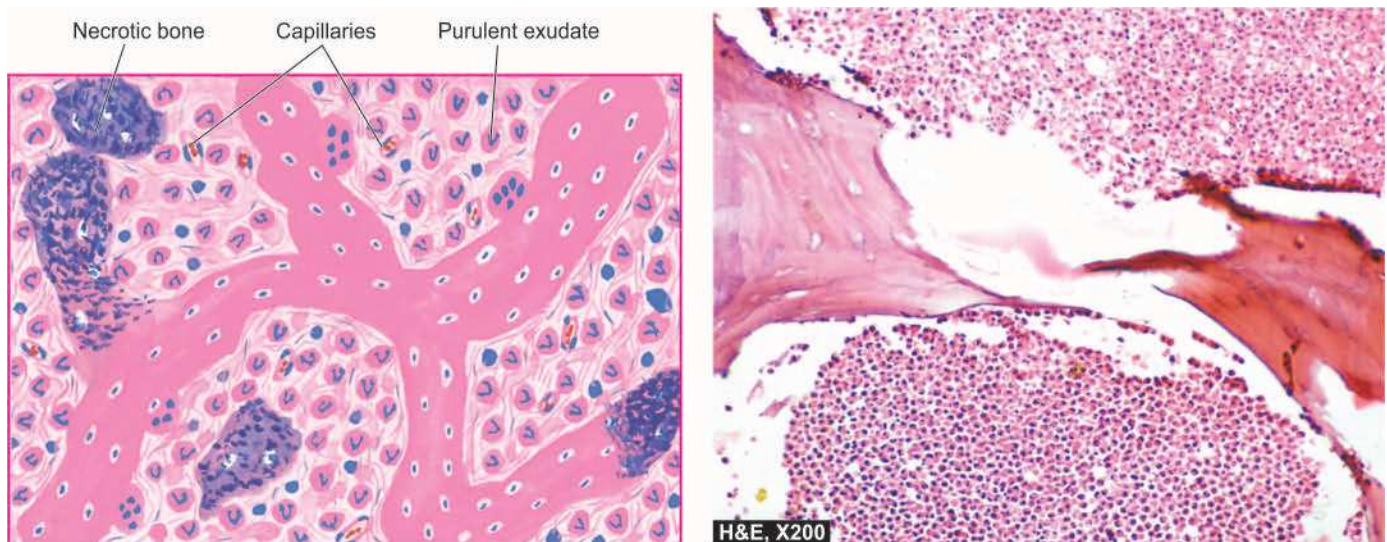

Figure 26.3 Chronic suppurative osteomyelitis. Histologic appearance shows necrotic bone and extensive purulent inflammatory exudate.

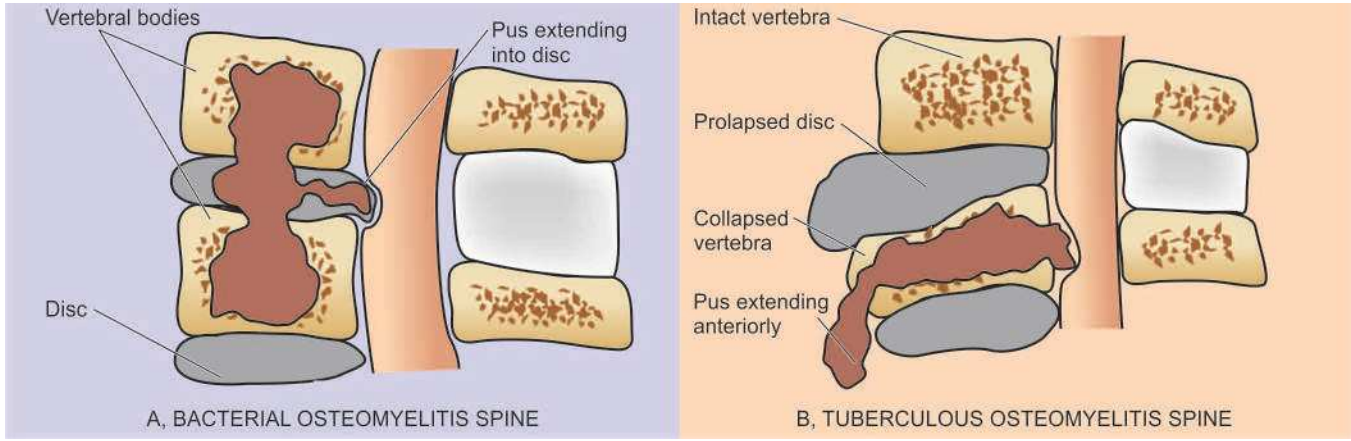

Figure 26.4 Osteomyelitis of the vertebral body.

5. Secondary amyloidosis in long-standing cases.
6. Vertebral osteomyelitis may cause vertebral collapse with paravertebral abscess, epidural abscess, cord compression and neurologic deficits.

Tuberculous Osteomyelitis

Tuberculous osteomyelitis, though rare in developed countries, continues to be a common condition in under-developed and developing countries of the world. The tubercle bacilli, *M. tuberculosis*, reach the bone marrow and synovium most commonly by haematogenous dissemination from infection elsewhere, usually from the lungs, and infrequently by direct extension from the pulmonary or gastrointestinal tuberculosis (page 143). The disease affects adolescents and young adults more often. Most frequently involved are the spine and bones of extremities.

MORPHOLOGIC FEATURES The bone lesions in tuberculosis have the same general histological appearance as in tuberculosis elsewhere and consist of central caseation necrosis surrounded by tuberculous granulation tissue and fragments of necrotic bone (Fig. 26.5). The tuberculous lesions appear as a focus of bone destruction and replacement of the affected tissue by caseous material and formation of multiple discharging sinuses through the soft tissues and skin. Involvement of joint spaces and intervertebral disc are frequent. Tuberculosis of the spine, *Pott's disease*, often commences in the vertebral body and may be associated with compression fractures and destruction of intervertebral discs, producing permanent damage and paraplegia. Extension of caseous material along with pus from the lumbar vertebrae to the sheaths of psoas muscle produces *psoas abscess* or *lumbar cold abscess* (Fig. 26.4,B). The cold abscess may burst through the skin and form sinus. Long-standing cases may develop systemic amyloidosis.

AVASCULAR NECROSIS (OSTEONECROSIS)

Avascular necrosis of the bones or osteonecrosis results from ischaemia. It is a relatively common condition.

ETIOPATHOGENESIS Some of the common causes are as follows:

1. Fracture or dislocation

2. Sickle cell disease
3. Corticosteroid administration
4. Radiation therapy
5. Chronic alcoholism
6. Idiopathic

The mechanism of osteonecrosis in many cases remains obscure, while in others it is by interruption in the blood supply to the bones induced by direct trauma, compression, or thromboembolic obstruction.

MORPHOLOGIC FEATURES There are pathological fractures of the involved bone due to infarcts. Most common sites are the ones where the disruption in blood supply is at end-arterial circulation. The infarcts mainly involve the medulla of the long bone in the diaphysis. This is because the nutrient arteries supply blood to sinusoids of the medulla and the inner cortex after penetrating the cortex, while the cortex is relatively unaffected due to collateral circulation.

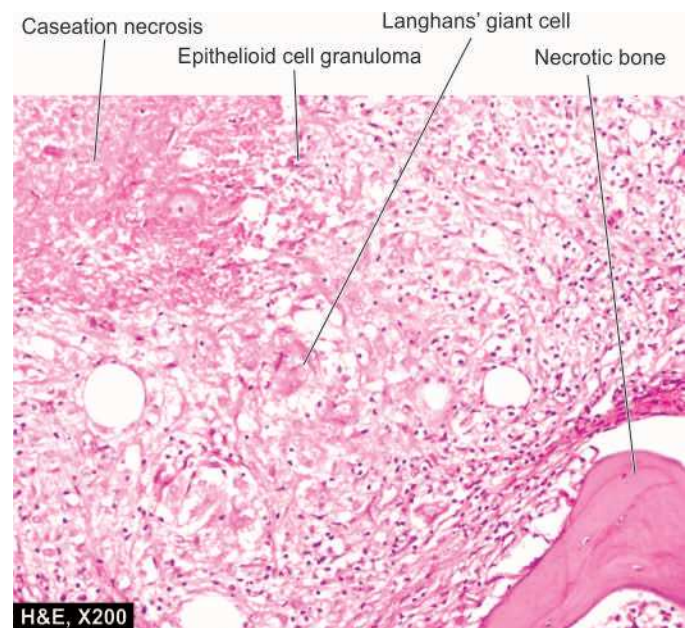

Figure 26.5 Tuberculous osteomyelitis. There are epithelioid cell granulomas with minute areas of caseation necrosis and surrounded by Langhans' giant cells. Pieces of necrotic bone are also seen.

Grossly, the lesional area shows a wedge-shaped area of infarction in the subchondral bone under the convex surface of the joint.

Microscopically, the infarcted medulla shows saponified marrow fat. The overlying cartilage and the cortex of the long bones are relatively unaffected.

Long-term sequelae of osteonecrosis include occurrence of malignant tumours in this location such as osteosarcoma, malignant fibrous histiocytoma and fibrosarcoma etc.

FRACTURE HEALING

Fracture of the bone initiates a series of tissue changes which eventually lead to restoration of normal structure and function of the affected bone. Fracture of a bone is commonly associated with injury to the soft tissues. The various types of fractures and their mechanism of healing are discussed along with healing of specialised tissues in Chapter 5 (page 161).

GIST BOX 26.2 Infection, Necrosis, Fracture Healing

- ▣ Suppurative or pyogenic osteomyelitis is usually caused by bacterial infection and rarely by fungi. It may be by haematogenous route or by direct spread of infection.
- ▣ Tuberculous osteomyelitis continues to be a common condition in developing countries of the world, either by haematogenous spread or by direct spread from adjacent focus.
- ▣ Avascular necrosis or osteonecrosis results from ischaemia and may occur be idiopathic or result from steroid administration, alcoholism etc.
- ▣ Healing of fractures occurs by callus formation, either as a primary or secondary union.

DISORDERS OF BONE GROWTH AND DEVELOPMENT

A number of abnormalities of the skeleton are due to disordered bone growth and development and are collectively termed *skeletal dysplasias*. These include both local and systemic disorders.

◆ *Local defects* involve a single bone or a group of bones such as: absence or presence in diminished form, fused with neighbouring bones (e.g. syndactyly), and formation of extra bones (e.g. supernumerary ribs).

◆ However, more importantly, skeletal dysplasias include *systemic disorders* involving particular epiphyseal growth plate. These include: achondroplasia (disorder of chondroblasts), osteogenesis imperfecta (disorder of osteoblasts), osteopetrosis (disorder of osteoclasts) and foetal rickets (disorder of mineralisation). Though multiple exostoses (osteochondromas) is a hereditary lesion, it is described later along with solitary sporadic exostosis on page 835.

ACHONDROPLASIA

Achondroplasia is an autosomal dominant genetic abnormality. There is selective interference with normal endochondral ossification at the level of epiphyseal cartilaginous growth plates of long bones. Thus, the long bones are abnormally short

but the skull grows normally leading to relatively large skull. Achondroplasia is the commonest cause of dwarfism.

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta is an autosomal dominant or recessive disorder of synthesis of type I collagen that constitutes 90-95% of bone matrix. The disorder, thus, involves not only the skeleton but other extra-skeletal tissues as well containing type I collagen such as sclera, eyes, joints, ligaments, teeth and skin. The skeletal manifestations of osteogenesis imperfecta are due to defective osteoblasts which normally synthesise and irregular trabeculae (*too little bone*) so that the bones are very fragile and liable to multiple fractures. The growth plate cartilage is, however, normal. The condition may be evident at birth (osteogenesis imperfecta congenita) when it is more severe, or may appear during adolescence (osteogenesis imperfecta tarda) which is a less incapacitating form. Extra-skeletal lesions of osteogenesis imperfecta include blue and translucent sclerae, hearing loss due to bony abnormalities of the middle and inner ear, and imperfect teeth.

OSTEOPETROSIS

Osteopetrosis, also called *marble bone disease*, is an autosomal dominant or recessive disorder of increased skeletal mass or osteosclerosis caused by a hereditary defect in osteoclast function. The condition may appear in 2 forms: autosomal recessive (malignant infantile form) and autosomal dominant (benign adult form). Failure of normal osteoclast function of bone resorption coupled with continued bone formation and endochondral ossification results in net overgrowth of calcified dense bone (*too much bone*) which occupies most of the available marrow space. Despite increased density of the bone, there is poor structural support so that the skeleton is susceptible to fractures. Besides the skeletal abnormalities, the infantile malignant form is characterised by effects of marrow obliteration such as anaemia, neutropenia, thrombocytopenia, hepatosplenomegaly with extramedullary haematopoiesis, hydrocephalus and neurologic involvement with consequent deafness, optic atrophy and blindness. Metabolically, hypocalcaemia occurs due to defective osteoclast function.

Histologically, the number of osteoclasts is increased which have dysplastic, bizarre and irregular nuclei and are dysfunctional.

GIST BOX 26.3 Skeletal Dysplasias

- ▣ Disordered bone growth and development cause skeletal dysplasias which may be as local or systemic defects.
- ▣ Achondroplasia is form of dwarfism in which there is selective interference with normal endochondral ossification at the level of epiphyseal cartilaginous growth plates of long bones.
- ▣ Osteogenesis imperfecta is an autosomal dominant or recessive disorder of synthesis of type I collagen involving the skeleton (*too little bone*) and extra-skeletal tissues.
- ▣ Osteopetrosis or marble bone disease, is an autosomal disorder of increased skeletal mass (*too much bone*) caused by a hereditary defect in osteoclast function.

METABOLIC AND ENDOCRINE BONE DISEASES

A large number of metabolic and endocrine disorders produce generalised skeletal disorders. These include the following:

1. **Osteoporosis**—Resulting from quantitative reduction in otherwise normal bone.
2. **Osteomalacia and rickets**—Characterised by qualitative abnormality in the form of impaired bone mineralisation due to deficiency of vitamin D in adults and children respectively (page 244).
3. **Scurvy**—Caused by deficiency of vitamin C resulting in subperiosteal haemorrhages (page 246).
4. **Hyperparathyroidism**—Leading to osteitis fibrosa cystica (page 806).
5. **Pituitary dysfunctions**—Hyperpituitarism causing gigantism and acromegaly and hypopituitarism resulting in dwarfism (page 784).
6. **Thyroid dysfunctions**—Hyperthyroidism causing osteoporosis and hypothyroidism leading to cretinism (page 793).
7. **Renal osteodystrophy**—Occurring in chronic renal failure and resulting in features of osteitis fibrosa cystica, osteomalacia and areas of osteosclerosis.
8. **Skeletal fluorosis**—Occurring due to excess of sodium fluoride content in the soil and water in an area.

Many of the conditions listed above have been discussed in respective chapters already; others are considered below.

OSTEOPOROSIS

Osteoporosis or osteopenia is a common clinical syndrome involving multiple bones in which there is quantitative reduction of bone tissue mass but the bone tissue mass is otherwise normal. This reduction in bone mass results in fragile skeleton associated with increased risk of fractures and consequent pain and deformity. The condition is particularly common in elderly people and more frequent in postmenopausal women. The condition may remain asymptomatic or may cause only backache. However, more extensive involvement is associated with fractures, particularly of distal radius, femoral neck and vertebral bodies. Osteoporosis may be difficult to distinguish radiologically from other osteopenias such as osteomalacia, osteogenesis imperfecta, osteitis fibrosa of hyperparathyroidism, renal osteodystrophy and multiple myeloma. Radiologic evidence becomes apparent only after more than 30% of bone mass has been lost. Levels of serum calcium, inorganic phosphorus and alkaline phosphatase are usually within normal limits.

Many non-invasive techniques are now available for measurement of bone mass e.g. DEXA and SEXA scans (dual-energy and single-energy X-ray absorptiometry), quantitative CT and ultrasound.

PATHOGENESIS Osteoporosis is conventionally classified into 2 major groups: primary and secondary.

◆ **Primary osteoporosis** results primarily from osteopenia without an underlying disease or medication. Primary osteoporosis is further subdivided into 2 types: *idiopathic type* found in the young and juveniles and is less frequent, and *involutional type* seen in postmenopausal women and ageing individuals and is more common. The exact mechanism of

primary osteoporosis is not known but there is a suggestion that it is the result of an excessive osteoclastic resorption and slow bone formation. A number of risk factors have been attributed to cause this imbalance between bone resorption and bone formation. These include the following:

1. *Genetic factors*—more marked in whites and Asians than blacks.
2. *Sex*—more frequent in females than in males.
3. *Reduced physical activity*—as in old age.
4. *Deficiency of sex hormones*—oestrogen deficiency in women as in postmenopausal osteoporosis and androgen deficiency in men.
5. *Combined deficiency of calcitonin and oestrogen*.
6. *Hyperparathyroidism*.
7. *Deficiency of vitamin D*.
8. *Local factors*—which may stimulate osteoclastic resorption or slow osteoblastic bone formation.

◆ **Secondary osteoporosis** is attributed to a number of factors and conditions (e.g. immobilisation, chronic anaemia, acromegaly, hepatic disease, hyperparathyroidism, hypogonadism, thyrotoxicosis and starvation), or as an effect of medication (e.g. hypercortisonism, administration of anticonvulsant drugs and large dose of heparin).

MORPHOLOGIC FEATURES Except disuse or immobilisation osteoporosis which is localised to the affected limb, other forms of osteoporosis have systemic skeletal distribution. Most commonly encountered osteoporotic fractures are: vertebral crush fracture, femoral neck fracture and wrist fracture. There is enlargement of the medullary cavity and thinning of the cortex.

Histologically, osteoporosis may be active or inactive type.

◆ **Active osteoporosis** is characterised by increased bone resorption and formation i.e. *accelerated turnover*. There is an increase in the number of osteoclasts with increased resorptive surface as well as increased quantity of osteoid with increased osteoblastic surfaces. The width of osteoid seams is normal.

◆ **Inactive osteoporosis** has the features of minimal bone formation and reduced resorptive activity i.e. *reduced turnover*. Histological changes of inactive osteoporosis include decreased number of osteoclasts with decreased resorptive surfaces, and normal or reduced amount of osteoid with decreased osteoblastic surface. The width of osteoid seams is usually reduced or may be normal.

OSTEITIS FIBROSA CYSTICA

Hyperparathyroidism of primary or secondary type results in oversecretion of parathyroid hormone which causes increased osteoclastic resorption of the bone. General aspects of hyperparathyroidism are discussed on page 807. Here, skeletal manifestations of hyperparathyroidism are considered. Severe and prolonged hyperparathyroidism results in osteitis fibrosa cystica. The lesion is generally induced as a manifestation of primary hyperparathyroidism, and less frequently, as a result of secondary hyperparathyroidism such as in chronic renal failure (renal osteodystrophy).

The clinical manifestations of bone disease in hyperparathyroidism are its susceptibility to fracture, skeletal deformities, joint pains and dysfunctions as a result of deranged weight bearing. The bony changes may disappear after cure of primary hyperparathyroidism such as removal of functioning adenoma. The chief biochemical abnormality of excessive parathyroid hormone is hypercalcaemia, hypophosphataemia and hypercalciuria.

MORPHOLOGIC FEATURES The bone lesions of primary hyperparathyroidism affect the long bones more severely and may range from minor degree of generalised bone rarefaction to prominent areas of bone destruction with cyst formation or brown tumours.

Grossly, there are focal areas of erosion of cortical bone and loss of lamina dura at the roots of teeth.

Histologically, the following sequential changes appear over a period of time:

- i) Earliest change is *demineralisation* and *increased bone resorption* beginning at the subperiosteal and endosteal surface of the cortex and then spreading to the trabecular bone.
- ii) There is replacement of bone and bone marrow by fibrosis coupled with increased number of bizarre osteoclasts at the surfaces of moth-eaten trabeculae and cortex (*osteitis fibrosa*).
- iii) As a result of increased resorption, microfractures and microhaemorrhages occur in the marrow cavity leading to development of cysts (*osteitis fibrosa cystica*).
- iv) Haemosiderin-laden macrophages and multinucleate giant cells appear at the areas of haemorrhages producing an appearance termed 'brown tumour' or 'reparative giant cell granuloma of hyperparathyroidism' requiring differentiation from giant cell tumour or osteoclastoma (page 837). However, the so-called brown tumours, unlike

osteoclastoma, are not true tumours but instead regress or disappear on surgical removal of hyperplastic or adenomatous parathyroid tissue.

RENAL OSTEODYSTROPHY (METABOLIC BONE DISEASE)

Renal osteodystrophy is a loosely used term that encompasses a number of skeletal abnormalities appearing in cases of chronic kidney disease and in patients treated by dialysis for several years (page 641). Renal osteodystrophy is more common in children than in adults. Clinical symptoms of bone disease in advanced renal failure appear in less than 10% of patients but radiologic and histologic changes are observed in fairly large proportion of cases.

PATHOGENESIS Renal osteodystrophy involves two main events: *hyperphosphataemia* and *hypocalcaemia* which, in turn, leads to parathormone elaboration and resultant osteoclastic activity and major lesions of renal osteodystrophy—osteomalacia (rickets in children), secondary hyperparathyroidism, osteitis fibrosa cystica, osteosclerosis and metastatic calcification.

The mechanisms underlying renal osteodystrophy are schematically illustrated in **Fig. 26.6** and briefly outlined below:

1. Hyperphosphataemia In CRF, there is impaired renal excretion of phosphate, causing phosphate retention and hyperphosphataemia. Hyperphosphataemia, in turn, causes hypocalcaemia which is responsible for secondary hyperparathyroidism.

2. Hypocalcaemia Hypocalcaemia may also result from the following:

- ◆ Due to renal dysfunction, there is decreased conversion of vitamin D metabolite 25(OH) cholecalciferol to its active form 1,25(OH)₂ cholecalciferol.
- ◆ Reduced intestinal absorption of calcium.

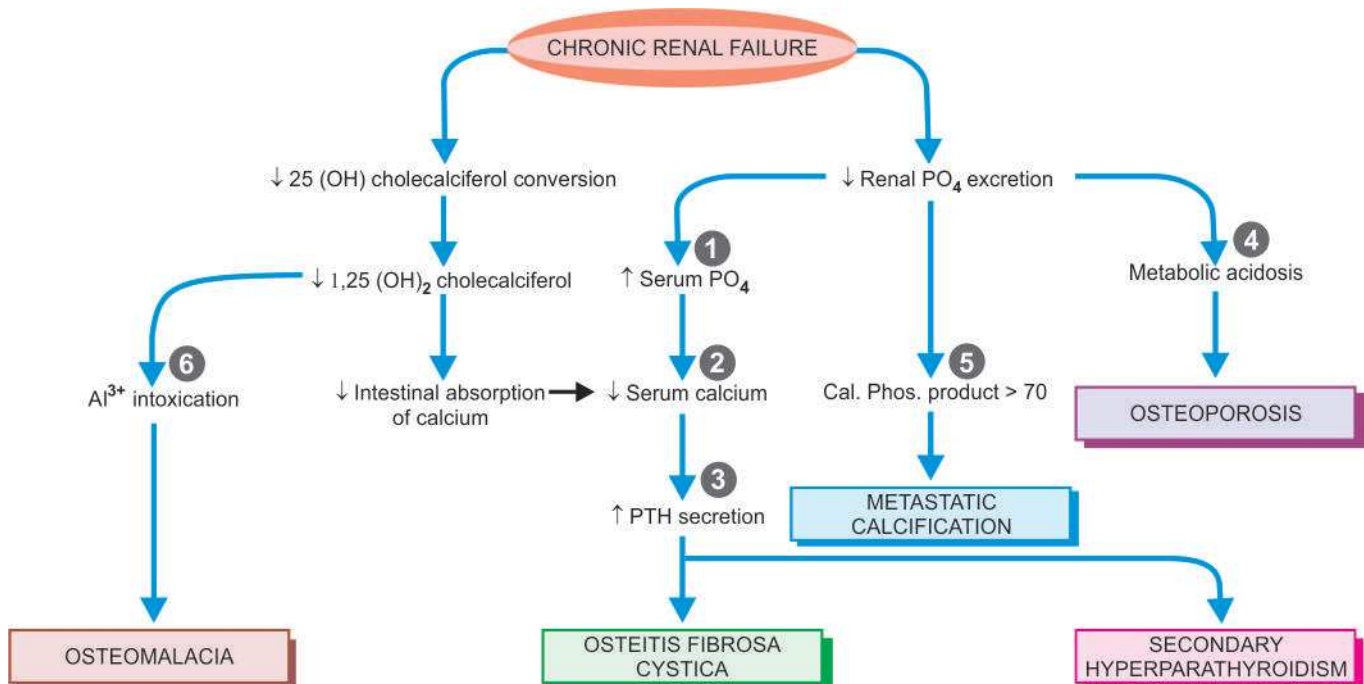

Figure 26.6 Pathogenesis of renal osteodystrophy in chronic renal failure. Circled serial numbers in the graphic representation correspond to the sequence described in the text under pathogenesis.

3. Parathormone secretion Hypocalcaemia stimulates secretion of parathormone, eventually leading to secondary hyperparathyroidism which, in turn, causes increased osteoclastic activity.

4. Metabolic acidosis As a result of decreased renal function, acidosis sets in which may cause osteoporosis and bone decalcification.

5. Calcium phosphorus product > 70 When the product of biochemical value of calcium and phosphate is higher than 70, metastatic calcification may occur at extrasosseous sites.

6. Dialysis-related metabolic bone disease Long-term dialysis employing use of aluminium-containing dialysate is currently considered to be a major cause of metabolic bone lesions. Aluminium interferes with deposition of calcium hydroxyapatite in bone and results in osteomalacia, secondary hyperparathyroidism and osteitis fibrosa cystica. In addition, accumulation of β_2 -microglobulin amyloid in such cases causes dialysis-related amyloidosis (page 71).

MORPHOLOGIC FEATURES The following skeletal lesions can be identified in renal osteodystrophy:

1. *Mixed osteomalacia-osteitis fibrosa* is the most common manifestation of renal osteodystrophy resulting from disordered vitamin D metabolism and secondary hyperparathyroidism.
2. *Pure osteitis fibrosa* results from metabolic complications of secondary hyperparathyroidism.
3. *Pure osteomalacia* of renal osteodystrophy is attributed to aluminium toxicity.
4. *Renal rickets* resembling the changes seen in children with nutritional rickets with widened osteoid seams may occur (page 244).
5. *Osteosclerosis* is characterised by enhanced bone density in the upper and lower margins of vertebrae.
6. *Metastatic calcification* is seen at extrasosseous sites such as in medium-sized blood vessels, periarticular tissues, myocardium, eyes, lungs and gastric mucosa (page 36).

SKELETAL FLUOROSIS

Fluorosis of bones occurs due to high sodium fluoride content in soil and water consumed by people in some geographic areas and is termed endemic fluorosis. Such endemic regions exist in some tropical and subtropical areas; in India it exists in some parts of Punjab and Andhra Pradesh. The condition affects farmers who consume drinking water from wells. Non-endemic fluorosis results from occupational exposure in manufacturing industries of aluminium, magnesium, and superphosphate.

PATHOGENESIS In fluorosis, fluoride replaces calcium as the mineral in the bone and gets deposited without any regulatory control. This results in heavily mineralised bones which are thicker and denser but are otherwise weak and deformed (just as in osteopetrosis). In addition, there are also deposits of fluoride in soft tissues, particularly as nodules in the interosseous membrane. The patient develops skeletal deformities and mottling of teeth.

MORPHOLOGIC FEATURES *Grossly*, the long bones and vertebrae develop nodular swellings which are present both inside the bones and on the surface.

Microscopically, these nodules are composed of heavily mineralised irregular osteoid admixed with fluoride which requires confirmation chemically.

PAGET'S DISEASE OF BONE (OSTEITIS DEFORMANS)

Paget's disease of bone* or osteitis deformans was first described by Sir James Paget in 1877. Paget's disease of bone is an osteolytic and osteosclerotic bone disease of uncertain etiology involving one (monostotic) or more bones (polyostotic). The condition affects predominantly males over the age of 50 years. Though the etiology remains obscure, following factors have been implicated:

1. There has been some evidence that osteitis deformans is a form of *slow-virus infection* by paramyxovirus (e.g. respiratory syncytial virus, measles) in osteoclasts. However, the virus has not been cultured from the osteoclasts of Paget's disease.
2. Autosomal dominant inheritance and *genetic susceptibility* have been proposed on the basis of observation of 7-10 fold higher prevalence of disease in first-degree relatives. The susceptibility gene located on chromosome 18q encodes for a member of tumour necrosis factor called *RANK* (receptor activator of nuclear factor κ B).

Clinically, the *monostotic form* of the disease may remain asymptomatic and the lesion is discovered incidentally or on radiologic examination. *Polyostotic form*, however, is more widespread and may produce pain, fractures, skeletal deformities, and occasionally, sarcomatous transformation. Typically, there is marked elevation of serum alkaline phosphatase and normal to high serum calcium level.

MORPHOLOGIC FEATURES Monostotic Paget's disease involves most frequently: tibia, pelvis, femur, skull and vertebra, while the order of involvement in polyostotic Paget's disease is: vertebrae, pelvis, femur, skull, sacrum and tibia. Three sequential stages are identified in Paget's disease:

1. **Initial osteolytic stage:** This stage is characterised by areas of osteoclastic resorption produced by increased number of large osteoclasts.
2. **Mixed osteolytic-osteoblastic stage:** In this stage, there is imbalance between osteoblastic laying down of new bone and osteoclastic resorption so that mineralisation of the newly-laid matrix lags behind, resulting in development of characteristic *mosaic pattern* or *jigsaw puzzle appearance* of osteoid seams or cement lines. The narrow space between the trabeculae and cortex is filled with collagen which gradually becomes less vascular.
3. **Quiescent osteosclerotic stage:** After many years, excessive bone formation results and thus the bone becomes more compact and dense producing osteosclerosis. However, newly-formed bone is poorly mineralised, soft and susceptible to fractures. Radiologically, this stage produces characteristic *cotton-wool appearance* of the affected bone.

*It is pertinent to recall here that James Paget described Paget's disease at three different anatomic sites which are not mutually interlinked in any way: Paget's disease of nipple (page 755), Paget's disease of vulva (page 711) and Paget's disease of bone.

GIST BOX 26.4

Metabolic and Endocrine Bone Diseases and Paget's Disease

- ▣ Osteoporosis or osteopenia is a common clinical condition involving multiple bones in which there is quantitative reduction of bone tissue mass resulting in fragile skeleton associated with increased risk of fractures.
- ▣ Severe and prolonged hyperparathyroidism results in osteitis fibrosa cystica.
- ▣ Renal osteodystrophy is appearance of skeletal abnormalities appearing in cases of chronic kidney disease. It involves hyperphosphataemia and hypocalcaemia.
- ▣ Skeletal fluorosis is due to consumption of high sodium fluoride content present in soil and water. In this, fluoride replaces calcium as the mineral in the bone and gets deposited without any regulatory control.
- ▣ Paget's disease of bone or osteitis deformans is an osteolytic and osteosclerotic bone disease of uncertain etiology involving one (monostotic) or more bones (polyostotic).

TUMOUR-LIKE LESIONS OF BONE

In the context of bones, several non-neoplastic conditions resemble true neoplasms and have to be distinguished from them clinically, radiologically and morphologically. **Table 26.1** gives a list of such tumour-like lesions. A few common conditions are described below.

FIBROUS DYSPLASIA

Fibrous dysplasia is not an uncommon tumour-like lesion of the bone. It is a benign condition, possibly of developmental origin, characterised by the presence of localised area of replacement of bone by fibrous connective tissue with a characteristic whorled pattern and containing trabeculae of woven bone. Radiologically, the typical focus of fibrous dysplasia has well-demarcated ground-glass appearance.

Three types of fibrous dysplasia are distinguished—monostotic, polyostotic, and Albright syndrome. The spectrum of phenotype of the disease is due to activating mutation in *GNAS1* gene, which encodes for α -subunits of the stimulatory G-protein, $G_{s\alpha}$.

◆ **Monostotic fibrous dysplasia** Monostotic fibrous dysplasia affects a solitary bone and is the most common type, comprising about 70% of all cases. The condition affects either sex and most patients are between 20 and 30 years of age. The bones most often affected, in descending order of frequency, are: ribs, craniofacial bones (especially maxilla), femur, tibia and humerus. The condition generally remains asymptomatic

and is discovered incidentally, but infrequently may produce tumour-like enlargement of the affected bone.

◆ **Polyostotic fibrous dysplasia** Polyostotic form of fibrous dysplasia affecting several bones constitutes about 25% of all cases. Both sexes are affected equally but the lesions appear at a relatively earlier age than the monostotic form. Most frequently affected bones are: craniofacial, ribs, vertebrae and long bones of the limbs. Approximately a quarter of cases with polyostotic form have more than half of the skeleton involved by disease. The lesions may affect one side of the body or may be distributed segmentally in a limb. Spontaneous fractures and skeletal deformities occur in childhood polyostotic form of the disease.

◆ **Albright syndrome** Also called McCune-Albright syndrome, this is a form of polyostotic fibrous dysplasia associated with endocrine dysfunctions and accounts for less than 5% of all cases. Unlike monostotic and polyostotic varieties, Albright syndrome is more common in females. The syndrome is characterised by polyostotic bone lesions, skin pigmentation (*café-au-lait* macular spots) and sexual precocity, and infrequently other endocrinopathies.

MORPHOLOGIC FEATURES All forms of fibrous dysplasia have an identical pathologic appearance.

Grossly, the lesions appear as sharply-demarcated, localised defects measuring 2-5 cm in diameter, present within the cancellous bone, having thin and smooth overlying cortex. The epiphyseal cartilages are generally spared in the monostotic form but involved in the polyostotic form of disease. Cut section of the lesion shows replacement of normal cancellous bone of the marrow cavity by gritty, grey-pink, rubbery soft tissue which may have areas of haemorrhages, myxoid change and cyst formation.

Histologically, the lesions of fibrous dysplasia have characteristic benign-looking fibroblastic tissue arranged in a loose, whorled pattern in which there are irregular and curved trabeculae of woven (non-lamellar) bone in the form fish-hook appearance or Chinese letter shapes. Characteristically, there are no osteoblasts rimming then trabeculae of the bone, suggesting a maturation defect in the bone (**Fig. 26.7**). Rarely, malignant change may occur in fibrous dysplasia, most often an osteogenic sarcoma.

FIBROUS CORTICAL DEFECT (METAPHYSEAL FIBROUS DEFECT, NON-OSSIFYING FIBROMA)

Fibrous cortical defect or metaphyseal fibrous defect is a rather common benign tumour-like lesion occurring in the metaphyseal cortex of long bones in children. Most commonly involved bones are upper or lower end of tibia or lower end of femur. The lesion is generally solitary but rarely there may be multiple and bilaterally symmetrical defects. Radiologically, the lesion is eccentrically located in the metaphysis and has a sharply-delimited border. The pathogenesis of fibrous cortical defect is unknown. Possibly, it arises as a result of some developmental defect at the epiphyseal plate, or could be a tumour of histiocytic origin because of close resemblance to fibrohistiocytic tumours (page 855).

Clinically, fibrous cortical defect causes no symptoms and is usually discovered accidentally when X-ray of the region is done for some other reason.

Table 26.1 Classification of tumour-like lesions of bone.

1. Fibrous dysplasia
2. Fibrous cortical defect (metaphyseal fibrous defect, non-ossifying fibroma)
3. Solitary bone cyst (simple or unicameral bone cyst)
4. Aneurysmal bone cyst
5. Ganglion cyst of bone (intraosseous ganglion)
6. Brown tumour of hyperparathyroidism (reparative granuloma) (page 826)
7. Langerhans' cell histiocytosis (Histiocytosis-X) (page 365)

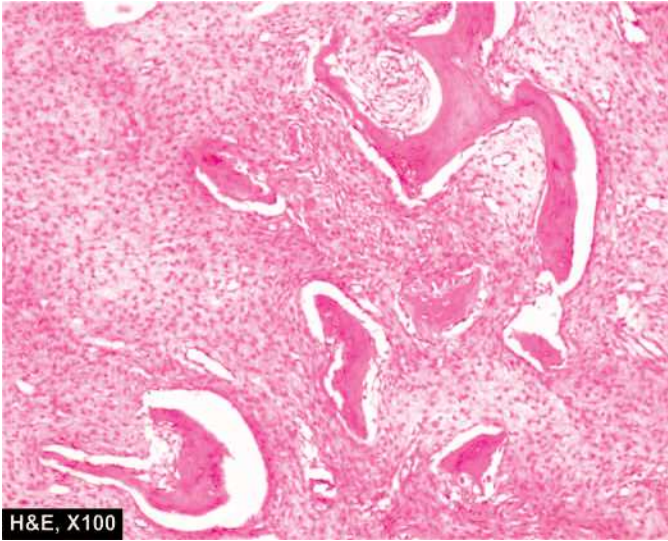

Figure 26.7 Fibrous dysplasia of the bone. The bony trabeculae have fish-hook appearance (or Chinese-letter appearance) surrounded by fibrous tissue. The osteoblastic rimming of the bony trabeculae are characteristically absent.

MORPHOLOGIC FEATURES *Grossly*, the lesion is generally small, less than 4 cm in diameter, granular and brown. Larger lesion (5-10 cm) occurring usually in response to trauma is referred to as *non-ossifying fibroma*.

Microscopically, fibrous cortical defect consists of cellular masses of fibrous tissue showing storiform pattern. There are numerous multinucleate osteoclast-like giant cells, haemosiderin-laden macrophages and foamy cells; hence the lesion is also termed histiocytic xanthogranuloma or fibrous xanthoma of bone.

SOLITARY (SIMPLE, UNICAMERAL) BONE CYST

Solitary, simple or unicameral bone cyst is a benign condition occurring in children and adolescents, most frequently located in the metaphyses at the upper end of humerus and femur. The cyst expands the bone causing thinning of the overlying cortex. Possibly, the lesion arises due to local disorder of bone growth and development. Clinically, solitary bone cyst may remain asymptomatic or may cause pain and fracture.

MORPHOLOGIC FEATURES *Grossly*, simple cyst of the bone is generally unilocular with smooth inner surface. The cavity is filled with clear fluid.

Histologically, the cyst wall consists of thin collagenous tissue having scattered osteoclast giant cells and newly formed reactive bony trabeculae. Fracture alters the appearance and produces sanguineous fluid in the cavity, and haemorrhages, haemosiderin deposits and macrophages in the cyst wall.

ANEURYSMAL BONE CYST

Aneurysmal bone cyst, true to its name, is an expanding osteolytic lesion filled with blood (*aneurysm* = dilatation, distension). The condition is seen more commonly in young patients under 30 years of age. Most frequently involved bones are shafts of metaphyses of long bones or the vertebral column. The radiographic appearance shows characteristic ballooned-out expansile lesion underneath the periosteum. Clinically, the aneurysmal bone cyst may enlarge over a period of years and produce pain, tenderness and pathologic fracture.

The pathogenesis is not clear but it has been suggested by some authors that the condition probably arises from persistent local alteration in haemodynamics. 17p13 translocation has been identified in these cases.

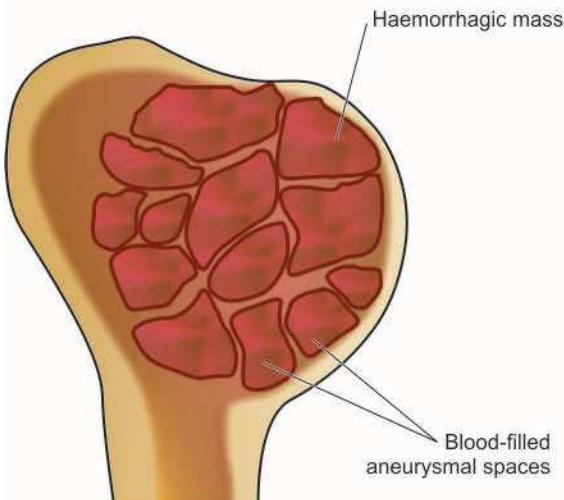

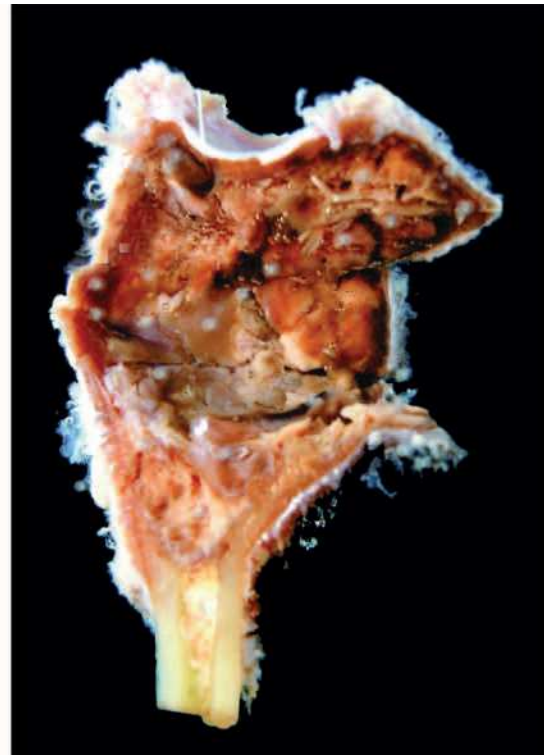

Figure 26.8 Aneurysmal bone cyst, ulna. The end of the long bone is expanded due to a cyst. The inner wall of the cyst is tan and haemorrhagic.

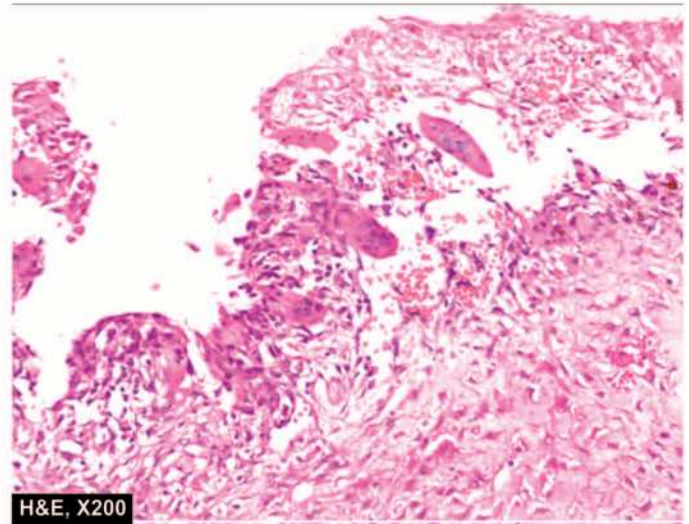

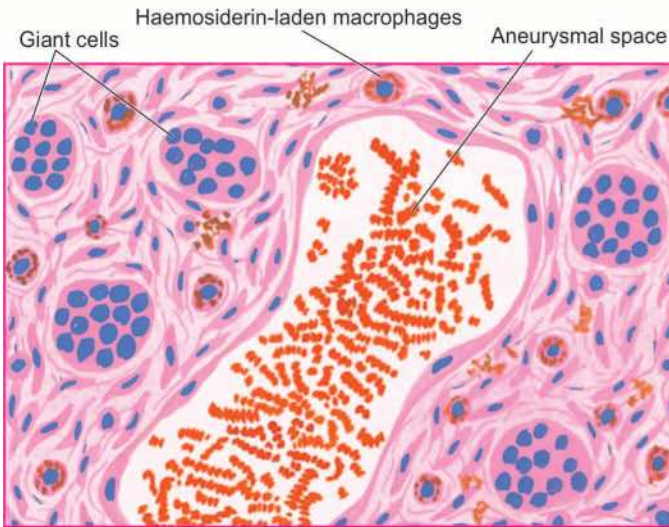

Figure 26.9 Aneurysmal bone cyst. Histologic hallmark of lesion is presence of aneurysmal spaces filled with blood, partly lined by endothelium and separated by connective tissue septa containing osteoclast-like giant cells along the wall of vascular spaces.

MORPHOLOGIC FEATURES *Grossly*, the lesion consists of a large haemorrhagic mass covered over by thinned out reactive bone (**Fig. 26.8**).

Histologically, the cyst consists of blood-filled aneurysmal spaces of variable size, some of which are endothelium-lined. The spaces are separated by connective tissue septa containing osteoid tissue, numerous osteoclast-like multinucleate giant cells and trabeculae of bone (**Fig. 26.9**). The condition has to be distinguished histologically from giant cell tumour or osteoclastoma (page 837) and telangiectatic osteosarcoma (page 833).

GIST BOX 26.5 Tumour-like Lesions of Bone

- ▣ Fibrous dysplasia is a benign condition having presence of localised area of replacement of bone by fibrous connective tissue with a characteristic whorled pattern. It is of three types—monostotic, polyostotic, and Albright syndrome.
- ▣ Fibrous cortical defect or metaphyseal fibrous defect occurs in the metaphyseal cortex of long bones in children, most commonly on upper or lower end of tibia or lower end of femur and resembles fibrohistiocytic tumours.
- ▣ Solitary, simple or unicameral bone cyst is a benign condition occurring in children and adolescents, frequently located in the metaphyses at the upper end of humerus and femur.
- ▣ Aneurysmal bone cyst is an expanding osteolytic lesion filled with blood and requires distinction from giant cell tumour of bone.

TUMOURS OF BONE AND CARTILAGE

Bone and cartilage tumours, commonly called together as bone tumours, are comparatively infrequent but they are clinically quite significant since some of them are highly malignant. Bone tumours may be primary or metastatic.

Since histogenesis of some bone tumours is obscure, the WHO has recommended a widely accepted classification of primary bone tumours based on both histogenesis and histologic criteria. **Table 26.2** lists the various types of bone tumours arising from different tissue components—osseous and non-osseous, indigenous to the bone. However, in the following discussion, only osseous bone tumours are considered, while non-osseous bone tumours are described elsewhere in the book. The anatomic origin of common primary bone tumours is illustrated in **Fig. 26.10**.

It may be mentioned here that the diagnosis of any bone lesion is established by a combination of clinical, radiological and pathological examination, supplemented by biochemical and haematological investigations wherever necessary. These include: serum levels of calcium, phosphorus, alkaline phosphatase and acid phosphatase. Specific investigations like plasma and urinary proteins and the bone marrow examination in case of myeloma, urinary catecholamines in metastatic neuroblastoma and haematologic profile in lymphoma and leukaemic involvement of the bone, are of considerable help.

BONE-FORMING (OSTEOBLASTIC) TUMOURS

Bone-forming or osteoblastic group of bone tumours are characterised by the common property of synthesis of osteoid or bone, or both, directly by the tumour cells (osteogenesis). Formation of reactive bone and endochondral ossification should not be construed as osteogenesis. Benign bone-forming tumours include: osteoma, osteoid osteoma and osteoblastoma, while the malignant counterpart is osteosarcoma (osteogenic sarcoma).

Osteoma

An osteoma is a rare benign, slow-growing lesion, regarded by some as a hamartoma rather than a true neoplasm. Similar lesions may occur following trauma, subperiosteal haematoma or local inflammation. Osteoma is almost exclusively restricted to flat bones of the skull and face. It may grow into paranasal sinuses or protrude into the orbit. An osteoma may form a

Table 26.2 Classification of primary bone and cartilage tumours.

| | HISTOLOGIC DERIVATION | BENIGN | MALIGNANT |
|------|--|---|---|
| A. | OSSEOUS TUMOURS | | |
| I. | <i>Bone-forming (osteogenic, osteoblastic) tumours</i> | Osteoma (40-50 yrs) Osteoid osteoma (20-30 yrs) Osteoblastoma (20-30 yrs) | Classic osteosarcoma (10-20 yrs) Surface osteosarcoma (50-60 yrs) |
| II. | <i>Cartilage-forming (chondrogenic) tumours</i> | Enchondroma (20-50 yrs) Osteochondroma (20-50 yrs) (Osteocartilaginous exostosis) Chondroblastoma (10-20 yrs) Chondromyxoid fibroma (20-30 yrs) | Chondrosarcoma (40-60 yrs) |
| III. | <i>Haematopoietic (marrow) tumours</i> | — | Myeloma (50-60 yrs) Lymphoplasmacytic lymphoma (50-60 yrs) |
| IV. | <i>Unknown</i> | Giant cell tumour (20-40 yrs) (osteoclastoma) | Malignant giant cell tumour (30-50 yrs) Ewing's sarcoma (5-20 yrs) Adamantinoma of long bones |
| V. | <i>Notochordal tumour</i> | — | Chordoma (40-50 yrs) |
| B. | NON-OSSEOUS TUMOURS | | |
| I. | <i>Vascular tumours</i> | Haemangioma | Haemangioendothelioma Haemangiopericytoma Angiosarcoma |
| II. | <i>Fibrogenic tumours</i> | Non-ossifying fibroma (metaphyseal fibrous defect) | Fibrosarcoma |
| III. | <i>Neurogenic tumours</i> | Neurilemmoma and neurofibroma | Neurofibrosarcoma |
| IV. | <i>Lipogenic tumours</i> | Lipoma | Liposarcoma |
| V. | <i>Histiocytic tumours</i> | Fibrous histiocytoma | Malignant fibrous histiocytoma |

Figures in brackets indicate common age of occurrence.

component of Gardner's syndrome (page 570). Radiologic appearance is of a dense ivory-like bony mass.

Microscopically, the lesion is composed of well-differentiated mature lamellar bony trabeculae separated by fibrovascular tissue.

Osteoid Osteoma and Osteoblastoma

Osteoid osteoma and osteoblastoma (or giant osteoid osteoma) are closely related benign tumours occurring in children and young adults. Osteoid osteoma is more common than osteoblastoma. There are no clear-cut histologic criteria to distinguish the two. The distinction between them is based on clinical features, size and radiographic appearance.

◆ **Osteoid osteoma** is small (usually less than 1 cm) tumour located in the cortex of a long bone, associated characteristically with nocturnal pain. The tumour is clearly demarcated having surrounding zone of reactive bone formation which radiographically appears as a small radiolucent central focus or nidus surrounded by dense sclerotic bone. The pain is possibly due to increased elaboration of prostaglandin E₂ by proliferating osteoblasts.

◆ **Osteoblastoma**, on the other hand, is larger in size (usually more than 1 cm), painless, located in the medulla, commonly in the vertebrae, ribs, ilium and long bones, and there is absence of reactive bone formation.

Histologically, the distinction between osteoid osteoma and osteoblastoma is not obvious. In either case, the lesion consists of trabeculae of osteoid, rimmed by osteoblasts and separated by highly vascularised connective tissue stroma. Later, some of the trabeculae are mineralised and calcified.

Osteosarcoma

Osteosarcoma or osteogenic sarcoma is the most common primary malignant tumour of the bone. The tumour is characterised by *formation of osteoid or bone, or both, directly by sarcoma cells*. The tumour is thought to arise from primitive osteoblast-forming mesenchyme. Depending upon their locations within the bone, osteosarcomas are classified into 2 main categories: central (medullary or classic) and surface (parosteal and periosteal).

CENTRAL (MEDULLARY) OSTEOSARCOMA

This is the more common and classic type and is generally referred to as 'osteosarcoma' if not specified. The tumour occurs in young patients between the age of 10 and 20 years. Males are affected more frequently than females. The tumour arises in the metaphysis of long bones. Most common sites, in descending order of frequency, are: the lower end of femur and upper end of tibia (i.e. around knee joint about 60%); the upper end of humerus (10%); pelvis and the upper end of femur (i.e. around hip joint about 15%); and less often in jaw

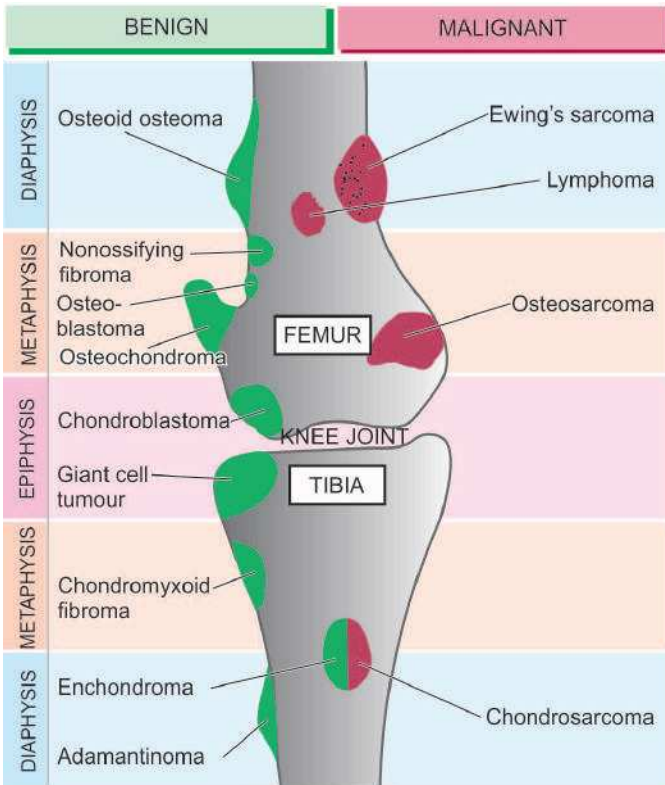

Figure 26.10 Anatomic locations of common primary bone and cartilage tumours.

bones, vertebrae and skull. Rarely, an osteosarcoma may occur in extraskeletal soft tissues.

Based upon the pathogenesis, osteosarcoma is divided into 2 types: primary and secondary.

◆ **Primary osteosarcoma** is more common and occurs in the absence of any known underlying disease. Its etiology is unknown but there is an evidence linking this form of osteosarcoma with genetic factors (e.g. hereditary mutation of chromosome 13 in common with retinoblastoma locus), period of active bone growth (occurrence of the tumour in younger age), and with certain environmental influences (e.g. radiation, oncogenic virus). Cases of hereditary retinoblastoma have a very high prevalence risk of development of osteosarcoma implicating *RB* gene in their pathogenesis. About 20% sporadic osteosarcomas show mutation in *p53* tumour suppressor gene; some have overexpression of *MDM2* gene and mutation in *cyclin D1*, *p16* and *CDK4*.

◆ **Secondary osteosarcoma**, on the other hand, develops following pre-existing bone disease e.g. Paget's disease of bone, fibrous dysplasia, multiple osteochondromas, chronic osteomyelitis, infarcts and fractures of bone. The tumour has a more aggressive behaviour than the primary osteosarcoma.

Medullary osteosarcoma is a highly malignant tumour. The tumour arises centrally in the metaphysis, extends longitudinally for variable distance into the medullary cavity, expands laterally on either side breaking through the cortex and lifting the periosteum. If the periosteum is breached, the tumour grows relentlessly into the surrounding soft tissues. The only tissue which is able to stop its spread, *albeit* temporarily, is the cartilage of epiphyseal plate. The radiographic appearance is quite distinctive: characteristic '*sunburst pattern*' due to

osteogenesis within the tumour and presence of *Codman's triangle* formed at the angle between the elevated periosteum and underlying surface of the cortex.

Clinically, the usual osteosarcoma presents with pain, tenderness and an obvious swelling of affected extremity. Serum alkaline phosphatase level is generally raised but calcium and phosphorus levels are normal. The tumour metastasises rapidly and widely to distant sites by haematogenous route and disseminates commonly to the lungs, other bones, brain and various other sites.

MORPHOLOGIC FEATURES *Grossly*, the tumour appears as a grey-white, bulky mass at the metaphyseal end of a long bone of the extremity. The articular end of the bone is generally uninvolved in initial stage. Codman's triangle, though identified radiologically, may be obvious on macroscopic examination (**Fig. 26.11**). Cut surface of the tumour is grey-white with areas of haemorrhages and necrotic bone. Tumours which form abundance of osteoid, bone and cartilage may have hard, gritty and mucoid areas.

Histologically, osteosarcoma shows considerable variation in pattern from case-to-case and even within a tumour from one area to the other. However, the following two features characterise all classic forms of osteosarcomas (**Fig. 26.12**):

- 1. Sarcoma cells** The tumour cells of osteosarcomas are undifferentiated mesenchymal stromal cells which show marked pleomorphism and polymorphism i.e. variation in size as well as shape. The tumour cells may have various shapes such as spindled, round, oval and polygonal and bizarre tumour giant cells. The tumour cells have variable size and show hyperchromatism and atypical mitoses. Histochemically, these tumour cells are positive for alkaline phosphatase. Immunohistochemically, sarcoma cells of osteosarcoma express vimentin, osteocalcin, osteonectin and type I collagen.
- 2. Osteogenesis** The anaplastic sarcoma cells form osteoid matrix and bone directly; this is found interspersed in the areas of tumour cells. In addition to osteoid and bone, the tumour cells may produce cartilage, fibrous tissue or myxoid tissue.

VARIANTS A few histologic variants of the classic osteosarcoma have been described as under:

- 1. Telangiectatic osteosarcoma** The tumour in this variant presents with pathological fractures. The tumour has large, cavernous, dilated vascular channels. This variant has a more aggressive course.
- 2. Small cell osteosarcoma** This variant has small, uniform tumour cells just like the tumour cells of Ewing's sarcoma or lymphoma but osteogenesis by these tumour cells is the distinguishing feature.
- 3. Fibrohistiocytic osteosarcoma** This variant resembles malignant fibrous histiocytoma but having osteogenesis by the tumour cells.
- 4. Anaplastic osteosarcoma** In this variant, the tumour has so marked anaplasia that it may resemble any other type of pleomorphic sarcoma and is identified by the presence of osteoid formed directly by the tumour cells.
- 5. Well-differentiated osteosarcoma** Although generally classic form of osteosarcoma is a highly malignant tumour,

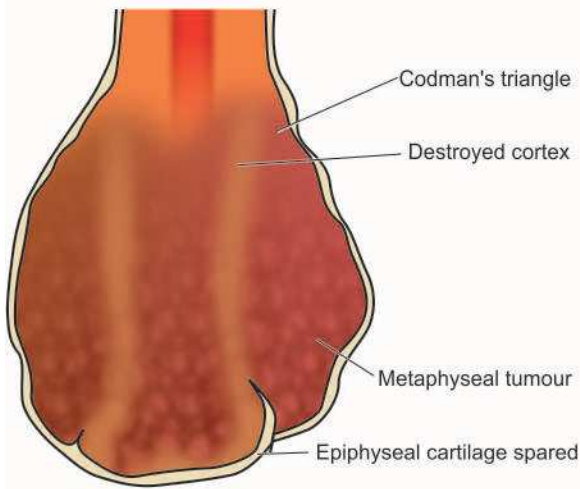

Figure 26.11 Osteosarcoma. The lower end of the femur shows a bulky expanded tumour in the region of metaphysis sparing the epiphyseal cartilage. Sectioned surface of the tumour shows lifting of the periosteum by the tumour and eroded cortical bone. The tumour is grey-white with areas of haemorrhage and necrosis.

rarely a well-differentiated variant having minimal cytologic atypia resembling parosteal osteosarcoma may be seen.

SURFACE OSTEOSARCOMA

About 5% of osteosarcomas occur on the surface of bone and are slow-growing tumours compared to medullary osteosarcomas. Surface osteosarcoma includes 2 variants: parosteal and periosteal.

Parosteal or juxtacortical osteosarcoma is an uncommon form of slow-growing osteosarcoma having its origin from the metaphysis on the external surface of the bone (*parosteal* or

juxtacortical means outer to cortex). The tumour should be distinguished from the more common medullary osteosarcoma because of its better prognosis and different presentation. The tumour occurs in older age group (3rd to 4th decade), has no sex predilection and is slow growing. Its common locations are metaphysis of long bones, most frequently lower end of the femur and upper end of the humerus. X-ray examination usually reveals a dense bony mass attached to the outer cortex of the affected long bone.

Grossly, the tumour is lobulated and circumscribed, calcified mass in the subperiosteal location.

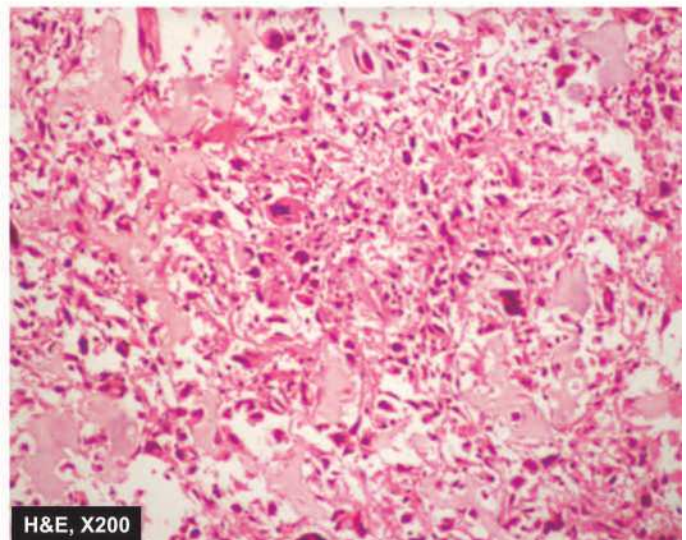

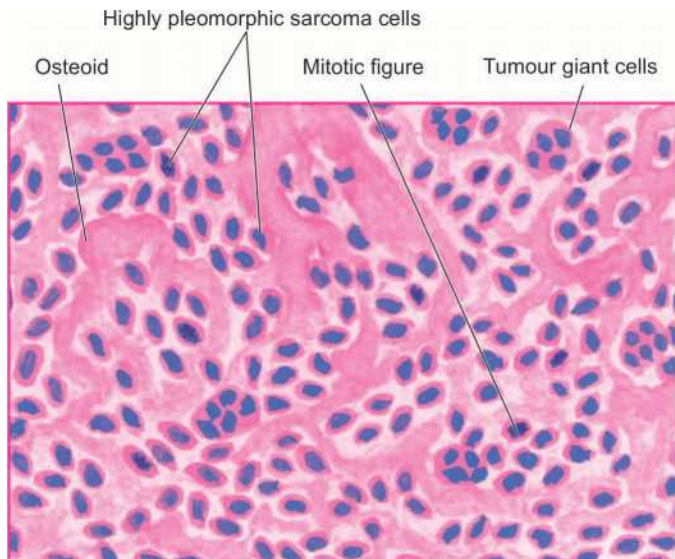

Figure 26.12 Osteosarcoma. Hallmarks of microscopic picture of the usual osteosarcoma are the sarcoma cells characterised by variation in size and shape of tumour cells, bizarre mitosis and multinucleate tumour giant cells, and osteogenesis i.e. production of osteoid matrix and bone directly by the tumour cells.

Microscopically, the features which characterise the usual osteosarcoma (sarcomatous stroma and production of neoplastic osteoid and bone) are present, but the tumour shows a high degree of structural differentiation, and there are generally well-formed bony trabeculae. These features account for distinctly better prognosis in these cases.

Periosteal osteosarcoma is a rarer form of osteosarcoma than parosteal type and arises between the cortex and the overlying periosteum. Its common location is the diaphysis of the tibia or the femur. It occurs in young adults (average age 25 years).

Microscopically, periosteal osteosarcoma has cartilaginous differentiation and higher degree of anaplasia than that seen in parosteal osteosarcoma but lower grade than conventional osteosarcoma i.e. it is an intermediate grade sarcoma.

Table 26.3 sums up the contrasting features of central (medullary) and surface (parosteal and periosteal) osteosarcomas.

CARTILAGE-FORMING (CHONDROBLASTIC) TUMOURS

The tumours which are composed of frank cartilage or derived from cartilage-forming cells are included in this group. This group comprises benign lesions like osteocartilaginous exostoses (osteochondromas), enchondroma, chondroblastoma and chondromyxoid fibroma, and a malignant counterpart, chondrosarcoma.

Osteocartilaginous Exostoses (Osteochondromas)

Osteocartilaginous exostoses or osteochondromas are the commonest of benign cartilage-forming lesions. Though

designated and discussed with neoplasms, exostosis or osteochondroma is not a true tumour but is regarded as a disorder of growth and development (page 825). It may occur as a 'solitary sporadic exostosis' or there may be 'multiple hereditary exostoses.' Hereditary forms are due to germline mutation in *EXT1* or *EXT2* gene while sporadic type is due to mutated *EXT1* only.

Exostoses arise from metaphyses of long bones as exophytic lesions, most commonly lower femur and upper tibia (i.e. around knee) and upper humerus but may also be found in other bones such as the scapula or ilium. They are discovered most commonly in late childhood or adolescence and are more frequent in males. They may remain asymptomatic and discovered as an incidental radiographic finding or may produce obvious deformity. Both solitary and multiple exostoses may undergo transformation into chondrosarcoma but the risk is much greater with multiple hereditary exostoses.

MORPHOLOGIC FEATURES *Grossly*, osteochondromas have a broad or narrow base (i.e. may be either sessile or pedunculated) which is continuous with the cortical bone. They protrude exophytically as mushroom-shaped, cartilage-capped lesions enclosing well-formed cortical bone and marrow (**Fig. 26.13**).

Microscopically, they are composed of outer cap composed of mature cartilage resembling epiphyseal cartilage and the inner mature lamellar bone and bone marrow (**Fig. 26.14**).

Enchondroma

Enchondroma is the term used for the benign cartilage-forming tumour that develops centrally within the interior of the affected bone, while chondroma refers to the peripheral development of lesion similar to osteochondromas. Enchondromas may occur singly or they may be multiple, forming a non-hereditary

Table 26.3 Contrasting features of central (medullary) and surface (parosteal and periosteal) osteosarcoma.

| FEATURE | CENTRAL (MEDULLARY) | SURFACE (PAROSTEAL AND PERIOSTEAL) |
|--------------------------|--|--|
| 1. Age | 10-20 years | Older patients |
| 2. Sex | More common in males | No sex predilection |
| 3. Anatomic site | Metaphysis | Metaphysis/diaphysis |
| 4. Location | Femur (lower end), tibia (upper end), humerus (upper end), around hip | Femur (lower-end), humerus (upper end) |
| 5. Pathogenesis | Primary: genetic factors (mutations in <i>Rb</i> gene, <i>p53</i> , <i>MDM2</i>) Secondary: Paget's disease, fibrous dysplasia | Parosteal: Arises outer to cortex Periosteal: Arises between cortex and periosteum |
| 6. Behaviour | Highly malignant | Slow growing |
| 7. G/A | Bulky, necrotic, forms Codman's triangle | Smaller, well-formed bone present |
| 8. M/E | i. Sarcomas cells: Polymorphic and pleomorphic ii. Osteoid formation | i. Parosteal: Fibrous stromal cells with subtle atypia ii. Periosteal: High grade iii. Both form bony trabeculae |
| 9. Histologic types | Telangiectatic, small cell, fibrohistiocytic, well-differentiated, anaplastic | Parosteal (juxta cortical), periosteal |
| 10. Spread and prognosis | Haematogenous spread, prognosis poor | Recurrences common, may metastasise, prognosis generally good, better for parosteal than periosteal |

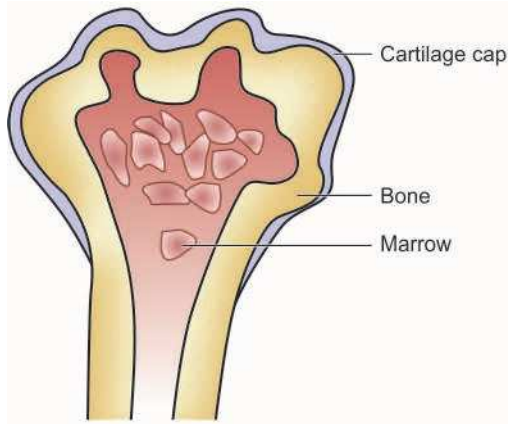

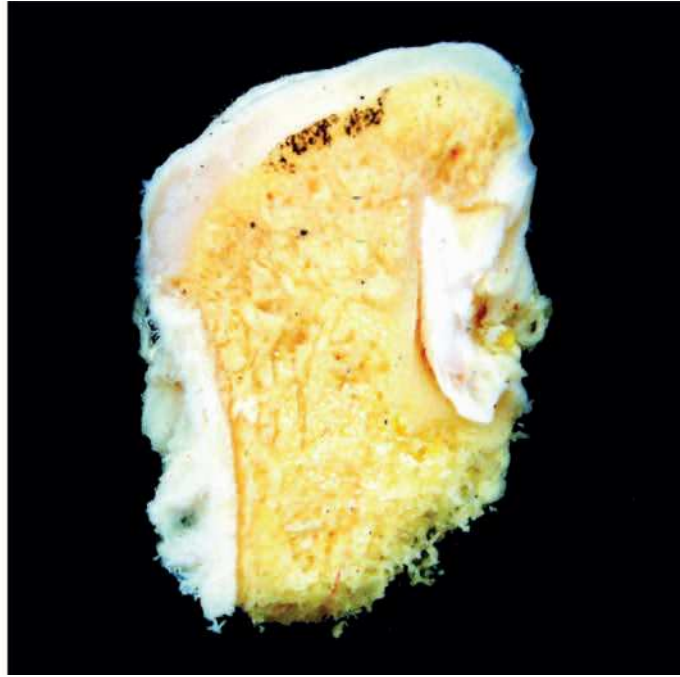

Figure 26.13 Osteochondroma (osteocartilaginous exostosis), upper end humerus. The amputated head of the long bone shows mushroom-shaped elevated nodular areas. These nodules have cartilaginous caps and inner osseous tissue.

disorder called *enchondromatosis* or *Ollier's disease*. The coexistence of multiple enchondromas with multiple soft tissue haemangiomas constitutes a familial syndrome called *Maffucci's syndrome*.

Most common locations for enchondromas are short tubular bones of the hands and feet, and less commonly, they involve the ribs or the long bones. They may appear at any age and in either sex. Enchondromas, like osteochondromas, may remain asymptomatic or may cause pain and pathologic fractures. X-ray reveals a radiolucent, lobulated tumour mass with spotty calcification. Malignant transformation of solitary enchondroma is rare but multiple enchondromas may develop into chondrosarcoma.

MORPHOLOGIC FEATURES *Grossly*, the enchondroma is lobulated, bluish-grey, translucent, cartilaginous mass lying within the medullary cavity.

Histologically, the tumour has characteristic lobulated appearance. The lobules are composed of normal adult hyaline cartilage separated by vascularised fibrous stroma. Foci of calcification may be evident within the tumour. Enchondroma is distinguished from chondrosarcoma by the absence of invasion into surrounding tissues and lack of cellular features of malignancy.

Chondroblastoma

Chondroblastoma is a relatively rare benign tumour arising from the epiphysis of long bones adjacent to the epiphyseal cartilage plate. Most commonly affected bones are upper tibia and lower femur (i.e. about knee) and upper humerus. The tumour usually occurs in patients under 20 years of age with male preponderance (male-female ratio 2:1). The radiographic appearance is of a sharply-circumscribed, lytic lesion with multiple small foci of calcification. Chondroblastoma may be asymptomatic, or may produce local pain, tenderness and discomfort. The behaviour of the tumour is benign though it may recur locally after curettage.

MORPHOLOGIC FEATURES *Grossly*, chondroblastoma is a well-defined mass, up to 5 cm in diameter, lying in the epiphysis. The tumour is surrounded by thin capsule of dense sclerotic bone. Cut surface reveals a soft chondroid tumour with foci of haemorrhages, necrosis and calcification.

Histologically, the tumour is highly cellular and is composed of small, round to polygonal mononuclear cells resembling chondroblasts and has multinucleate osteoclast-like giant cells. There are small areas of cartilaginous intercellular matrix and focal calcification.

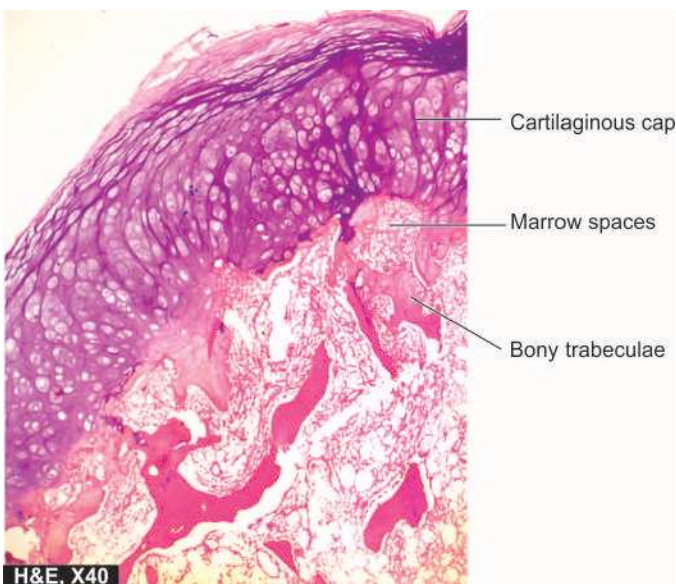

Figure 26.14 Osteochondroma. The overlying cap shows mature cartilage cells covering the underlying mature lamellar bone containing marrow spaces.

Chondromyxoid Fibroma

Chondromyxoid fibroma is an uncommon benign tumour of cartilaginous origin arising in the metaphysis of long bones. Most common locations are upper end of tibia and lower end of femur i.e. around the knee joint. Majority of tumours appear in 2nd to 3rd decades of life with male preponderance. Radiographically, the tumour appears as a sharply-outlined radiolucent area with foci of calcification and expansion of affected end of the bone. The lesion may be asymptomatic, or may cause pain, swelling and discomfort in the affected joint. The lesions may recur after curettage. Thus, there are many similarities with chondroblastoma.

MORPHOLOGIC FEATURES *Grossly*, chondromyxoid fibroma is sharply-demarcated, grey-white lobulated mass, not exceeding 5 cm in diameter, lying in the metaphysis. The tumour is often surrounded by a layer of dense sclerotic bone. Cut surface of the tumour is soft to firm and lobulated but calcification within the tumour is not as common as with other cartilage-forming tumours.

Histologically, the tumour has essentially lobulated pattern. The lobules are separated by fibrous tissue and variable number of osteoclast-like giant cells. The lobules themselves are composed of immature cartilage consisting of spindle-shaped or stellate cells with abundant myxoid or chondroid intercellular matrix.

In view of close histogenetic relationship between chondromyxoid fibroma and chondroblastoma, occasional tumours show a combination of histological features of both.

Chondrosarcoma

Chondrosarcoma is a malignant tumour of chondroblasts. In frequency, it is next in frequency to osteosarcoma but is relatively slow-growing and thus has a much better prognosis than that of osteosarcoma. Two types of chondrosarcoma are distinguished: *central* and *peripheral*.

◆ **Central chondrosarcoma** is more common and arises within the medullary cavity of diaphysis or metaphysis. This type of chondrosarcoma is generally primary i.e. occurs *de novo*.

◆ **Peripheral chondrosarcoma** arises in the cortex or periosteum of metaphysis. It may be primary or secondary occurring on a pre-existing benign cartilaginous tumour such as osteocartilaginous exostoses (osteochondromas), multiple enchondromatosis, and rarely, chondroblastoma.

Both forms of chondrosarcoma usually occur in patients between 3rd and 6th decades of life with slight male preponderance. In contrast to benign cartilaginous tumours, majority of chondrosarcomas are found more often in the central skeleton (i.e. in the pelvis, ribs and shoulders); sometimes around the knee joint. Radiologic appearance is of hugely expansile and osteolytic growth with foci of calcification. Clinically, the tumour is slow-growing and comes to attention because of pain and gradual enlargement over the years. Lower grades of the tumour recur following surgical removal but higher grades cause metastatic dissemination, commonly to the lungs, liver, kidney and brain.

MORPHOLOGIC FEATURES *Grossly*, chondrosarcoma may vary in size from a few centimeters to extremely large

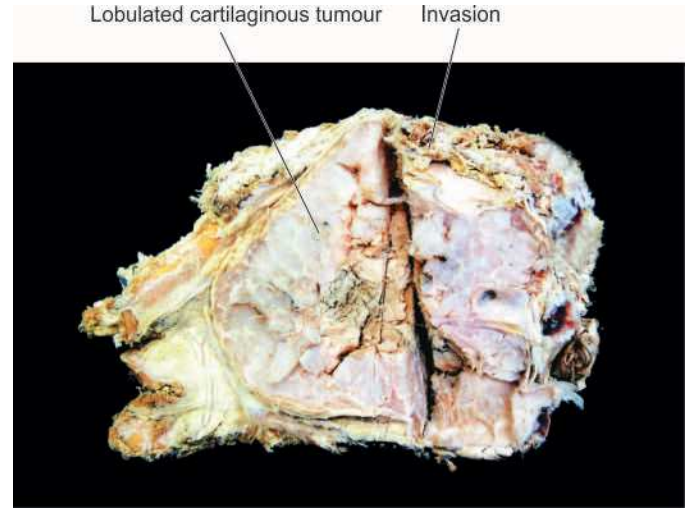

Figure 26.15 Chondrosarcoma, scapula. The bone is expanded externally due to a gelatinous tumour. Sectioned surface shows lobulated mass with bluish cartilaginous hue infiltrating the soft tissues.

and lobulated masses of firm consistency. Cut section of the tumour shows translucent, bluish-white, gelatinous or myxoid appearance with foci of ossification (**Fig. 26.15**).

Histologically, the two hallmarks of chondrosarcoma are: invasive character and formation of lobules of anaplastic cartilage cells. These tumour cells show cellular features of malignancy such as hyperchromatism, pleomorphism, two or more cells in the lacunae and tumour giant cells (**Fig. 26.16**). However, sometimes distinction between a well-differentiated chondrosarcoma and a benign chondroma may be difficult and in such cases location, clinical features and radiological appearance are often helpful.

Rare variants of chondrosarcoma are mesenchymal chondrosarcoma, dedifferentiated chondrosarcoma and clear cell chondrosarcoma.

GIANT CELL TUMOUR (OSTEOCLASTOMA)

Giant cell tumour or osteoclastoma is a distinctive neoplasm with uncertain histogenesis and hence classified separately. The tumour arises in the epiphysis of long bones close to the articular cartilage. Most common sites of involvement are lower end of femur and upper end of tibia (i.e. about the knee), lower end of radius and upper end of fibula. Giant cell tumour occurs in patients between 20 and 40 years of age with no sex predilection. Clinical features at presentation include pain, especially on weight-bearing and movement, noticeable swelling and pathological fracture. Radiologically, giant cell tumour appears as a large, lobulated and osteolytic lesion at the end of an expanded long bone with characteristic 'soap bubble' appearance.

MORPHOLOGIC FEATURES *Grossly*, giant cell tumour is eccentrically located in the epiphyseal end of a long bone which is expanded. The tumour is well-circumscribed, dark-tan and covered by a thin shell of subperiosteal bone. Cut surface of the tumour is characteristically haemorrhagic, necrotic, and honey-combed due to focal areas of cystic degeneration (**Fig. 26.17**).

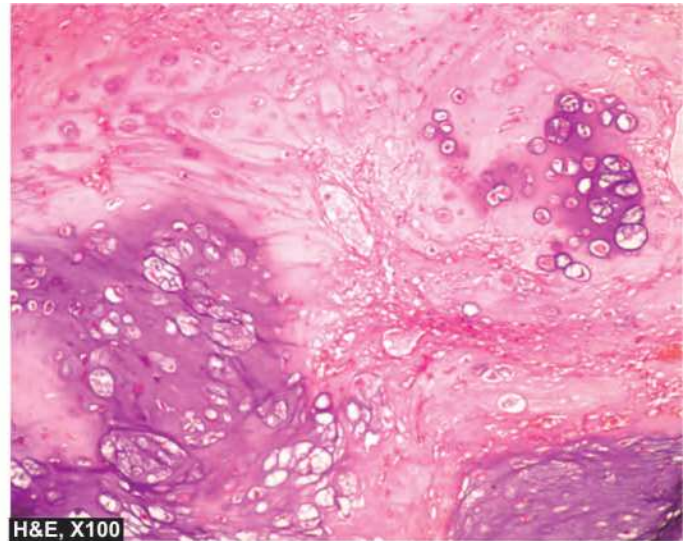

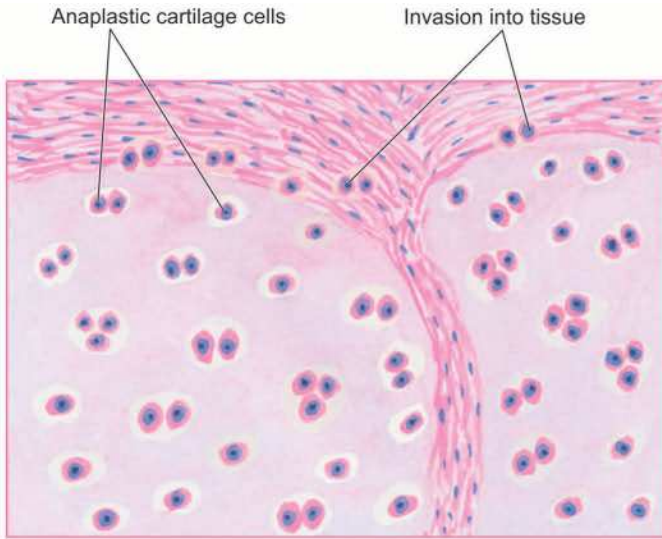

Figure 26.16 Chondrosarcoma. Histologic features include invasion of the tumour into adjacent soft tissues and cytologic characteristics of malignancy in the tumour cells.

Histologically, the hallmark features of giant cell tumour are the presence of large number of multinucleate osteoclast-like giant cells regularly scattered throughout the stromal mononuclear cells (**Fig. 26.18**):

- 1. Giant cells** often contain as many as 100 benign nuclei and have many similarities to normal osteoclasts. These cells have very high acid phosphatase activity.
- 2. Stromal cells** are mononuclear cells and are the real tumour cells and their histologic appearance determines the biologic behaviour of the tumour. Typically, they are uniform, plump, spindle-shaped or round to oval cells with numerous mitotic figures.
- 3. Other features** of the stroma include its scanty collagen content, rich vascularity, areas of haemorrhages and presence of macrophages.

Giant cell tumour of the bone has certain peculiarities which deserve further elaboration. These are: its *cell of origin*, its *differentiation from other giant cell lesions* and its *biologic behaviour*.

CELL OF ORIGIN Though designated as giant cell tumour or osteoclastoma, the actual tumour cells are round to spindle mononuclear cells while proliferated osteoclastic giant cells are seen as background cells. Histogenesis of stromal cells is uncertain but possibly they are of mesenchymal origin. Molecular profiling of giant cell tumour suggests that *RANK* (receptor activator of nuclear factor κ B), a physiologic growth factor for osteoclastic proliferation, is expressed in stromal cells. Giant osteoclastic cells are believed to be formed by *RANK/RANKL* signaling pathway.

OTHER GIANT CELL LESIONS This peculiar tumour with above description is named 'giant cell tumour' but giant cells

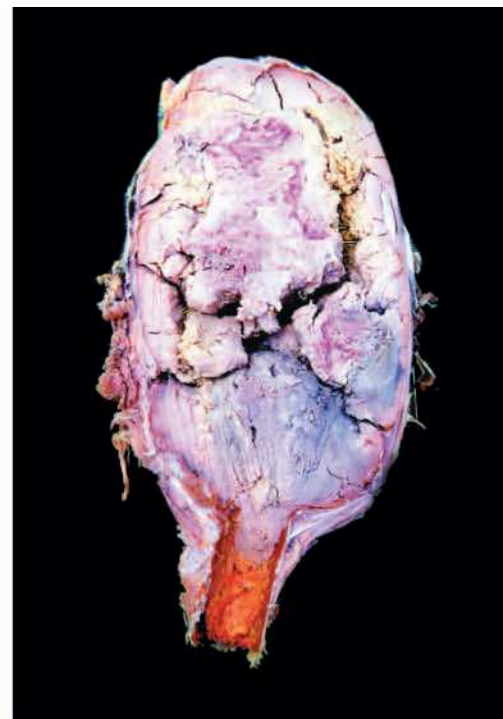

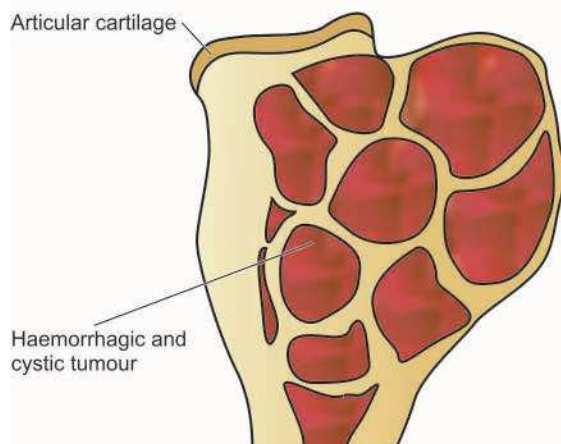

Figure 26.17 Giant cell tumour (osteoclastoma). The end of the long bone is expanded in the region of epiphysis. Sectioned surface shows circumscribed, dark tan, haemorrhagic and necrotic tumour.

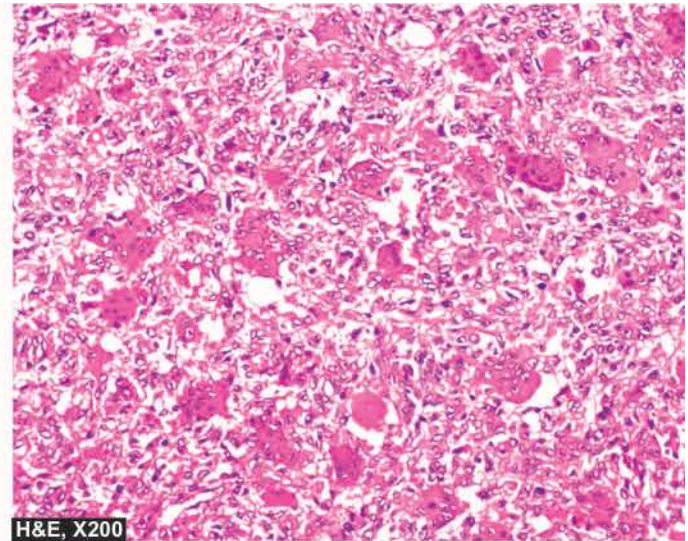

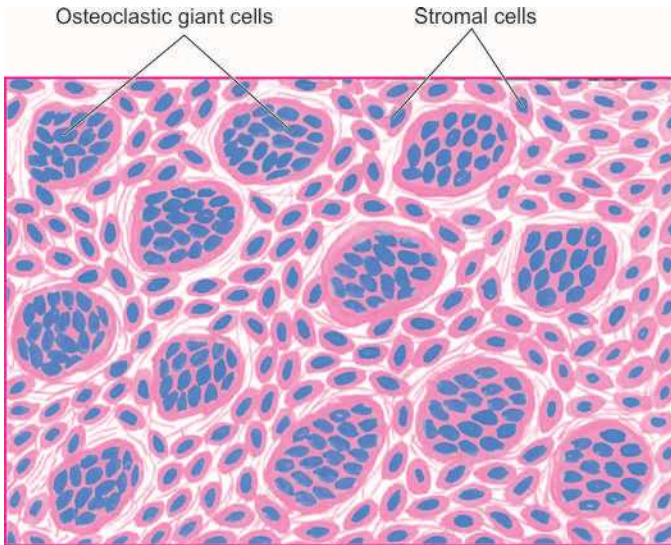

Figure 26.18 Osteoclastoma. Microscopy reveals osteoclast-like multinucleate giant cells which are regularly distributed among the mononuclear stromal cells.

are present in several other benign tumours and tumour-like lesions from which the giant cell tumour is to be distinguished. These *benign giant cell lesions* are: chondroblastoma, brown tumour of hyperparathyroidism, reparative giant cell granuloma, aneurysmal bone cyst, simple bone cyst and metaphyseal fibrous defect (non-ossifying fibroma).

BIOLOGIC BEHAVIOUR Giant cell tumours are best described as aggressive and recurrent tumours. About 40 to 60% of them recur after curettage, sometimes after a few decades of initial resection. Approximately 4% cases result in distant metastases, mainly to lungs. Metastases are histologically benign and there is usually history of repeated curettages and recurrences. Thus attempts at histologic grading of giant cell tumour do not always yield satisfactory results. One of the factors considered significant in malignant transformation of this tumour is the role of radiotherapy resulting in development of post-radiation bone sarcoma.

EWING'S SARCOMA AND PRIMITIVE NEUROECTODERMAL TUMOUR (ES/PNET)

Ewing's sarcoma (ES) is a highly malignant small round cell tumour occurring in patients between the age of 5 and 20 years with predilection for occurrence in females. Since its first description by James Ewing in 1921, histogenesis of this tumour has been a debatable issue. At different times, the possibilities suggested for the cell of origin have been endothelial, pericytic, bone marrow, osteoblastic, and mesenchymal; currently it is settled for its origin from primitive neuroectodermal cells. Now, Ewing's sarcoma includes 3 variants:

- i) classic (skeletal) Ewing's sarcoma;
- ii) soft tissue Ewing's sarcoma; and
- iii) primitive neuroectodermal tumour (PNET).

The three are linked together by a common neuroectodermal origin and by a common cytogenetic translocation abnormality $t(11; 22)(q24; q12)$. This suggests a phenotypic spectrum in these conditions varying from undifferentiated Ewing's sarcoma to PNET positive for rosettes and neural markers (neuron-specific enolase, S-100). However, PNET ultimately has a worse prognosis.

The skeletal Ewing's sarcoma arises in the medullary canal of diaphysis or metaphysis. The common sites are shafts and metaphysis of long bones, particularly femur, tibia, humerus and fibula, although some flat bones such as pelvis and scapula may also be involved.

Clinical features include pain, tenderness and swelling of the affected area accompanied by fever, leucocytosis and elevated ESR. These signs and symptoms may lead to an erroneous clinical diagnosis of osteomyelitis. However, X-ray examination reveals a predominantly osteolytic lesion with patchy subperiosteal reactive bone formation producing characteristic 'onion-skin' radiographic appearance.

MORPHOLOGIC FEATURES *Grossly*, Ewing's sarcoma is typically located in the medullary cavity and produces expansion of the affected diaphysis (shaft) or metaphysis, often extending into the adjacent soft tissues. The tumour tissue is characteristically grey-white, soft and friable (**Fig. 26.19**).

Histologically, Ewing's tumour is a member of *small round cell tumours* which includes other tumours such as: PNET, neuroblastoma, embryonal rhabdomyosarcoma, lymphoma-leukaemias, and metastatic small cell carcinoma. Ewing's tumour shows the following histologic characteristics (**Fig. 26.20**):

1. Pattern The tumour is divided by fibrous septa into irregular lobules of closely-packed tumour cells. These tumour cells are characteristically arranged around capillaries forming *pseudorosettes*.

2. Tumour cells The individual tumour cells comprising the lobules are small and uniform resembling lymphocytes and have ill-defined cytoplasmic outlines, scanty cytoplasm and round nuclei having 'salt and pepper' chromatin and frequent mitoses. Based on these cytological features the tumour is also called *round cell tumour* or *small blue cell tumour*. The cytoplasm contains glycogen that stains with periodic acid-Schiff (PAS) reaction. A consistently expressed cell surface marker by tumour cells of ES/PNET group is CD99 which is a product of *MIC-2* gene located on X and Y chromosome.

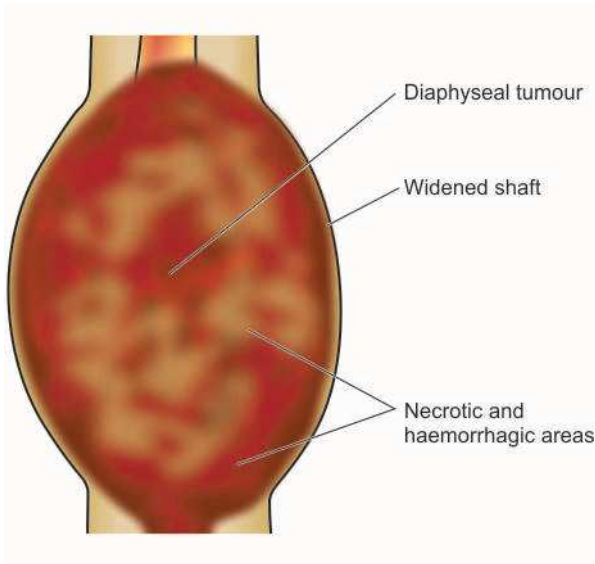

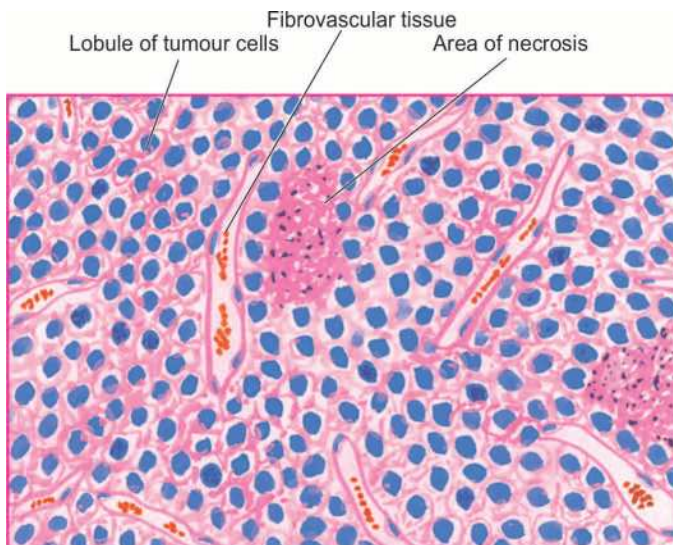

Figure 26.19 Ewing's sarcoma. The tumour is largely extending into soft tissues including the skeletal muscle. Cut surface of the tumour is grey-white, cystic, soft and friable.

3. Other features The tumour is richly vascularised and lacks the intercellular network of reticulin fibres. There may be areas of necrosis and acute inflammatory cell infiltration. Focal areas of reactive bone formation may be present.

Ewing's sarcoma metastasises early by haematogenous route to the lungs, liver, other bones and brain. Involvement of other bones has prompted a suggestion of *multicentric origin* of Ewing's sarcoma. The prognosis of Ewing's sarcoma used to be dismal (5-year survival rate less than 10%). But currently, use of combined regimen consisting of radiotherapy and systemic chemotherapy has improved the outcome greatly (5-year survival rate 40-80%).

CHORDOMA

Chordoma is a slow-growing malignant tumour arising from remnants of notochord. Notochord is the primitive axial skeleton which subsequently develops into the spine. Normally, remnants of notochord are represented by notochordal or physaliphorous (*physalis* = bubble, *phorous* = bearing) cells present in the nucleus pulposus and a few clumps within the vertebral bodies. Chordomas thus occur in the axial skeleton, particularly sacrum and coccyx (50%), sphenoid-occipital region (35%), and less often in the spine (15%). Chordoma is usually found in patients over the age of 40 years with no sex predilection. Radiographically, the tumour usually appears as an osteolytic lesion. Symptoms of spinal cord compression may

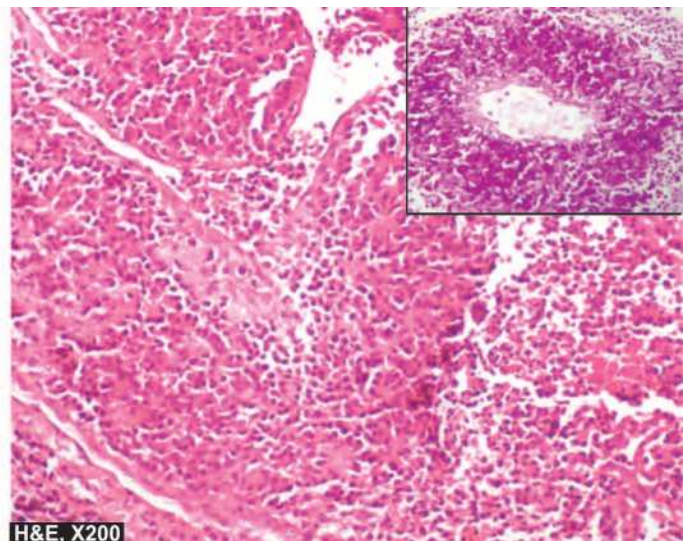

Figure 26.20 Ewing's sarcoma. Characteristic microscopic features are irregular lobules of uniform small tumour cells with indistinct cytoplasmic outlines which are separated by fibrous tissue septa having rich vascularity. Areas of necrosis and inflammatory infiltrate are also included. Inset in the right photomicrograph shows PAS positive tumour cells in perivascular location.

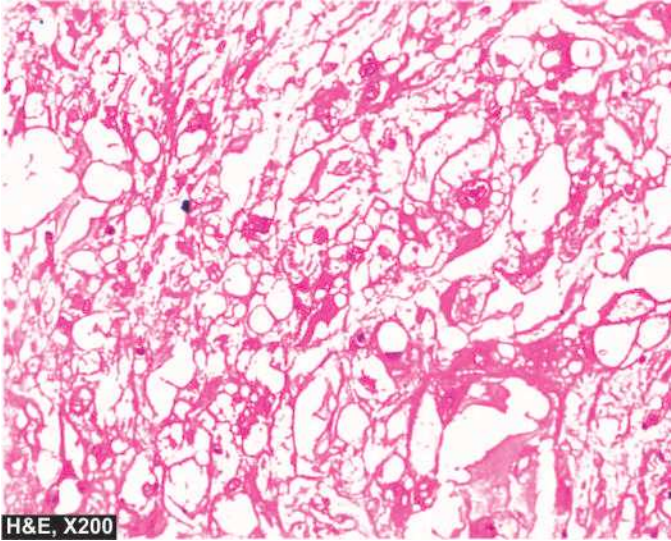

Figure 26.21 Chordoma. The tumour cells are quite variable in size having characteristic bubbly cytoplasm (physaliphorous cells) and anisonucleocytoplasts. The background is myxoid.

be present. The tumour grows slowly and infiltrates adjacent structures but metastases develop rarely. Recurrences after local excision are frequent and the tumour almost invariably proves fatal.

MORPHOLOGIC FEATURES *Grossly*, the tumour is soft, lobulated, translucent and gelatinous with areas of haemorrhages.

Microscopically, chordoma is composed of highly vacuolated physaliphorous cells surrounded by a sea of intercellular mucoïd material (**Fig. 26.21**). Histologic differentiation between chordoma and chondrosarcoma or mucin-secreting carcinoma may sometimes be difficult and is facilitated by positive cytokeratin and S-100 immunostaining in the former.

METASTATIC BONE TUMOURS

Metastases to the skeleton are more frequent than the primary bone tumours. Metastatic bone tumours are exceeded in frequency by only 2 other organs—lungs and liver. Most skeletal metastases are derived from haematogenous spread.

Bony metastases of carcinomas predominate over the sarcomas. Some of the common *carcinomas* metastasising to the bones are from: breast, prostate, lung, kidney, stomach, thyroid, cervix, body of uterus, urinary bladder, testis, melanoma and neuroblastoma of adrenal gland. Examples of *sarcomas* which may metastasise to the bone are: embryonal and alveolar rhabdomyosarcoma, Ewing's sarcoma and osteosarcoma.

Skeletal metastases may be single or multiple. Most commonly involved bones are: the spine, pelvis, femur, skull, ribs and humerus. Usual radiographic appearance is of an *osteolytic* lesion. *Osteoblastic* bone metastases occur in cancer of the prostate, carcinoid tumour and small cell carcinoma of lung.

Metastatic bone tumours generally reproduce the microscopic picture of primary tumour (**Fig. 26.22**). Many a times, evidence of skeletal metastases is the first clinical manifestation of an occult primary cancer in the body.

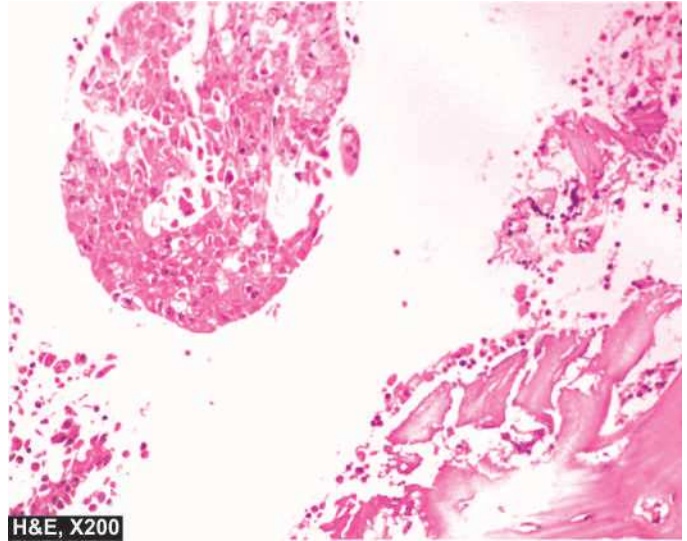

Figure 26.22 Osseous deposits from carcinoma breast.

GIST BOX 26.6 Tumours of Bone and Cartilage

- ▣ Primary bone tumours are classified on the basis of histogenesis and histologic criteria and include osseous and non-osseous tumours. Each of these may be benign or malignant.
- ▣ Benign bone-forming osseous tumours are osteoma, osteoid osteoma and osteoblastoma.
- ▣ Osteosarcoma is the common malignant bone-forming tumour. The classic form (medullary osteosarcoma) occurs in young patients between the age of 10 and 20 years, arising in the metaphysis. Most common site is around the knee joint and is a highly malignant tumour. Surface osteosarcomas include parosteal and periosteal type, occur in older age group than classic osteosarcoma and have a better prognosis.
- ▣ Osteochondromas are the commonest of benign cartilage-forming lesions. Others are enchondroma, chondroblastoma and chondromyxoid fibroma.
- ▣ Chondrosarcoma occurs in 4th to 6th decade, is seen more often in central skeleton and is a slow growing malignant tumour.
- ▣ Giant cell tumour is an aggressive and recurrent tumour arising in epiphysis, often occurring in young adults.
- ▣ Ewing's sarcoma occurs in the age group of 5-20 years, and arises in diaphysis. It is a malignant small round cell tumour.
- ▣ Metastatic bone tumours are more common and may arise from various carcinomas and some sarcomas.

JOINTS

NORMAL STRUCTURE

The joints are of 2 types—*diarthrodial* or *synovial joints* with a joint cavity, and *synarthrodial* or *nonsynovial joints* without a joint cavity. Most of the diseases of joints affect diarthrodial or synovial joints. In diarthrodial joints, the ends of two

bones are held together by joint capsule with ligaments and tendons inserted at the outer surface of the capsule. The articular surfaces of bones are covered by hyaline cartilage which is thicker in weight-bearing areas than in nonweight-bearing areas. The joint space is lined by synovial membrane or synovium which forms synovial fluid that lubricates the joint during movements. The synovium may be smooth or thrown into numerous folds and villi. The synovial membrane is composed of inner layer of 1-4 cell thick synoviocytes and outer layer of loose vascular connective tissue. On electron microscopy, two types of synoviocytes are distinguished: type A and type B. *Type A* synoviocytes are more numerous and are related to macrophages and produce degradative enzymes, while *type B* synthesise hyaluronic acid.

Diseases of joints are numerous and joints are also involved in several systemic disorders. In the following discussion, only those joint diseases which are morphologically significant are described. Synovial tumours are discussed in the next chapter together with other soft tissue tumours.

DEGENERATIVE JOINT DISEASE (OSTEOARTHRITIS)

Osteoarthritis (OA), also called osteoarthrosis or degenerative joint disease (DJD), is the most common form of chronic disorder of synovial joints. It is characterised by progressive degenerative changes in the articular cartilages over the years, particularly in weight-bearing joints.

TYPES AND PATHOGENESIS OA occurs in 2 clinical forms—primary and secondary.

◆ **Primary OA** occurs in the elderly, more commonly in women than in men. The process begins by the end of 4th decade and then progressively and steadily increases producing clinical symptoms. Little is known about the etiology and pathogenesis of primary OA. The condition may be regarded as a reward of longevity. Probably, wear and tear with repeated minor trauma, heredity, obesity, ageing *per se*, all contribute to focal degenerative changes in the articular cartilage of the joints. Genetic factors favouring susceptibility to develop OA have been observed; genetic mutations in proteins which regulate the cartilage growth have been identified e.g. *FRZB* gene.

◆ **Secondary OA** may appear at any age and is the result of any previous wear and tear phenomena involving the joint such as previous injury, fracture, inflammation, loose bodies and congenital dislocation of the hip.

The molecular mechanism of damage to cartilage in OA appears to be the breakdown of collagen type II, probably by IL-1, TNF and nitric oxide.

MORPHOLOGIC FEATURES As mentioned above, the weight-bearing joints such as hips, knee and vertebrae are most commonly involved but interphalangeal joints of fingers may also be affected. The pathologic changes occur in the articular cartilages, adjacent bones and synovium (Fig. 26.23):

1. Articular cartilages The regressive changes are most marked in the weight-bearing regions of articular cartilages. Initially, there is loss of cartilaginous matrix (proteoglycans)

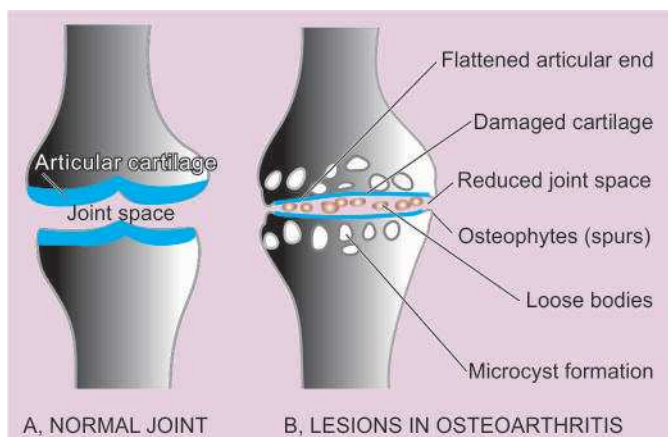

Figure 26.23 Fully-developed lesions in osteoarthritis (B), contrasted with appearance of a normal joint (A).

resulting in progressive loss of normal metachromasia. This is followed by focal loss of chondrocytes, and at other places, proliferation of chondrocytes forming clusters. Further progression of the process causes loosening, flaking and fissuring of the articular cartilage resulting in breaking off of pieces of cartilage exposing subchondral bone. Radiologically, this progressive loss of cartilage is apparent as narrowed joint space.

2. Bone The denuded subchondral bone appears like polished ivory. There is death of superficial osteocytes and increased osteoclastic activity causing rarefaction, microcyst formation and occasionally microfractures of the subjacent bone. These changes result in remodelling of bone and changes in the shape of joint surface leading to flattening and mushroom-like appearance of the articular end of the bone. The margins of the joints respond to cartilage damage by *osteophyte* or *spur formation*. These are cartilaginous outgrowths at the joint margins which later get ossified. Osteophytes give the appearance of lipping of the affected joint. Loosened and fragmented osteophytes may form free 'joint mice' or loose bodies.

3. Synovium. Initially, there are no pathologic changes in the synovium but in advanced cases there is low-grade chronic synovitis and villous hypertrophy. There may be some amount of synovial effusion associated with chronic synovitis.

The manifestations of OA are most conspicuous in large joints such as hips, knee and back. However, the pattern of joint involvement may be related to the type of physical activity such as ballet-dancers' toes, karate fingers etc. Minor degree of OA may remain asymptomatic. In symptomatic cases, clinical manifestations are joint stiffness, diminished mobility, discomfort and pain. The symptoms are more prominent on waking up from bed in the morning. Degenerative changes in the interphalangeal joints lead to hard bony and painless enlargements in the form of nodules at the base of terminal phalanx called *Heberden's nodes*. These nodes are more common in females and heredity seems to play a role. In the spine, osteophytes of OA may cause compression of cervical and lumbar nerve root with pain, muscle spasms and neurologic abnormalities.

INFLAMMATORY JOINT DISEASES

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a chronic multisystem disease of unknown cause. Though the most prominent manifestation of RA is inflammatory arthritis of the peripheral joints, usually with a symmetrical distribution, its systemic manifestations include haematologic, pulmonary, neurological and cardiovascular abnormalities.

RA is a common disease having peak incidence in 3rd to 4th decades of life, with 3-5 times higher preponderance in females. The condition has high association with HLA-DR4 and HLA-DR1 and familial aggregation. This association is particularly marked in those RA cases who have cyclic citrullinated polypeptide (CCP) antibodies. The onset of disease is insidious, beginning with prodrome of fatigue, weakness, joint stiffness, vague arthralgias and myalgias. This is followed by pain and swelling of joints usually in symmetrical fashion, especially involving joints of hands, wrists and feet. Unlike migratory polyarthritis of rheumatic fever, RA usually persists in the involved joint. Approximately 20% of patients develop rheumatoid nodules located over the extensor surfaces of the elbows and fingers. Extra-articular manifestations infrequently produce symptoms, but when present complicate the diagnosis.

ETIOPATHOGENESIS Present concept on etiology and pathogenesis proposes that RA occurs in an *immunogenetically predisposed individual to the effect of microbial agents acting as trigger antigen*. The role of *superantigens* which are produced by several microorganisms with capacity to bind to HLA-DR molecules (MHC-II region) has also emerged.

I. Immunologic derangements A number of observations in patients and experimental animals indicate the role of immune processes, particularly autoimmune phenomenon, in the development of RA. These include the following:

1. Detection of circulating autoantibody called rheumatoid factor (RF) against Fc portion of autologous IgG in about 80% cases of RA. RF antibodies are heterogeneous and consist of IgM and IgG class.
2. The presence of antigen-antibody complexes (IgG-RF complexes) in the circulation as well as in the synovial fluid.
3. The presence of other autoantibodies such as antinuclear factor (ANF), antibodies to collagen type II, and antibodies to cytoskeleton.
4. Antigenicity of proteoglycans of human articular cartilage.
5. The presence of γ -globulin, particularly IgG and IgM, in the synovial fluid.
6. Association of RA with amyloidosis.
7. Activation of cell-mediated immunity as observed by presence of numerous inflammatory cells in the synovium, chiefly CD4+ T lymphocytes and some macrophages.

II. Trigger events Though the above hypothesis of a possible role of autoimmunity in the etiology and pathogenesis of RA is generally widely accepted, controversy continues as regards the trigger events which initiate the destruction of articular cartilage. Various possibilities which have been suggested are as follows:

1. The existence of an infectious agent such as mycoplasma, Epstein-Barr virus (EBV), cytomegalovirus (CMV) or rubella virus, either locally in the synovial fluid or systemic infection some time prior to the attack of RA.
2. The possible role of HLA-DR4 and HLA-DR1 in initiation of immunologic damage.

The proposed events in **immunopathogenesis** of RA are as under (**Fig. 26.24**):

- i) In response to antigenic exposure (e.g. infectious agent) in a genetically predisposed individual (HLA-DR), CD4+ T-cells are activated.
- ii) These cells elaborate *cytokines*, the important ones being tumour necrosis factor (TNF)- α , interferon (IF)- γ , interleukin (IL)-1 and IL-6.
- iii) These cytokines *activate* endothelial cells, B lymphocytes and macrophages.
- iv) Activation of B-cells releases IgM antibody against IgG (i.e. anti-IgG); this molecule is termed *rheumatoid factor (RF)*.
- v) IgG and IgM immune complexes trigger *inflammatory damage* to the synovium, small blood vessels and collagen.
- vi) Activated endothelial cells express *adhesion molecules* which stimulate collection of inflammatory cells.
- vii) Activation of macrophages releases more cytokines which cause damage to joint tissues and vascularisation of cartilage termed *pannus formation*.
- viii) Eventually damage and destruction of bone and cartilage are followed by *fibrosis* and *ankylosis* producing joint deformities.

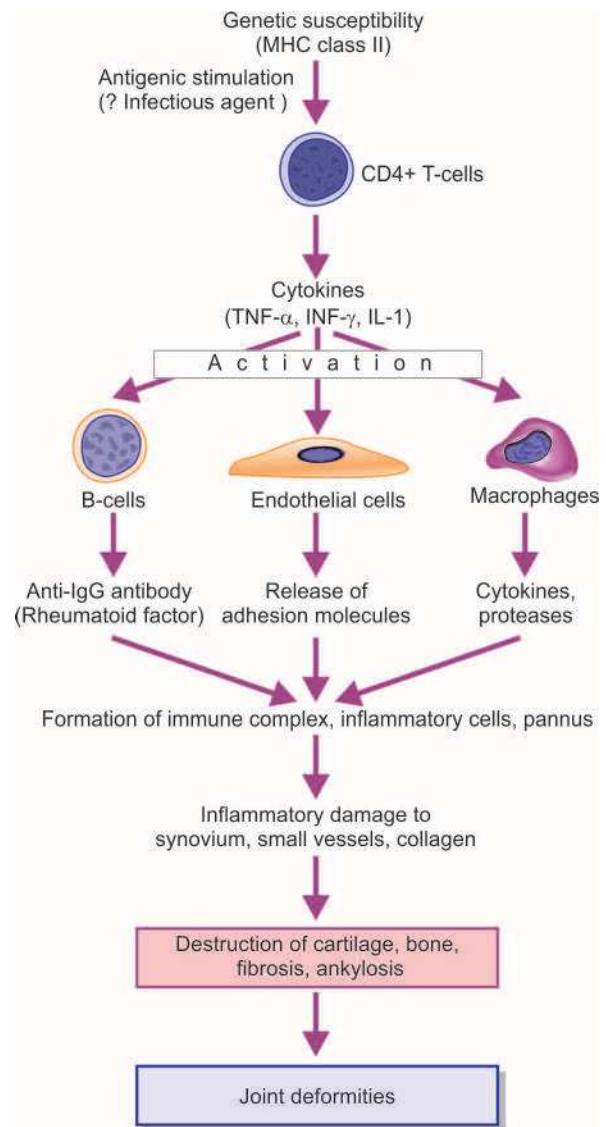

Figure 26.24 Pathogenesis of rheumatoid arthritis.

LABORATORY FINDINGS These include following investigations:

- i) About 80% of cases are seropositive for *RA factor*. However, RA factor titres are elevated in certain unrelated diseases too such as in viral hepatitis, cirrhosis, sarcoidosis and leprosy.
- ii) *HLA-DR4 and HLA-DR1* association in familial cases.
- iii) *Anti-CCP antibodies* for evaluation of association of RA factor with HLA.
- iv) Other laboratory findings include mild normocytic and normochromic anaemia, elevated ESR, mild leucocytosis and hypergammaglobulinaemia.
- v) Advanced cases show characteristic radiologic abnormalities such as narrowing of joint space and ulnar deviation of the fingers and radial deviation of the wrist.

MORPHOLOGIC FEATURES The predominant pathologic lesions are found in the joints and tendons, and less often, extra-articular lesions are encountered.

ARTICULAR LESIONS RA involves first the small joints of hands and feet and then symmetrically affects the joints of wrists, elbows, ankles and knees. The proximal interphalangeal and metacarpophalangeal joints are affected most severely. Frequently cervical spine is involved but lumbar spine is spared.

Histologically, the characteristic feature is diffuse proliferative synovitis with formation of pannus. The microscopic changes are as under (**Fig. 26.25**):

1. Numerous folds of large villi of synovium.
2. Marked thickening of the synovial membrane due to oedema, congestion and multilayering of synoviocytes.
3. Intense inflammatory cell infiltrate in the synovial membrane with predominance of lymphocytes, plasma cells and some macrophages, at places forming lymphoid follicles.
4. Foci of fibrinoid necrosis and fibrin deposition.

The pannus progressively destroys the underlying cartilage and subchondral bone. This invasion of pannus results in demineralisation and cystic resorption of underlying bone. Later, fibrous adhesions or even bony ankylosis may unite the two opposing joint surfaces. In addition, persistent inflammation causes weakening and even rupture of the tendons.

EXTRA-ARTICULAR LESIONS Nonspecific inflammatory changes are seen in the blood vessels (acute vasculitis), lungs, pleura, pericardium, myocardium, lymph nodes, peripheral nerves and eyes. But one of the characteristic extra-articular manifestation of RA is occurrence of rheumatoid nodules in the skin. *Rheumatoid nodules* are particularly found in the subcutaneous tissue over pressure points such as the elbows, occiput and sacrum. The centre of these nodules consists of an area of fibrinoid necrosis and cellular debris, surrounded by several layers of palisading large epithelioid cells, and peripherally there are numerous lymphocytes, plasma cells and macrophages. Similar nodules may be found in the lung parenchyma, pleura, heart valves, myocardium and other internal organs.

There are a few *variant forms* of RA:

1. **Juvenile RA** found in adolescent patients under 16 years of age is characterised by acute onset of fever and predominant involvement of knees and ankles. Pathologic changes are similar but RF is rarely present.
2. **Felty's syndrome** consists of polyarticular RA associated with splenomegaly and hypersplenism and consequent haematologic derangements.
3. **Ankylosing spondylitis or rheumatoid spondylitis** is rheumatoid involvement of the spine, particularly sacroiliac joints, in young male patients. The condition has a strong HLA-B27 association and may have associated inflammatory diseases such as inflammatory bowel disease, anterior uveitis and Reiter's syndrome.

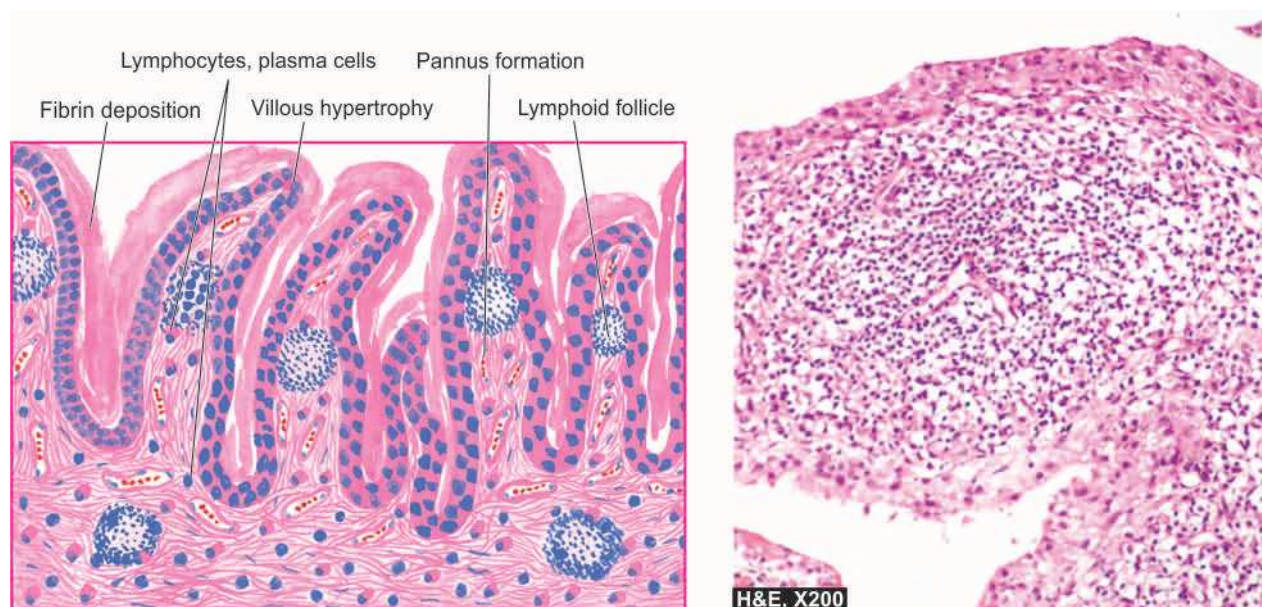

Figure 26.25 Rheumatoid arthritis. The characteristic histologic features are villous hypertrophy of the synovium and marked mononuclear inflammatory cell infiltrate in synovial membrane with formation of lymphoid follicles at places.

SUPPURATIVE ARTHRITIS

Infectious or suppurative arthritis is invariably an acute inflammatory involvement of the joint. Bacteria usually reach the joint space from the bloodstream but other routes of infection by direct contamination of an open wound or lymphatic spread may also occur. Immunocompromised and debilitated patients are increasingly susceptible to suppurative arthritis. The common causative organisms are gonococci, meningococci, pneumococci, staphylococci, streptococci, *H. influenzae* and gram-negative bacilli. Clinically, the patients present with manifestations of any local infection such as redness, swelling, pain and joint effusion. Constitutional symptoms such as fever, neutrophilic leucocytosis and raised ESR are generally associated.

MORPHOLOGIC FEATURES The haematogenous infectious joint involvement is more often monoarticular rather than polyarticular. The large joints of lower extremities such as the knee, hip and ankle, shoulder and sternoclavicular joints are particularly favoured sites. The process begins with hyperaemia, synovial swelling and infiltration by polymorphonuclear and mononuclear leucocytes along with development of effusion in the joint space. There may be formation of inflammatory granulation tissue and onset of fibrous adhesions between the opposing articular surfaces resulting in permanent ankylosis.

TUBERCULOUS ARTHRITIS

Tuberculous infection of the joints results most commonly from haematogenous dissemination of the organisms from pulmonary or other focus of infection. Another route of infection is direct spread from tuberculous osteomyelitis close to the joint. Uncommon in the West, the disease is seen not infrequently in developing countries more commonly in children and also in adults.

MORPHOLOGIC FEATURES Tuberculous involvement of the joints is usually monoarticular type but tends to be more destructive than the suppurative arthritis. Most commonly involved sites are the spine, hip joint and knees, and less often other joints are affected. Tuberculosis of the spine is termed *Pott's disease* or *tuberculous spondylitis*.

Grossly, the affected articular surface shows deposition of grey-yellow exudate and occasionally tubercles are present. The joint space may contain tiny grey-white loose bodies and excessive amount of fluid.

Histologically, the synovium is studded with solitary or confluent caseating tubercles. The underlying articular cartilage and bone may be involved by extension of tuberculous granulation tissue and cause necrosis (*caries*).

GOUT AND GOUTY ARTHRITIS

Gout is a disorder of purine metabolism manifested by the following features, occurring singly or in combination:

1. Increased serum uric acid concentration (*hyperuricaemia*).
2. Recurrent attacks of characteristic type of acute arthritis in which crystals of *monosodium urate monohydrate* may be demonstrable in the leucocytes present in the synovial fluid.
3. Aggregated deposits of monosodium urate monohydrate (*tophi*) in and around the joints of the extremities.

4. *Renal disease* involving interstitial tissue and blood vessels.
5. *Uric acid nephrolithiasis*.

The disease usually begins in 3rd decade of life and affects men more often than women. A family history of gout is present in a fairly large proportion of cases indicating role of inheritance in hyperuricaemia. Clinically, the natural history of gout comprises 4 stages: asymptomatic hyperuricaemia, acute gouty arthritis, asymptomatic intervals of intercritical periods, and chronic tophaceous stage. In addition, gout nephropathy and urate nephrolithiasis may occur (page 673).

TYPES AND PATHOGENESIS The fundamental biochemical hallmark of gout is *hyperuricaemia*. A serum uric acid level in excess of 7 mg/dl, which represents the upper limit of solubility of monosodium urate in serum at 37°C at blood pH, is associated with increased risk of development of gout. Thus, *pathogenesis of gout is pathogenesis of hyperuricaemia*.

Hyperuricaemia and gout may be classified into 2 types: *metabolic* and *renal*, each of which may be *primary* or *secondary*. Primary refers to cases in which the underlying biochemical defect causing hyperuricaemia is not known, while secondary denotes cases with known causes of hyperuricaemia.

1. Hyperuricaemia of metabolic origin This group comprises about 10% cases of gout which are characterised by overproduction of uric acid. There is either an accelerated rate of purine biosynthesis *de novo*, or an increased turnover of nucleic acids. The causes of *primary metabolic gout* include a number of specific enzyme defects in purine metabolism which may be either of unknown cause or are inborn errors of metabolism. The *secondary metabolic gout* is due to either increased purine biosynthesis or a deficiency of glucose-6-phosphatase.

2. Hyperuricaemia of renal origin About 90% cases of gout are the result of reduced renal excretion of uric acid. Altered renal excretion could be due to reduced glomerular filtration of uric acid, enhanced tubular reabsorption or decreased secretion. The causes of gout of renal origin include diuretic therapy, drug-induced (e.g. aspirin, pyrazinamide, nicotinic acid, ethambutol and ethanol), adrenal insufficiency, starvation, diabetic ketosis, and disorders of parathyroid and thyroid. Renal disease *per se* rarely causes secondary hyperuricaemia such as in polycystic kidney disease and leads to urate nephropathy.

MORPHOLOGIC FEATURES The pathologic manifestations of gout include: acute gouty arthritis, chronic tophaceous arthritis, tophi in soft tissues, and renal lesions as under:

1. Acute gouty arthritis This stage is characterised by acute synovitis triggered by precipitation of sufficient amount of needle-shaped crystals of monosodium urate from serum or synovial fluid. There is joint effusion containing numerous polymorphs, macrophages and microcrystals of urates. The mechanism of acute inflammation appears to include phagocytosis of crystals by leucocytes, activation of the kallikrein system, activation of the complement system and urate-mediated disruption of lysosomes within the leucocytes leading to release of lysosomal products in the joint effusion. Initially, there is monoarticular involvement accompanied with intense pain, but later it becomes polyarticular along with constitutional symptoms like fever. Acute gouty arthritis is predominantly a disease of lower extremities, affecting

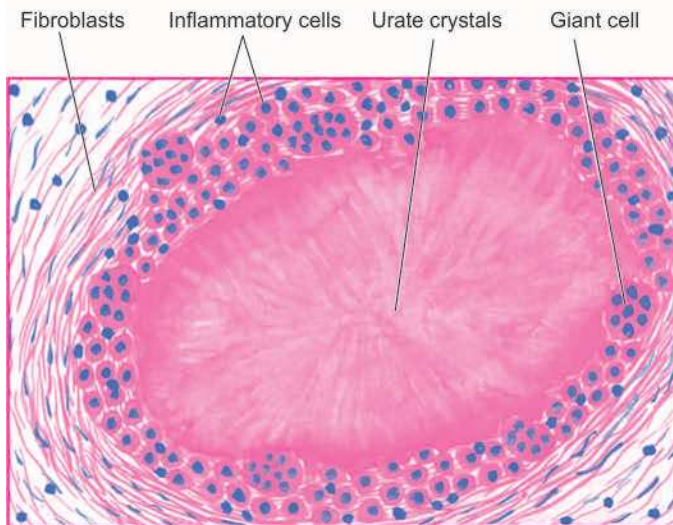

Figure 26.26 A gouty tophus, showing central aggregates of urate crystals surrounded by inflammatory cells, fibroblasts and occasional giant cells.

most commonly *great toe*. Other joints affected, in order of decreasing frequency, are: the instep, ankles, heels, knees, wrists, fingers and elbows.

2. Chronic tophaceous arthritis Recurrent attacks of acute gouty arthritis lead to progressive evolution into chronic arthritis. The deposits of urate encrust the articular cartilage. There is synovial proliferation, pannus formation and progressive destruction of articular cartilage and subchondral bone. Deposits of urates in the form of tophi may be found in the periarticular tissues.

3. Tophi in soft tissue A *tophus* (meaning 'a porous stone') is a mass of urates measuring a few millimeters to a few centimeters in diameter. Tophi may be located in the periarticular tissues as well as subcutaneously such as on the hands and feet. Tophi are surrounded by inflammatory reaction consisting of macrophages, lymphocytes, fibroblasts and foreign body giant cells (Fig. 26.26).

4. Renal lesions Chronic gouty arthritis frequently involves the kidneys. Three types of renal lesions are described in the kidneys: acute urate nephropathy, chronic urate nephropathy and uric acid nephrolithiasis.

- i) *Acute urate nephropathy* is attributed to the intratubular deposition of monosodium urate crystals resulting in acute obstructive uropathy.
- ii) *Chronic urate nephropathy* refers to the deposition of urate crystals in the renal interstitial tissue.
- iii) *Uric acid nephrolithiasis* is related to hyperuricaemia resulting in hyperuricaciduria (page 673).

PSEUDOGOUT (PYROPHOSPHATE ARTHROPATHY)

Pseudogout refers to an inflammatory joint involvement due to deposition of calcium pyrophosphate in the joint space. The condition is seen in middle-aged and elderly individuals of either sex. The pain is usually less severe and involvement of big toe is rare. The pathogenesis is unclear but several factors have been implicated. These include: associated metabolic disease (e.g. hyperparathyroidism, hypothyroidism, gout, ochronosis, Wilson's disease and haemochromatosis), heredity, familial occurrence, rheumatoid arthritis and osteoarthritis.

MORPHOLOGIC FEATURES The involvement may be monoarticular or polyarticular but large joints such as knees, hips and shoulders are more often affected. The joint effusion contains crystals of calcium pyrophosphate. There is an acute inflammatory response and deposits of rhomboid crystals on the articular cartilage, ligaments, tendons and joint capsule, termed *chondrocalcinosis*.

PIGMENTED VILLODULAR SYNOVITIS AND TENOSYNOVIAL GIANT CELL TUMOUR (NODULAR TENOSYNOVITIS)

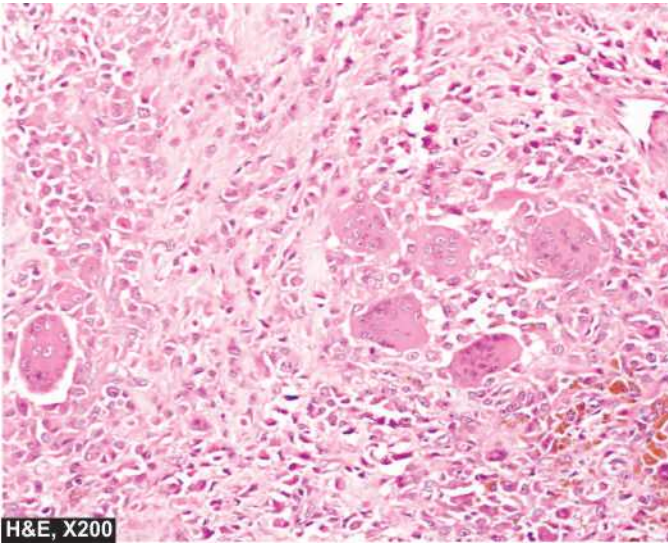

The terms 'pigmented villonodular synovitis' and 'nodular tenosynovitis' represent diffuse and localised forms respectively of the same underlying process. The localised form of lesion is also termed *xanthofibroma* or *benign synovioma*. When the giant cells are numerous in localised tenosynovitis, the condition is called *giant cell tumour of tendon sheath*.

The origin and histogenesis of these conditions are unknown. They were initially regarded as inflammatory in origin and hence the name synovitis. But currently cytogenetic studies have shown clonal proliferation of cells indicating that these lesions are neoplastic. Clinically, they present with pain, swelling and limitation of movement of the affected joint and may be easily mistaken for rheumatoid or infective arthritis. The lesions are adequately treated by excision but recurrences are common.

MORPHOLOGIC FEATURES Though the two conditions have many morphologic similarities, they are best described separately.

◆ **Giant cell tumour of tendon sheath (Nodular tenosynovitis)** The localised nodular tenosynovitis is seen most commonly in the tendons of fingers.

Grossly, it takes the form of a solitary, circumscribed, pedunculated, small and lobulated nodule, measuring less than 2 cm in diameter. It is closely attached to and sometimes grooved by the underlying tendon. On section, the lesion is yellowish-brown.

H&E, X200

Figure 26.27 Tenosynovial giant cell tumour. The tumour shows infiltrate of small oval to spindle-shaped cells with numerous interspersed multinucleate giant cells lying in a background of fibrous tissue.

Histologically, it is well encapsulated and is composed of sheets of small oval to spindle-shaped cells, foamy xanthoma cells, scattered multinucleate giant cells and irregular bundles of collagen. Many of the spindle-shaped cells are haemosiderin-laden (**Fig. 26.27**).

◆ **Pigmented villonodular tenosynovitis** This is a diffuse form of synovial overgrowth seen most commonly in the knee and hip.

Grossly, the synovium has characteristic sponge-like reddish-brown or tan appearance with intermingled elongated villous projections and solid nodules.

Histologically, the changes are modified by recurrent injury. The enlarged villi are covered by hyperplastic synovium and abundant subsynovial infiltrate of lymphocytes, plasma cells and macrophages, many of which are lipid-laden and haemosiderin-laden. Multinucleate giant cells are scattered in these areas.

CYST OF GANGLION

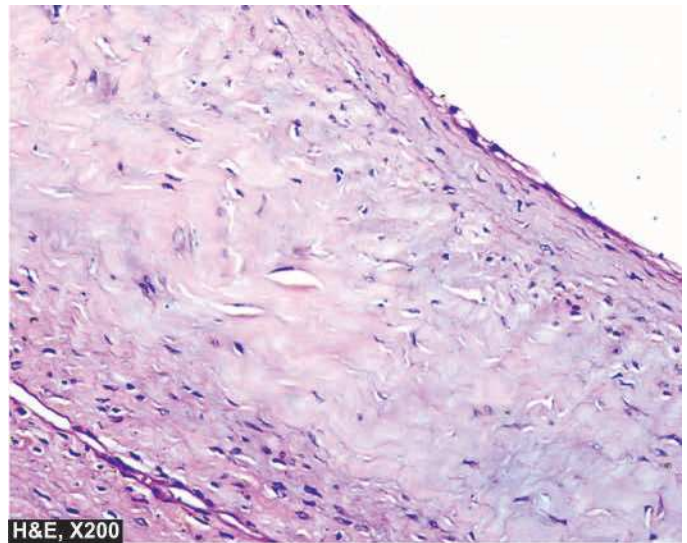

A ganglion is a small, round or ovoid, movable, subcutaneous cystic swelling of synovium. The most common location is dorsum of wrist but may be found on the dorsal surface of foot near the ankle. Histogenesis of the ganglion is disputed. It may be the result of herniated synovium, embryologically displaced synovial tissue, or post-traumatic degeneration of connective tissue.

MORPHOLOGIC FEATURES **Grossly**, a ganglion is a small cyst filled with clear mucinous fluid. It may or may not communicate with the joint cavity or tendon where it is located.

Microscopically, the cyst has a wall composed of dense or oedematous connective tissue which is sometimes lined by synovial cells but more often has indistinct lining (**Fig. 26.28**).

BURSITIS

Inflammation of bursa is termed bursitis. Bursae are synovial-lined sacs found over bony prominences. Bursitis occurs

H&E, X200

Figure 26.28 Cyst of ganglion. The cyst wall is composed of dense connective tissue lined internally by flattened lining. The cyst wall shows myxoid degeneration.

following mechanical trauma or inflammation. It may result following a single injury such as *olecranon bursitis* and *prepatellar bursitis*, but is more often due to repeated injuries from excessive pressure such as in *housemaid's knee* or *tennis elbow*.

MORPHOLOGIC FEATURES **Grossly**, the bursal sac is thick-walled and may contain watery, mucoid or granular brown material.

Histologically, the bursal wall is composed of dense fibrous tissue lined by inflammatory granulation tissue. The wall is infiltrated by lymphocytes, plasma cells and macrophages and may show focal calcium deposits.

GIST BOX 26.7 Diseases of Joints

- ▣ Osteoarthritis or degenerative joint disease is chronic disorder of synovial joints characterised by progressive degenerative changes in the articular cartilages over the years.
- ▣ Rheumatoid arthritis is a chronic multisystem disease of unknown cause occurring in 3rd to 4th decade of life commonly in women. It occurs in immunogenetically predisposed individual to the effect of some microbial infection as trigger event.
- ▣ Suppurative arthritis is an acute inflammatory involvement of the joint by bacteria, usually from the bloodstream.
- ▣ Gout is a disorder of purine metabolism manifested by hyperuricaemia, recurrent attacks of characteristic acute arthritis, deposits of tophi in and around the joints, and in some cases uric acid nephrolithiasis.
- ▣ Pigmented villonodular synovitis and nodular tenosynovitis are diffuse and localised form respectively of the same underlying process. When the giant cells are numerous in localised tenosynovitis, the condition is called giant cell tumour of tendon sheath.
- ▣ A ganglion is a small, round or ovoid, movable, subcutaneous cystic swelling due to degeneration of synovium.
- ▣ Bursal cyst or bursitis is inflammation of the sac-like synovial tissue.

NORMAL STRUCTURE

Striated skeletal muscles consist of bundles of fibres called *fascicles*, each of which is surrounded by connective tissue sheath termed *perimysium*. Perimysium contains blood vessels and nerve supply of the muscle fascicles. Each muscle fibre is enveloped by delicate fibrous stroma called *endomysium*.

Individual muscle fibre is an elongated multinucleated syncytium-like cell about 100 µm in diameter and several centimeters in length. The muscle nuclei are spindle-shaped and lie at the periphery of fibre under the sarcolemma, the plasma membrane of muscle fibre. The cytoplasm of the muscle fibre contains myofilaments which are contractile elements. Myofilaments are of 2 types—*myosin* comprising thick filaments and *actin* constituting thin filaments. These together produce cross-striations in muscle fibres seen in longitudinal sections on light microscopy. *Sarcomeres* are the partitions of myofilaments into equal zones. Each sarcomere represents the distance between consecutive *Z bands* and contains the *central A* (anisotropic) band, and the *lateral I* (isotropic) bands.

The major *functions* of striated skeletal muscle are to convert chemical energy into mechanical energy, to act as a store of energy and proteins, and to play a role in the metabolism of the body. The muscle, however, cannot function as a contractile organ without a nerve supply. For this purpose, there are **motor units**, each of which consists of the following:

1. *Motor neuron cell body* located in the spinal cord anterior horn, or a cranial nerve nucleus.
2. The *axon* of the motor neuron in the peripheral or cranial nerve.
3. The *neuromuscular junction*.
4. The *muscle fibres* innervated by the motor neuron.

The muscle fibre contraction occurs by action potential generated by chemical transmission of the impulse across the synaptic gap by acetylcholine.

Skeletal muscles are affected in a number of systemic diseases and pathologic processes such as ischaemia and toxic (Zenker's) necrosis; atrophy and hypertrophy; degeneration and regeneration; and polymyositis, dermatomyositis, and various forms of infective myositis (e.g. viral myositis, pyogenic myositis, gas gangrene and parasitic involvements such as cysticercosis). Most of the conditions have been considered already in different chapters. Here, two important groups of specific diseases—neurogenic and myopathic diseases, are discussed here. A classification of neuromuscular disorders based on the part of the motor unit involved is presented in **Table 26.4**.

NEUROGENIC DISEASES

The group of neurogenic diseases affecting skeletal muscles is characterised by a combination of muscular weakness and fatigability. The most common of these is myasthenia gravis; others are congenital myasthenia, an acquired Eaton-Lambert syndrome associated with carcinoma of the lung, and denervation atrophy.

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is a neuromuscular disorder of autoimmune origin in which the acetylcholine receptors

Table 26.4 Classification of neuromuscular diseases.

| | SITE OF MOTOR UNIT | DISEASE |
|------|--|-------------------------------|
| I. | ANTERIOR HORN CELL | |
| 1. | Without upper motor neuron involvement | Spinal muscular atrophy |
| 2. | With upper motor neuron involvement | Amyotrophic lateral sclerosis |
| II. | PERIPHERAL NERVE | |
| 1. | Unifocal | Carpal-tunnel syndrome |
| 2. | Multifocal | Mononeuritis multiplex |
| 3. | Diffuse | Diabetic neuropathy |
| III. | NEUROMUSCULAR JUNCTION | Myasthenia gravis |
| IV. | MUSCLE | Duchenne's muscular dystrophy |

(AChR) in the motor end-plates of the muscles are damaged. The term '*myasthenia*' means 'muscular weakness' and '*gravis*' implies 'serious'; thus both together denote the clinical characteristics of the disease. MG may be found at any age but adult women are affected more often than adult men in the ratio of 3:2. The condition presents clinically with muscular weakness and fatigability, initially in the ocular musculature but later spreads to involve the trunk and limbs. There is about 10% mortality in MG which is due to severe generalised disease and involvement of respiratory muscles. Several other autoimmune diseases have been found associated with MG such as autoimmune thyroiditis, rheumatoid arthritis, SLE, pernicious anaemia and collagen-vascular diseases.

PATHOGENESIS The pathogenesis of MG is best understood in the context of normal muscle metabolism (**Fig. 26.29**):

◆ **Normally**, acetylcholine is synthesised in the motor nerve terminal and stored in vesicles that are released spontaneously when an action potential reaches the nerve terminal. Acetylcholine from released vesicles combines with AChRs, initiating an action potential which is propagated along the muscle fibre triggering muscle contraction.

◆ **In MG**, the basic defect is reduction in the number of available AChRs at the postsynaptic muscle membrane. In addition, the postsynaptic folds are flattened. These changes result in decreased neuromuscular transmission leading to failure to trigger muscle action potentials and consequent weakened muscle contraction. The neuromuscular abnormalities in MG are mediated by autoimmune response. About 85-90% patients of MG have anti-AChR-antibodies in their sera. These antibodies reduce the number of available AChRs either by blocking the active sites of the receptors or by damaging the post-synaptic muscle membrane in collaboration with complement. The exact mechanism how autoimmune response is initiated is not completely understood but the thymus appears to play a role in this process (page 369). Majority of patients of MG may have either thymoma or thymic hyperplasia; thymectomy is helpful in ameliorating the condition. The thymus possibly sensitises B cells to produce anti-AChR antibodies.

MORPHOLOGIC FEATURES *Grossly*, the muscles appear normal until late in the course of disease when they become wasted.

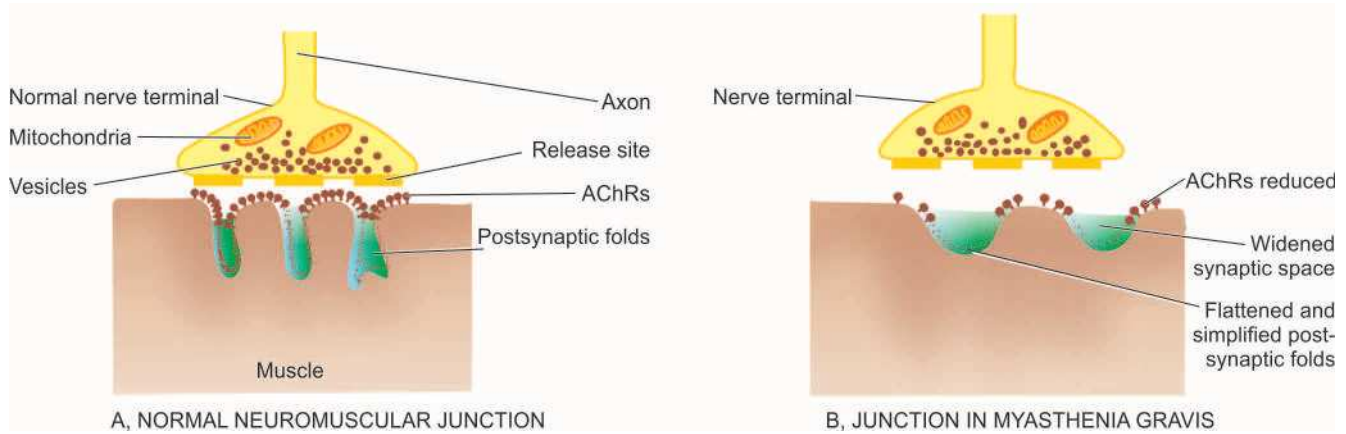

Figure 26.29 Neuromuscular junction in normal transmission (A) and in myasthenia gravis (B). The junction in MG shows reduced number of AChRs, flattened and simplified postsynaptic folds, a widened synaptic space but a normal nerve terminal.

By **light microscopy**, a few clumps of lymphocytes may be found around small blood vessels. Degenerating muscle fibres are present in half the cases.

Electron microscopy reveals reduction in synaptic area of the motor axons due to flattening or simplification of postsynaptic folds. The number of AChRs is greatly reduced. By immunocytochemistry combined with electron microscopy, it is possible to demonstrate the complex of IgG and complement at the neuromuscular junctions.

DENERVATION ATROPHY

If the muscle or a part of muscle is deprived of its motor nerve supply, the affected muscle undergoes atrophy. In demyelination, on the other hand, there is conduction block in the nerve impulse but no denervation and hence muscle atrophy does not occur.

Denervating diseases are characterised by axonal degeneration and consequent muscle atrophy. These include *amyotrophic lateral sclerosis* as an example of anterior horn cell disease, and *peripheral neuropathy* causing injury to myelinated axon. The clinical manifestations of denervation atrophy are combination of muscular weakness and reduced muscle bulk. In amyotrophic lateral sclerosis, there are characteristic fasciculations of muscles of the shoulder and tongue.

MORPHOLOGIC FEATURES Denervation atrophy is pathologically characterised by groups of small angulated muscle fibres alternating with groups of plump, normal or even hypertrophic fibres with intact innervation. Further progression of the process may produce superimposed changes of muscular dystrophy.

Table 26.5 Contrasting features of muscular dystrophies.

| TYPE | INHERITANCE | AGE AT ONSET | CLINICAL FEATURES | OTHER SYSTEMS INVOLVED | COURSE |
|-------------------------------------|---------------------|--------------------------|--|---|---|
| 1. <i>Duchenne's type</i> | X-linked recessive | By age 5 | Symmetric weakness; initially pelvifemoral; later weakness of girdle muscles; pseudo-hypertrophy of calf muscles | Cardiomegaly; reduced intelligence | Progressive; death by age 20 due to respiratory failure |
| 2. <i>Becker's type</i> | X-linked recessive | By 2nd decade | Slow progressive weakness of girdle muscle (minor variant of Duchenne's type) | Cardiomegaly | Benign |
| 3. <i>Myotonic type</i> | Autosomal dominant | Any decade | Slow progressive weakness and myotonia of eyelids, face, neck, distal limb muscles | Cardiac conduction defects; mental impairment; cataracts; frontal baldness; gonadal atrophy | Benign |
| 4. <i>Facioscapulo-humeral type</i> | Autosomal dominant | 2nd-4th decade | Slowly progressive weakness of facial, scapular and humeral muscles | Hypertension | Benign |
| 5. <i>Limb-girdle type</i> | Autosomal recessive | Early childhood to adult | Slowly progressive weakness of shoulder and hip girdle muscles | Cardiomyopathy | Variable progression |
| 6. <i>Oculo-pharyngeal type</i> | Autosomal dominant | 5th-6th decade | Slowly progressive weakness of extraocular eyelid, face and pharyngeal muscles | — | Rarely progressive |

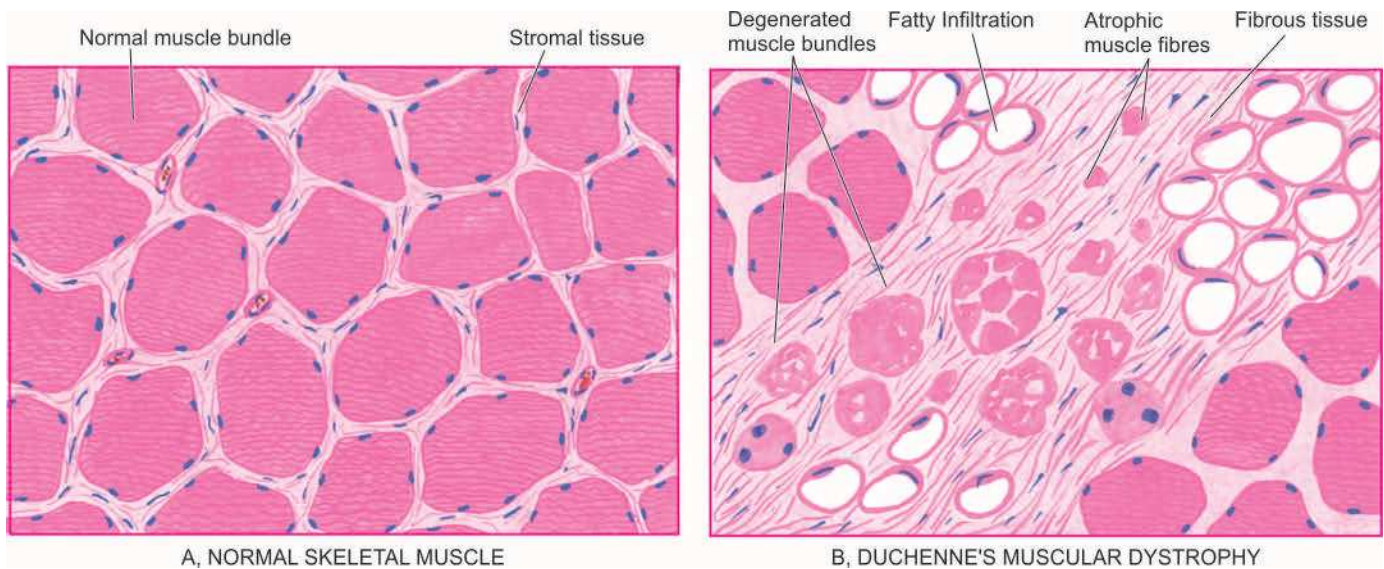

Figure 26.30 Normal skeletal muscle (A) contrasted with findings in Duchenne's muscular dystrophy (B) showing hyaline fibres, fibre degeneration, loss of fibres and replacement by interstitial fibrosis and adipose tissue.

MYOPATHIC DISEASES (MYOPATHIES)

Myopathies are primary skeletal muscle diseases resulting in chronic muscle weakness. These are divided into 5 broad groups: hereditary (muscular dystrophies), inflammatory, endocrine, metabolic and toxic myopathies. Only the hereditary myopathies, also termed muscular dystrophies, are briefly considered below.

MUSCULAR DYSTROPHIES

Muscular dystrophies are a group of genetically-inherited primary muscle diseases, having in common, progressive and unremitting muscular weakness. Six major forms of muscular dystrophies are described: *Duchenne's*, *Becker's*, *myotonic*, *facio-scapulohumeral*, *limb-girdle* and *oculopharyngeal* type. Each type of muscular dystrophy is a distinct entity having differences in inheritance pattern, age at onset, clinical features, other organ system involvements and clinical course. These differences are summarised in **Table 26.5**. However, in general, muscular dystrophies manifest in childhood or in early adulthood. Family history of neuromuscular disease is elicited in many cases.

MORPHOLOGIC FEATURES Common to all forms of muscular dystrophies are muscle fibre necrosis, regenerative activity, replacement by interstitial fibrosis and adipose tissue (**Fig. 26.30**).

GIST BOX 26.8

Diseases of Skeletal Muscles

- ▣ Neurogenic diseases affecting skeletal muscles have a combination of muscular weakness and fatiguability e.g. myasthenia gravis (due to damage to acetylcholine receptors) and denervation atrophy.
- ▣ Myopathies are primary skeletal muscle diseases resulting in chronic muscle weakness. These include hereditary or muscular dystrophies, inflammatory, endocrine, metabolic and toxic myopathies.

CLINICAL CASE 28

A 12 years old boy comes to orthopaedic surgeon with complaints of pain and progressive swelling around his right knee for one month which does not improve with rest. There is no history of any trauma.

Local examination shows diffuse hard swelling around upper part of right knee. An X-ray of the right knee shows an expanded and osteolytic mass in the right lower femur in the region of metaphysis.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 914 (Appendix II)

Soft Tissue Tumours

GENERAL FEATURES

INTRODUCTION

For the purpose of classification of this group of tumours, the WHO has defined soft tissues as all “non-epithelial extra-skeletal tissues of the body except the reticuloendothelial system, the glia and the supporting tissues of specific organs and viscera”. Thus, soft tissues included for the purpose of categorisation of these tumours are: fibrous tissue, adipose tissue, muscle tissue, synovial tissue, blood vessels and neuroectodermal tissues of the peripheral and autonomic nervous system (Table 27.1). The lesions of these tissues are embryologically derived

from mesoderm, except those of peripheral nerve which are derived from ectoderm. Tumours of smooth muscle tissue, blood vessels and nerves are described elsewhere in the book, while tumours and tumour-like lesions composed of other soft tissues are discussed in this chapter.

Benign soft tissue tumours are about 100 times more common than sarcomas. Sarcomas rarely arise from malignant transformation of a pre-existing benign tumour. Instead, sarcomas originate from the primitive mesenchymal cells having the capacity to differentiate along different cell pathways. As discussed in Chapter 7, soft tissue sarcomas metastasise most frequently by the haematogenous route and disseminate commonly to the lungs, liver, bone and brain. Lymph node metastases are often late and are associated with widespread dissemination of the tumour. Histologic differentiation and grading of soft tissue sarcomas are important because of varying clinical behaviour, prognosis and response to therapy.

Majority of soft tissue tumours have following important general features:

1. Superficially-located tumours tend to be benign while *deep-seated lesions* are more likely to be malignant.
2. *Large-sized tumours* are generally more malignant than small ones.
3. *Rapidly-growing tumours* often behave as malignant tumours than those that develop slowly.
4. Malignant tumours have frequently *increased vascularity* while benign tumours are selectively avascular.
5. Although soft tissue tumours may arise anywhere in the body but in general *more common locations* are lower extremity (40%), upper extremity (20%), trunk and retroperitoneum (30%) and head and neck (10%).
6. Generally, *males* are affected more commonly than females.
7. Approximately 15% of soft tissue tumours occur in *children* and include some specific examples of soft tissue sarcomas e.g. rhabdomyosarcoma, synovial sarcoma.

Table 27.1 Classification of common soft tissue tumours.

1. TUMOURS AND TUMOUR-LIKE LESIONS OF FIBROUS TISSUE
 - i) Fibromas
 - ii) Fibromatosis
 - Nodular fasciitis
 - iii) Superficial (palmar, plantar)
 - Deep (desmoid)
 - iv) Fibrosarcoma
2. FIBROHISTIOCYTIC TUMOURS
 - i) Benign fibrous histiocytoma
 - ii) Dermatofibrosarcoma protuberans
 - iii) Malignant fibrous histiocytoma (Pleomorphic sarcoma)
3. TUMOURS OF ADIPOSE TISSUE
 - i) Lipoma
 - ii) Liposarcoma
4. SKELETAL MUSCLE TUMOURS
 - i) Rhabdomyoma
 - ii) Rhabdomyosarcoma
5. SMOOTH MUSCLE TUMOURS
 - i) Leiomyoma (page 726)
 - ii) Leiomyosarcoma (page 726)
6. TUMOURS OF BLOOD VESSELS (see Table 13.5, page 391)
7. TUMOURS OF PERIPHERAL NERVES (page 885)
 - i) Neurofibroma
 - ii) Schwannoma
 - iii) Malignant peripheral nerve sheath tumour
8. TUMOURS OF UNCERTAIN HISTOGENESIS
 - i) Synovial sarcoma
 - ii) Alveolar soft part sarcoma
 - iii) Granular cell tumour
 - iv) Epithelioid sarcoma
 - v) Clear cell sarcoma
 - vi) Desmoplastic small round cell tumour

ETIOLOGY AND PATHOGENESIS

Etiology of soft tissue tumours remains largely unknown; however, a few common features in etiology and pathogenesis apply to many soft tissue tumours:

1. Frequently there is history of antecedent *trauma* which may bring the tumour to attention of the patient.
2. Molecular and cytogenetic studies in many soft tissue tumours reveal *chromosomal abnormalities and mutations* in genes which can be used as a marker for diagnosis and histogenesis e.g. translocations, various fusion genes etc.
3. Most of the soft tissue tumours occur *sporadically*; however, there are a few examples which are components of *genetic syndromes* e.g. neurofibromatosis type 1, Li-Fraumeni syndrome, Osler-Weber-Rendu syndrome etc.

CLASSIFICATION

Currently, the WHO classification divides all soft tissue tumours into following 4 categories:

Benign These soft tissue tumours generally do not recur and are cured by complete excision. Common example is lipoma.

Intermediate, locally aggressive These tumours are locally destructive, infiltrative and often recur but do not metastasise. Such tumours are generally treated by wide excision; for example desmoid tumour.

Intermediate, rarely metastasising This category of tumours is also locally destructive, infiltrative and recurrent but in addition about 2% cases may have clinical metastasis which may not be predicted by morphology. Common example in this category is dermatofibrosarcoma protuberans.

Malignant Tumours in this category are clearly malignant—they are locally destructive, infiltrative and they metastasise in a high percent of cases. The metastatic rate in low-grade sarcomas is about 2-10% and in high-grade sarcomas is 20-100%.

DIAGNOSTIC CRITERIA

Accurate pathological diagnosis of soft tissue tumours is based on histogenesis which is important for determining the prognosis and can be made by the following plan:

1. CELL PATTERNS Several morphological patterns in which tumour cells are arranged are peculiar in different tumours e.g.

- i) *Smooth muscle tumours*: interlacing fascicles of pink staining tumour cells.
- ii) *Fibrohistiocytic tumours*: characteristically have storiform pattern in which spindle tumour cells radiate from the centre in a spoke-wheel manner.
- iii) *Herringbone pattern*: is seen in fibrosarcoma in which the tumour cells are arranged like the vertebral column of seafish.
- iv) *Palisaded arrangement*: is characteristically seen in schwannomas in which the nuclei of tumour cells are piled upon each other.
- v) *Biphasic pattern*: is the term used for a combination arrangement of two types—fascicles and epithelial-like e.g. in synovial sarcoma.

2. CELL TYPES After looking at the pattern of cells described above, preliminary categorisation of soft tissue tumours is done on the basis of cell types comprising the soft tissue tumour:

- i) **Spindle cells**: These are the most common cell types in most sarcomas. However, there are subtle differences in different types of spindle cells e.g.
 - a) *Fibrogenic tumours* have spindle cells with light pink cytoplasm and tapering-ended nuclei.
 - b) *Neurogenic (Schwann cell) tumours* have tumour cells similar to fibrogenic cells but have curved nuclei.
 - c) *Leiomyomatous tumours* have spindle cells with blunt-ended (cigar-shaped) nuclei and more intense eosinophilic cytoplasm.
 - d) *Skeletal muscle tumours* have spindle cells similar to leiomyomatous cells but in addition have cytoplasmic striations.
- ii) **Small round cells**: Some soft tissue sarcomas are characterised by dominant presence of small round cells or blue cells

and are termed by various names such as malignant small round cell tumours, round cell sarcomas, or blue cell tumours (due to presence of lymphocyte-like round nuclear size and dense blue chromatin). Examples of this group of tumours are as under:

- a) Rhabdomyosarcoma (embryonal and alveolar types)
- b) Primitive neuroectodermal tumour (PNET)
- c) Ewing's sarcoma
- d) Neuroblastoma
- e) Malignant lymphomas.

A few examples of epithelial tumours such as small cell carcinoma and malignant carcinoid tumours enter in the differential diagnosis of small round cell tumours.

iii) Epithelioid cells: Some soft tissue tumours have either epithelioid cells as the main cells (e.g. epithelioid sarcoma) or have epithelial-like cells as a part of biphasic pattern of the tumour (e.g. synovial sarcoma).

3. IMMUNOHISTOCHEMISTRY Soft tissue tumours are distinguished by application of immunohistochemical stains. Antibody stains are available against almost each cell constituent. Based on differential diagnosis made on routine morphology, the panel of antibody stains is chosen for applying on paraffin sections for staining. Some common examples are as under:

- i) *Smooth muscle actin (SMA)*: for smooth muscle tumours.
- ii) *Vimentin*: as common marker to distinguish mesenchymal cells from epithelium.
- iii) *Desmin*: for skeletal muscle cells.
- iv) *S-100*: for nerve fibres.
- v) *Factor VIII*: antigen for vascular endothelium.
- vi) *LCA (leucocyte common antigen)*: common marker for lymphoid cells.

4. ELECTRON MICROSCOPY EM as such is mainly a research tool and does not have much diagnostic value in soft tissue tumours but can be applied sometimes to look for tonofilaments or cell organelles.

5. CYTOGENETICS Many soft tissue tumours have specific genetic and chromosomal changes which can be done for determining histogenesis, or for diagnosis and prognosis. Some of the common cytogenetic aberrations in soft tissue tumours are listed in **Table 27.2**.

GRADING

The number of pathological grades of soft tissue tumours may vary according to different grading systems: 2 grade system (grade I-II as low and high grade), 3-grade system (grade I, II, III as low, intermediate and high grade) and 4 grade system (grade I-IV). Pathological grading is based on following 3 features:

- i) Tumour differentiation or degree of cytologic atypia
- ii) Mitotic count
- iii) Tumour necrosis

STAGING

Different staging systems for soft tissue sarcomas have been described but two of the most accepted staging systems are *Enneking's staging* and American Joint Committee (AJC) staging system:

Enneking's staging: This staging system is accepted by most oncologists and is based on grade and location of tumour as under:

Table 27.2 Common chromosomal abnormalities in soft tissue tumours.

| TUMOUR | CYTOGENETIC ALTERATIONS | MOLECULAR ALTERATIONS | REASON FOR TESTING |
|---|--|--|---|
| 1. Ewing's sarcoma/PNET | t(11;22)(q24;q12) | <i>EWSR-FLI1</i> fusion gene | Differentiate from other small round cell tumours |
| 2. Alveolar rhabdomyosarcoma | t(1;13)(q36;q14) t(2;13)(p35;q14) | <i>PAX3-FOXO1A</i> fusion gene <i>PAX7-FOXO1A</i> fusion gene | Better prognosis Poorer prognosis |
| 3. Myxoid/ Round cell liposarcoma | t(12;16)(q13; p11) | <i>FUS-DDIT3</i> fusion gene | Diagnostic |
| 4. Synovial sarcoma | t(X;18)(p11;q11) | <i>SS18-SSX1</i> fusion gene | Differentiate biphasic from monophasic |
| 5. Extraskeletal myxoid chondrosarcoma | t(9;22)(q22;q12) | <i>EWSR1-NR4A3</i> fusion gene | Diagnostic |
| 6. Infantile fibrosarcoma | t(12;15)(p13;q26) trisomies 8, 11, 17, 20 | <i>ETV6-NTRK3</i> fusion gene | Differentiate from more aggressive adult fibrosarcoma |
| 7. Dermatofibrosarcoma protuberans | Ring forms of chromosomes 17, 22 | <i>COL1A1-PDGFB</i> fusion gene | Diagnostic |
| 8. Desmoplastic small round cell tumour | t(11;22)(p13;q12) | <i>EWSR1-WT1</i> fusion gene | Poor prognosis |
| 9. Alveolar soft part sarcoma | t(X;17)(p11;q25) | <i>TFE3-ASPL</i> fusion gene | Diagnostic |
| 10. Clear cell sarcoma | t(12;22)(q13;q12) | <i>EWSR1-ATF1</i> fusion gene | Distinguish from cutaneous melanoma |

◆ According to tumour location: T1 (intracompartmental) and T2 (extracompartmental) tumours.

◆ According to tumour grade : G1 (low grade) and G2 (high grade) tumours.

Accordingly, the stages of soft tissue tumours vary from stage I to stage III as under:

Stage I: G1 and T1-T2 tumours, but no metastases.

Stage II: G2 and T1 -T2 tumours, but without metastases.

Stage III: G1 or G2 , T1 or T2 tumours, but with metastases.

AJC staging: This AJC system of staging is similar to staging for other tumours. It is based on TNM system in which the primary tumor (T), the status of lymph nodes (N) and presence or absence of metastases (M) are taken into consideration for staging, besides the histologic grade of the tumour.

After these brief general comments, some important examples of tumours of different types of mesenchymal tissue origin are described here.

GIST BOX 27.1

General Features of Soft Tissue Tumours

- ☐ Soft tissue tumours are defined as tumours arising from non-epithelial extra-skeletal tissues of the body except the reticuloendothelial system, the glia and the supporting tissues of specific organs and viscera.
- ☐ Many of these tumours come to attention after trauma. Many of them have cytogenetic abnormalities. Most occur sporadically; others are part of genetic syndromes.
- ☐ Soft tissue tumours are divided into benign, intermediate (locally aggressive or rarely metastasising) and malignant.
- ☐ Their diagnosis rests on a few features: pattern, cellular features and aided by ancillary techniques of immunohistochemistry, EM and molecular profiling.
- ☐ Based on histologic features, they are divided into low-, intermediate- and high-grade.
- ☐ Staging of soft tissue tumours is based on either Enneking or AJC method, taking TNM and histologic grade into consideration.

SOFT TISSUE TUMOURS

TUMOURS AND TUMOUR-LIKE LESIONS OF FIBROUS TISSUE

Fibromas, reactive proliferations and fibromatosis, and fibrosarcoma are benign, tumour-like, and malignant neoplasms respectively, of fibrous connective tissue.

FIBROMAS

True fibromas are uncommon tumours in soft tissues. Many fibromas are actually examples of hyperplastic fibrous tissue rather than true neoplasms. On the other hand, combinations of fibrous growth with other mesenchymal tissue elements are more frequent e.g. neurofibroma, fibromyoma etc.

Three types of fibromas are distinguished:

1. Fibroma durum is a benign, often pedunculated and well-circumscribed tumour occurring on the body surfaces and mucous membranes. It is composed of fully matured and richly collagenous fibrous connective tissue (**Fig. 27.1**).

2. Fibroma molle or fibrolipoma, also termed **soft fibroma**, is similar type of benign growth composed of mixture of mature fibrous connective tissue and adult-type fat.

3. Elastofibroma is a rare benign fibrous tumour located in the subscapular region. It is characterised by association of collagen bundles and branching elastic fibres.

REACTIVE TUMOUR-LIKE PROLIFERATIONS

These include some of the common examples such as keloid, nodular fasciitis (pseudosarcomatous fasciitis) and myositis ossificans.

KELOID A keloid is a progressive fibrous overgrowth in response to cutaneous injury such as burns, incisions, insect bites, vaccinations and others. Keloids are found more often in blacks. Their excision is frequently followed by recurrences.

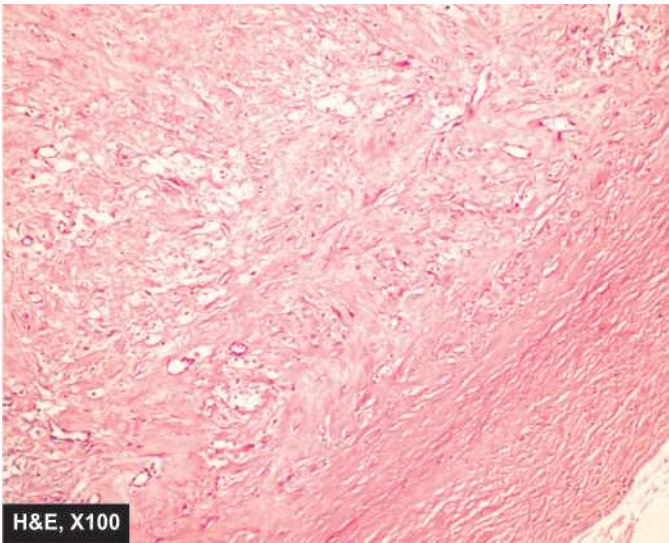

Figure 27.1 Fibroma of the oral cavity. The circumscribed lesion is composed of mature collagenised fibrous connective tissue.

Grossly, the keloid is a firm, smooth, pink, raised patch from which extend claw-like processes (keloid-claw).

Histologically, it is composed of thick, homogeneous, eosinophilic hyalinised bands of collagen admixed with thin collagenous fibres and large active fibroblasts. The adnexal structures are atrophic or destroyed.

There are some differences between a *keloid* and a *hypertrophic scar*. A hypertrophic scar of the skin is more cellular and has numerous fibroblasts than a keloid and is composed of thinner collagenous fibres. A keloid is a progressive lesion and liable to recurrences after surgical excision.

NODULAR FASCIITIS Nodular fasciitis, also called pseudo-sarcomatous fibromatosis, is a form of benign and reactive fibroblastic growth extending from superficial fascia into the subcutaneous fat, and sometimes into the subjacent muscle. The most common locations are the upper extremity, trunk and neck region of young adults. Local excision is generally curative. Less than 5% cases may have local recurrence.

Grossly, the lesion appears as a solitary well-circumscribed nodule (true to its name) in the superficial fascia. The size may vary from a centimeter to several centimeters in diameter.

Microscopically, various morphologic patterns may be seen but most common is a whorled or S-shaped pattern of fibroblasts present in oedematous background. The individual cells are spindle-shaped, plump fibroblasts showing mild nuclear atypia. Typical mitoses are frequent but atypical mitoses are not present.

MYOSITIS OSSIFICANS Myositis ossificans is a benign, tumour-like lesion characterised by osteoid and heterotopic bone formation in the soft tissues. It is a misnomer since the lesion neither occurs exclusively in the skeletal muscle as the name leads one to believe, nor are the inflammation or ossification always essential.

Myositis ossificans is generally preceded by history of antecedent trauma to a skeletal muscle or its tendon. The trauma may be minor and repetitive e.g. to the adductor muscles of the thigh of a horseman, or may be single injury followed by haemorrhage into the muscle. The patient generally complains of pain, tenderness and swelling. Richly vascularised granulation tissue replaces the affected muscle or tendon. Then follows development of osteoid and bone at the periphery, giving characteristic X-ray appearance.

Grossly, the lesion appears as unencapsulated, gritty mass replacing the muscle.

Histologically, the central region of the mass shows loosely-arranged fibroblasts having high mitotic activity. Towards the periphery, there is presence of osteoid matrix and formation of woven mineralised bone with trapped skeletal muscle fibres and regenerating muscle (myogenic) giant cells. The appearance is sufficiently atypical to suggest osteosarcoma but osteosarcoma lacks maturation phenomena seen in myositis ossificans. This is why the condition is also called *pseudomalignant osseous tumour* of the soft tissues.

FIBROMATOSIS

'Fibromatosis' is the term used for tumour-like lesions of fibrous tissue which continue to proliferate actively and may be difficult to differentiate from sarcomas. These lesions may, therefore, be regarded as non-metastasising fibroblastic tumours which tend to invade locally and recur after surgical excision. In addition, electron microscopy has shown that the cells comprising these lesions have features not only of fibroblasts but of both fibroblasts and smooth muscle cells, so called *myofibroblasts*. Depending upon the anatomic locations and the age group affected, fibromatoses are broadly grouped as under:

A. Infantile or juvenile fibromatoses These include: fibrous hamartoma of infancy, fibromatosis colli, diffuse infantile fibromatosis, juvenile aponeurotic fibroma, juvenile nasopharyngeal angiofibroma and congenital (generalised and solitary) fibromatosis.

B. Adult type of fibromatoses These are: palmar and plantar fibromatosis, nodular fasciitis, cicatricial fibromatosis, keloid, irradiation fibromatosis, penile fibromatosis (Peyronie's disease), abdominal and extra-abdominal desmoid fibromatosis, and retroperitoneal fibromatosis. These are further categorised into *superficial or deep-seated*.

Obviously, it is beyond the scope of the present discussion to cover all these lesions. Some of the important forms of fibromatoses are briefly discussed here.

PALMAR AND PLANTAR (SUPERFICIAL) FIBROMATOSIS

These fibromatoses, also called Dupuytren-like contractures are the most common form of fibromatoses occurring superficially.

◆ **Palmar fibromatosis** is more common in the elderly males occurring in the palmar fascia and leading to flexion contractures of the fingers (Dupuytren's contracture). It appears as a painless, nodular or irregular, infiltrating, benign fibrous subcutaneous lesion. In almost half the cases, the lesions are bilateral.

◆ **Plantar fibromatosis** is a similar lesion occurring on the medial aspect of plantar arch. However, plantar lesions are less common than palmar type and do not cause contractures as frequently as palmar lesions. They are seen more often in adults and are infrequently multiple and bilateral. Essentially similar lesions occur in the shaft of the penis (*penile fibromatosis* or *Peyronie's disease*) and in the soft tissues of the knuckles (*knuckle pads*).

Histologically, palmar and plantar fibromatoses have similar appearance. The nodules are composed of fibrovascular tissue having plump, tightly-packed fibroblasts which have high mitotic rate. Ultrastructurally, some of the fibroblasts have features of myofibroblasts having contractile nature. The palmar lesions frequently extend into soft tissues causing contractures. Both palmar and plantar lesions may remain stationary at nodular stage, progress, or regress spontaneously. Recurrence rate after surgical excision in both forms is as high as 50-60%.

DESMOID (DEEP-SEATED) FIBROMATOSSES Desmoid fibromatoses or musculo-aponeurotic fibromatoses, commonly referred to as desmoid tumours, are of 2 types: abdominal and extra-abdominal. Both types are, however, histologically similar. Clinically, both types behave in an aggressive manner and have to be distinguished from sarcomas. Recurrences are frequent and multiple. The pathogenesis of these lesions is not known but among the factors implicated are the role of antecedent trauma, genetic influences and relationship to oestrogen as observed by occurrence of these lesions in pregnancy.

◆ **Abdominal desmoids** are locally aggressive infiltrating tumour-like fibroblastic growths, often found in the musculo-aponeurotic structures of the rectus muscle in the anterior abdominal wall in women during or after pregnancy.

◆ **Extra-abdominal desmoids**, on the other hand, are more common in men and are widely distributed such as in the upper and lower extremities, chest wall, back, buttocks, and head and neck region.

◆ **Intra-abdominal desmoids** present at the root of the small bowel mesentery are associated with Gardner's syndrome (consisting of fibromatosis, familial intestinal polyposis, osteomas and epidermal cysts).

Grossly, desmoids are solitary, large, grey-white, firm and unencapsulated tumours infiltrating the muscle locally. Cut surface is whorled and trabeculated.

Microscopically, their appearance is rather misleadingly bland in contrast with aggressive local behaviour. They are composed of uniform-looking fibroblasts arranged in bands and fascicles. Pleomorphism and mitoses are infrequent. The older regions of the tumour have hypocellular hyalinised collagen.

FIBROSARCOMA

The number of soft tissue tumours diagnosed as fibrosarcoma has now dropped, partly because of reclassification of fibromatoses which have aggressive and recurrent behaviour, and partly due to inclusion of many of such tumours in the group of fibrous histiocytomas (described later).

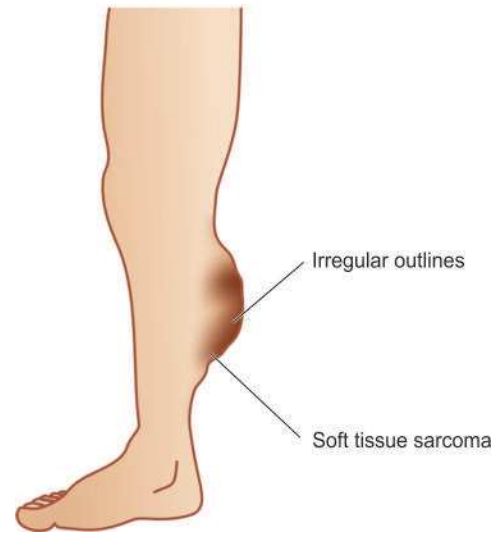

Figure 27.2 Fibrosarcoma, common clinical location.

Fibrosarcoma is a slow-growing tumour, affecting adults between 4th and 7th decades of life. Most common locations are the lower extremity (especially thigh and around the knee), upper extremity, trunk, head and neck, and retroperitoneum (**Fig. 27.2**). The tumour is capable of metastasis, chiefly via the blood stream.

Grossly, fibrosarcoma is a grey-white, firm, lobulated and characteristically circumscribed mass. Cut surface of the tumour is soft, fish-flesh-like, with foci of necrosis and haemorrhages.

Histologically, the tumour is composed of uniform, spindle-shaped fibroblasts arranged in intersecting fascicles. In well-differentiated tumours, such areas produce 'herring-bone pattern' (herring-bone is a sea fish) (**Fig. 27.3**). Poorly-differentiated fibrosarcoma, however, has highly pleomorphic appearance with frequent mitoses and bizarre cells.

GIST BOX 27.2

Tumours and Tumour-like Lesions of Fibrous Tissue

- ☐ True fibromas are uncommon benign tumours in fibrous tissues. Examples are fibroma durum, fibrolipoma and elastofibroma.
- ☐ Reactive proliferations of fibrous tissue are tumour-like lesions and include keloid, nodular fasciitis and myositis ossificans.
- ☐ Fibromatoses are a group of tumour-like lesions of fibrous tissue which continue to proliferate actively and may be difficult to differentiate from sarcomas. Examples of superficial type are palmar and plantar fibromatosis, and deep-seated desmoid fibromatosis.
- ☐ Fibrosarcoma is the malignant counterpart which is generally slow-growing tumour.

FIBROHISTIOCYTIC TUMOURS

The group of fibrohistiocytic tumours is characterised by distinctive light microscopic features that include presence

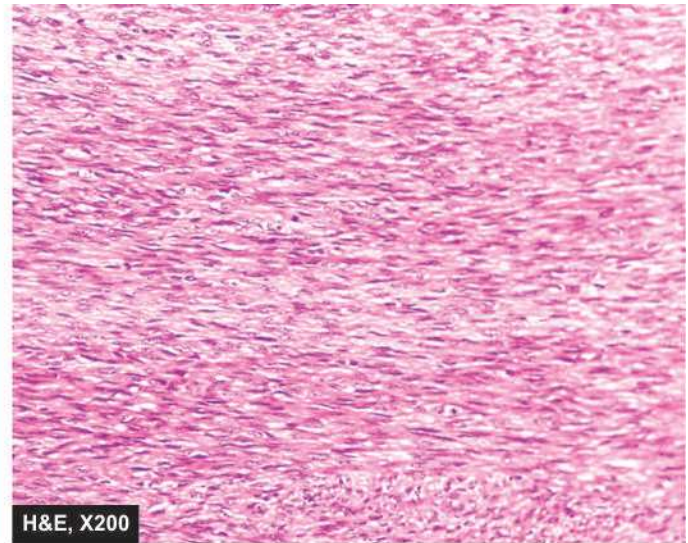

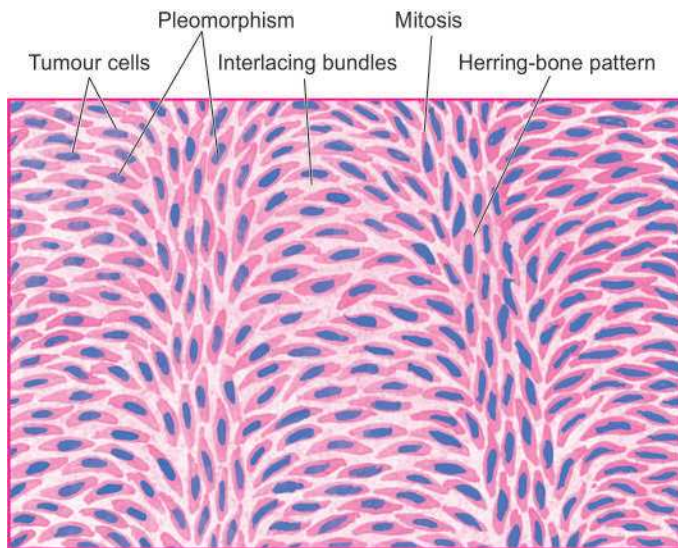

Figure 27.3 Fibrosarcoma. Microscopy shows a well-differentiated tumour composed of spindle-shaped cells forming interlacing fascicles producing a typical Herring-bone pattern. A few mitotic figures are also seen.

of cells with fibroblastic and histiocytic features in varying proportion and identification of characteristic *cart-wheel* or *storiform pattern* in which the spindle cells radiate outward from the central focus. The histogenesis of these cells is uncertain but possibly they arise from primitive mesenchymal cells or facultative fibroblasts which are capable of differentiating along different cell lines. The group includes full spectrum of lesions varying from *benign* (benign fibrous histiocytoma) to *malignant* (malignant fibrous histiocytoma), with dermatofibrosarcoma protuberans occupying the *intermediate* (low-grade malignancy) position.

BENIGN FIBROUS HISTIOCYTOMA

Depending upon the location and predominant pattern, benign fibrous histiocytomas include a number of diverse entities such as dermatofibroma, sclerosing haemangioma, fibroxanthoma, xanthogranuloma, giant cell tumour of tendon sheath and pigmented villonodular synovitis (page 846). All these tumours have mixed composition of benign fibroblastic and histiocytic pattern of cells and have been described in relevant sections already.

DERMATOFIBROSARCOMA PROTUBERANS

Dermatofibrosarcoma protuberans is a low-grade malignant cutaneous tumour of fibrohistiocytic origin. The tumour recurs locally, and in rare instances gives rise to distant metastases. Most frequent location is the trunk.

Grossly, the tumour forms a firm, solitary or multiple, satellite nodules extending into the subcutaneous fat and having thin and ulcerated skin surface.

Histologically, the tumour is highly cellular and is composed of fibroblasts arranged in a cart-wheel or storiform pattern.

MALIGNANT FIBROUS HISTIOCYTOMA (PLEOMORPHIC SARCOMA)

Malignant fibrous histiocytomas (MFH), also called pleomorphic sarcoma now, represent approximately 20-30% of all soft tissue

sarcomas. It is the most common soft tissue sarcoma and is the most frequent sarcoma associated with radiotherapy. The tumour occurs more commonly in males and more frequently in the age group of 5th to 7th decades. Most common locations are the lower and upper extremities and retroperitoneum. It begins as a painless, enlarging mass, generally in relation to skeletal muscle, deep fascia or subcutaneous tissue. The tumour is believed to arise from primitive mesenchymal cells which are capable of differentiating towards both fibroblastic and histiocytic cell lines.

Grossly, MFH is a multilobulated, well-circumscribed, firm or fleshy mass, 5-10 cm in diameter. Cut surface is grey-white, soft and myxoid (**Fig. 27.4**).

Histologically, there is marked variation in appearance from area to area within the same tumour. In general, there is admixture of spindle-shaped *fibroblast-like cells* and mononuclear round to oval *histiocyte-like cells* which

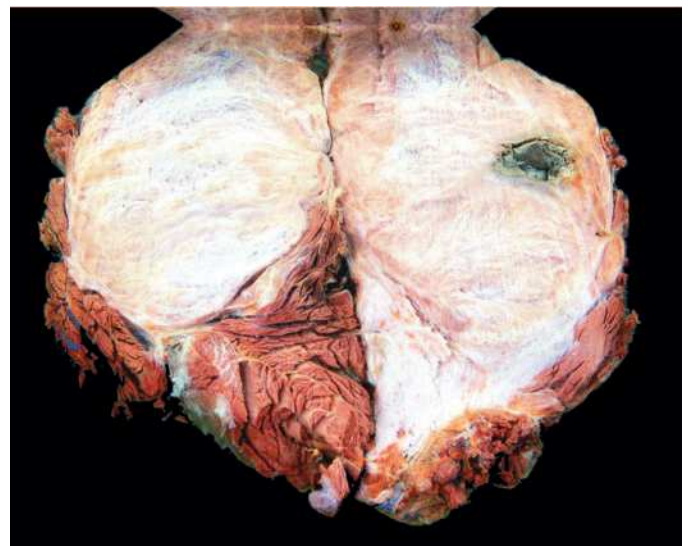

Figure 27.4 Malignant fibrous histiocytoma. The lobulated tumour infiltrating the skeletal muscle is somewhat circumscribed. Cut surface is grey-white fleshy with areas of haemorrhage and necrosis.

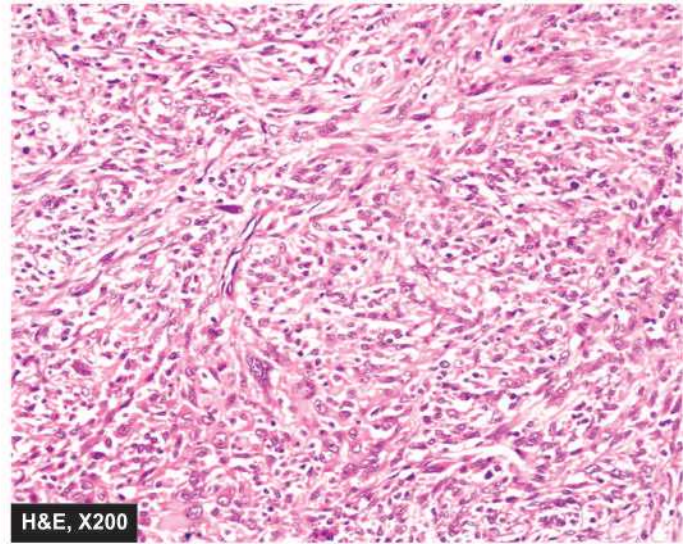

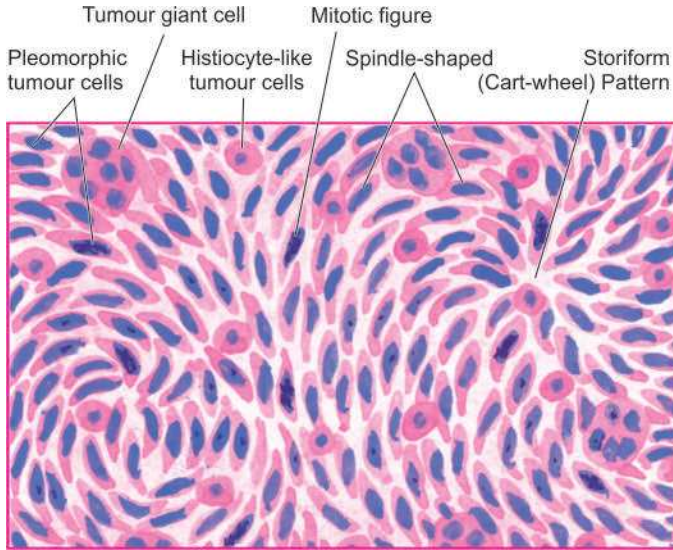

Figure 27.5 Malignant fibrous histiocytoma (pleomorphic sarcoma). The tumour shows admixture of spindle-shaped pleomorphic cells forming storiform (cart-wheel) pattern and histiocyte-like round to oval cells. Bizarre pleomorphic multinucleate tumour giant cells and some mononuclear inflammatory cells are also present.

may show phagocytic function. There is tendency for the spindle shaped cells to be arranged in characteristic cart-wheel or storiform pattern. The tumour cells show varying degree of pleomorphism, hyperchromatism, mitotic activity and presence of multinucleate bizarre tumour giant cells. Usually there are numerous blood vessels and some scattered lymphocytes and plasma cells (Fig. 27.5). Important immunohistochemical markers for MFH include vimentin, α -chymotrypsin, CD68 and factor VIII-a.

As per current concept, corresponding WHO categories of MFH as pleomorphic sarcoma are as under:

- 1. Storiform-pleomorphic MFH** as the prototype of *undifferentiated high-grade pleomorphic sarcoma*.
- 2. Inflammatory MFH** is an undifferentiated high-grade MFH having prominent neutrophilic infiltrate besides the presence of eosinophils, histiocytes and xanthoma cells. Currently, this is termed as *undifferentiated pleomorphic sarcoma with prominent inflammation*.
- 3. Giant cell MFH** having prominent presence of tumour giant cells called as *undifferentiated pleomorphic sarcoma with giant cells*.
- 4. Myxoid MFH** which shows areas of loose myxoid stroma in the cellular areas and has an overall better prognosis, is now categorised as a specific entity called *myxofibrosarcoma*.

Prognosis of MFH is determined by 2 parameters: depth of location and size of the tumour. Deep-seated and large MFH such as of the retroperitoneum have poorer prognosis than those small in size and located superficially which come to attention earlier. Metastases are frequent, most often to the lungs and regional lymph nodes. Five-year survival rate is approximately 30-50%.

GIST BOX 27.3 Fibrohistiocytic Tumours

- Fibrohistiocytic tumours are characterised by presence of cells with fibroblastic and histiocytic features in varying proportion and identification of characteristic cart-wheel or storiform pattern.

- Benign fibrous histiocytomas include dermatofibroma, sclerosing haemangioma, fibroxanthoma, xanthogranuloma, giant cell tumour of tendon sheath and pigmented villonodular synovitis.
- Dermatofibrosarcoma protuberans is a low-grade malignant cutaneous tumour of fibrohistiocytic origin.
- Malignant fibrous histiocytoma or pleomorphic sarcoma is the most common soft tissue sarcoma and has a few variants such as pleomorphic, inflammatory, giant cell type and myxoid.

TUMOURS OF ADIPOSE TISSUE

Lipomas and liposarcomas are the common examples of benign and malignant tumours respectively of adipose tissue. Uncommon varieties of adipose tissue tumours include hibernoma, a benign tumour arising from brown fat, and lipoblastoma (foetal lipoma) resembling foetal fat and found predominantly in children under 3 years of age.

LIPOMA

Lipoma is the commonest soft tissue tumour. It appears as a solitary, soft, movable and painless mass which may remain stationary or grow slowly. Lipomas occur most often in 4th to 5th decades of life and are frequent in females. They may be found at different locations in the body but most common sites are the subcutaneous tissues in the neck, back and shoulder (Fig. 27.6,A). A lipoma rarely ever transforms into liposarcoma.

Grossly, a subcutaneous lipoma is usually small, round to oval and encapsulated mass. The cut surface is soft, lobulated, yellowish-orange and greasy (Fig. 27.6, B).

Histologically, the tumour is composed of lobules of mature adipose cells separated by delicate fibrous septa. A thin fibrous capsule surrounds the tumour (Fig. 27.7).

A variety of admixture of lipoma with other tissue components may be seen. These include: fibrolipoma (admixture with fibrous tissue), angiolipoma (combination with proliferating blood vessels) and myelolipoma (admixture with

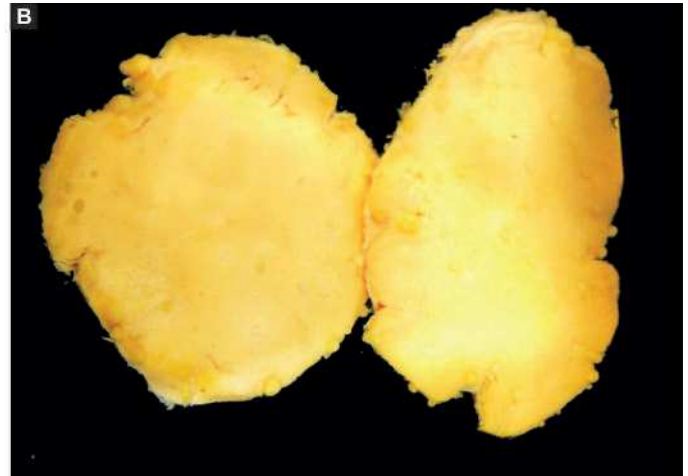

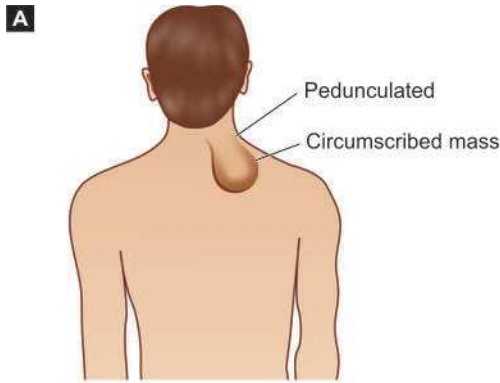

Figure 27.6 Lipoma. A, Common clinical location. B, The cut surface of the tumour is soft, lobulated, yellowish and greasy.

bone marrow elements as seen in adrenals). Infrequently, benign lipoma may infiltrate the striated muscle (infiltrating or intramuscular lipoma). Spindle cell lipoma and pleomorphic (atypical) lipoma are the other unusual variants of lipoma. The latter type may be particularly difficult to distinguish from well-differentiated liposarcoma.

LIPOSARCOMA

Liposarcoma is one of the most common soft tissue sarcomas in adults, perhaps next in frequency only to malignant fibrous histiocytoma. Unlike lipoma which originates from mature adipose cells, liposarcoma arises from primitive mesenchymal cells, the *lipoblasts*. The peak incidence is in 5th to 7th decades of life. In contrast to lipomas which are more frequently subcutaneous in location, liposarcomas often occur in the deep tissues. Most frequent sites are intermuscular regions in the thigh, buttocks and retroperitoneum.

Grossly, liposarcoma appears as a nodular mass, 5 cm or more in diameter. The tumour is generally circumscribed but infiltrative. Cut surface is grey-white to yellow, myxoid and gelatinous. Retroperitoneal masses are generally much larger.

Histologically, the hallmark of diagnosis of liposarcoma is the identification of variable number of *lipoblasts* which may be univacuolated or multivacuolated (**Fig. 27.8**). The vacuoles represent fat in the cytoplasm. Four major histologic varieties of liposarcomas are distinguished: well-differentiated, myxoid, round cell, and pleomorphic:

1. *Well-differentiated liposarcoma* resembles lipoma but contains uni- or multi-vacuolated lipoblasts.
2. *Myxoid liposarcoma* is the most common histologic type. It is composed of monomorphic, fusiform or stellate cells representing primitive mesenchymal cells, lying dispersed in mucopolysaccharide-rich ground substance. Occasional tumour giant cells may be present. Prominent meshwork of capillaries forming chicken-wire pattern is a conspicuous feature.
3. *Round cell liposarcoma* is composed of uniform, round to oval cells having fine multivacuolated cytoplasm with central hyperchromatic nuclei. Round cell liposarcoma may resemble a signet-ring carcinoma but mucin stains help in distinguishing the two.
4. *Pleomorphic liposarcoma* is highly undifferentiated and the most anaplastic type. There are numerous large tumour giant cells and bizarre lipoblasts.

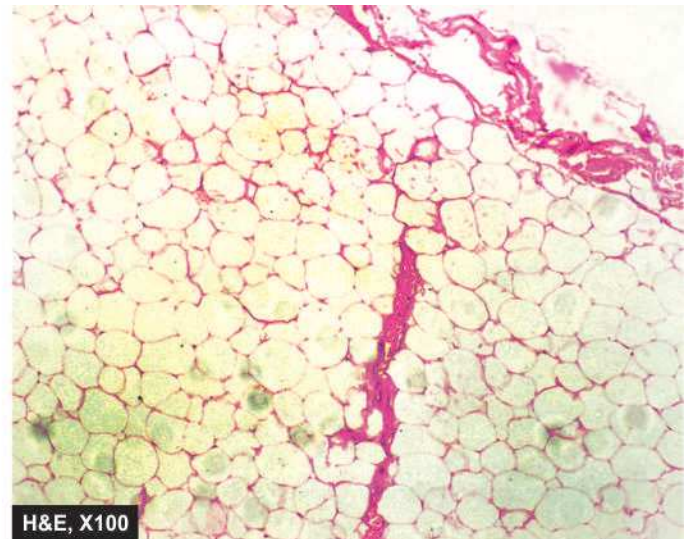

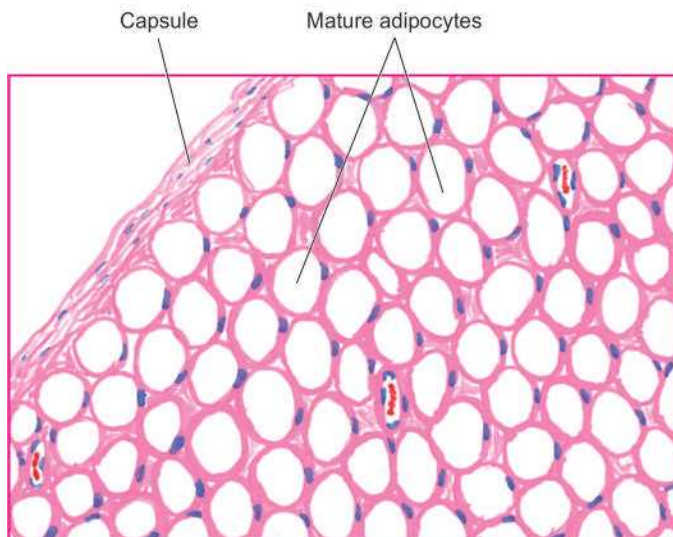

Figure 27.7 Lipoma. The tumour shows a thin capsule and underlying lobules of mature adipose cells separated by delicate fibrous septa.

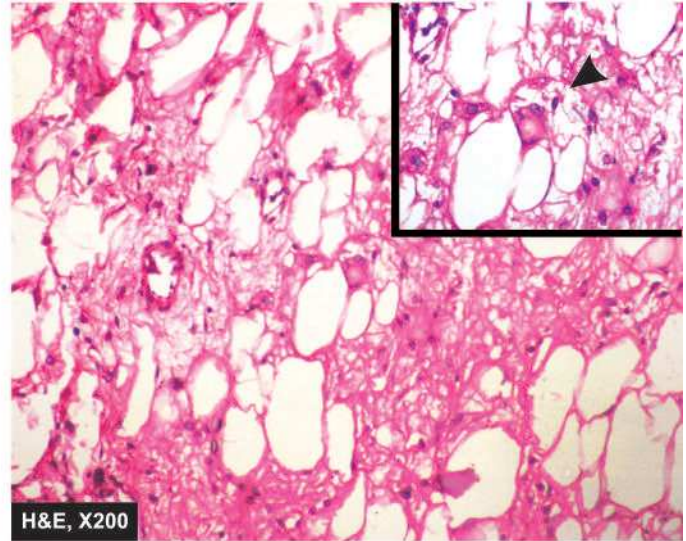

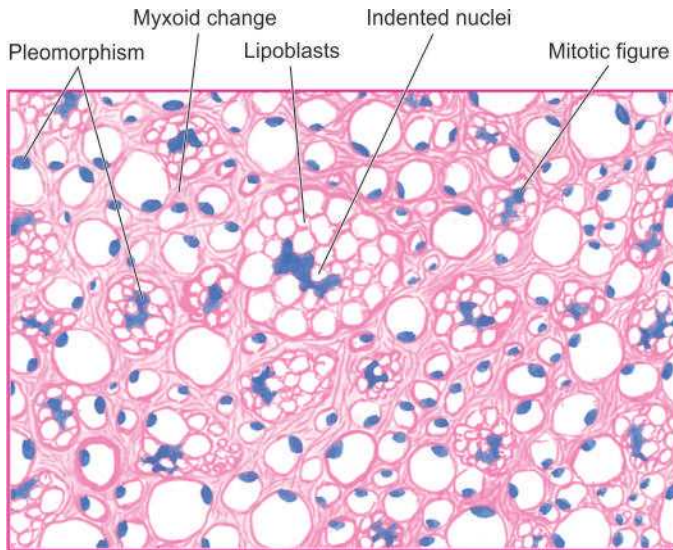

Figure 27.8 Liposarcoma. The tumour shows characteristic, univacuolated and multivacuolated lipoblasts with bizarre nuclei. Inset in the right photomicrograph shows close-up view of a typical lipoblast having multivacuolated cytoplasm indenting the atypical nucleus.

Myxoid and round cell liposarcoma show cytogenetic abnormality of translocation $t(12;16)(q13;p11)$ and molecular profiling of *FUS-DDIT3* fusion gene, features which help in distinguishing these variants from other types.

The *prognosis* of liposarcoma depends upon the location and histologic type. In general, well-differentiated and myxoid varieties have excellent prognosis, while pleomorphic liposarcoma has significantly poorer prognosis. Round cell and pleomorphic variants metastasise frequently to the lungs, other visceral organs and serosal surfaces.

GIST BOX 27.4 Tumours of Adipose Tissue

- ▣ Lipoma is the commonest soft tissue tumour appearing as a solitary, soft, movable and painless mass which may remain stationary or grow slowly.
- ▣ Liposarcoma occurs in 5th to 7th decades of life and arises from primitive mesenchymal cells, the *lipoblasts*. Unlike lipomas, liposarcomas often occur in the deep tissues.
- ▣ Histologic variants of liposarcoma having prognostic significance are well-differentiated, myxoid, round cell and pleomorphic type.

SKELETAL MUSCLE TUMOURS

Rhabdomyoma and rhabdomyosarcoma are the benign and malignant tumours respectively of striated muscle.

RHABDOMYOMA

Rhabdomyoma is a rare benign soft tissue tumour. It should not be confused with glycogen-containing lesion of the heart designated as cardiac rhabdomyoma which is probably a hamartomatous lesion and not a true tumour (page 435). Soft tissue rhabdomyomas are predominantly located in the head and neck, most often in the upper neck, tongue, larynx and pharynx.

Histologically, the tumour is composed of large, round to oval cells, having abundant, granular, eosinophilic cytoplasm which is frequently vacuolated and contains glycogen. Cross-striations are generally demonstrable in some cells with phosphotungstic acid-haematoxylin (PTAH) stain. The tumour is divided into adult and foetal types, depending upon the degree of resemblance of tumour cells to normal muscle cells.

RHABDOMYOSARCOMA

Rhabdomyosarcoma is a much more common soft tissue tumour than rhabdomyoma, and is the commonest soft tissue sarcoma in children and young adults. It is a highly malignant tumour arising from rhabdomyoblasts in varying stages of differentiation with or without demonstrable cross-striations. Depending upon the growth pattern and histology, 4 types are distinguished: embryonal, botryoid, alveolar and pleomorphic.

1. EMBRYONAL RHABDOMYOSARCOMA The embryonal form is the most common of the rhabdomyosarcomas. It occurs predominantly in children under 12 years of age. The common locations are in the head and neck region, most frequently in the orbit, urogenital tract and the retroperitoneum.

Grossly, the tumour forms a gelatinous mass growing between muscles or in the deep subcutaneous tissues but generally has no direct relationship to the skeletal muscle.

Histologically, the tumour cells have resemblance to embryonal stage of development of muscle fibres. There is considerable variation in cell types. Generally, the tumour consists of a mixture of small, round to oval cells and spindle-shaped strap cells having tapering bipolar cytoplasmic processes in which cross-striations may be evident. The tumour cells form broad fascicles or bands. Mitoses are frequent.

2. BOTRYOID RHABDOMYOSARCOMA Botryoid variety is regarded as a variant of embryonal rhabdomyosarcoma

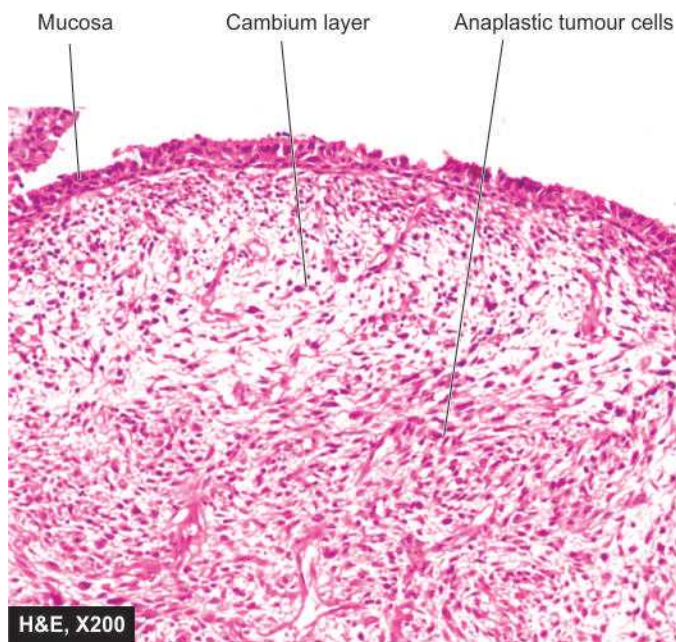

Figure 27.9 Botryoid rhabdomyosarcoma, nose. The tumour shows the characteristic submucosal Cambium layer of tumour cells. The tumour cells are round to oval and have anaplasia.

occurring in children under 10 years of age. It is seen most frequently in the vagina, urinary bladder and nose (page 713).

Grossly, the tumour forms a distinctive grape-like gelatinous mass protruding into the hollow cavity.

Histologically, the tumour grows underneath the mucosal layer, forming the characteristic *cambium layer* of tumour cells. The tumour is hypocellular and myxoid with predominance of small, round to oval tumour cells (**Fig. 27.9**).

3. ALVEOLAR RHABDOMYOSARCOMA Alveolar type of rhabdomyosarcoma is more common in older children and

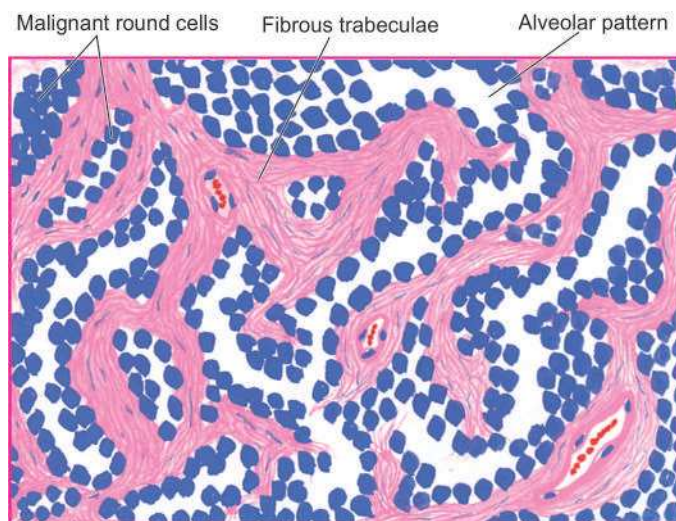

Figure 27.10 Alveolar rhabdomyosarcoma. The tumour is divided into alveolar spaces composed of fibrocollagenous tissue. The fibrous trabeculae are lined by small, dark, undifferentiated tumour cells, with some cells floating in the alveolar spaces. A few multinucleate tumour giant cells are also present.

young adults under the age of 20 years. The most common locations, unlike the embryonal variety, are the extremities.

Grossly, the tumour differs from embryonal type in arising directly from skeletal muscle and grows rapidly as soft and gelatinous mass.

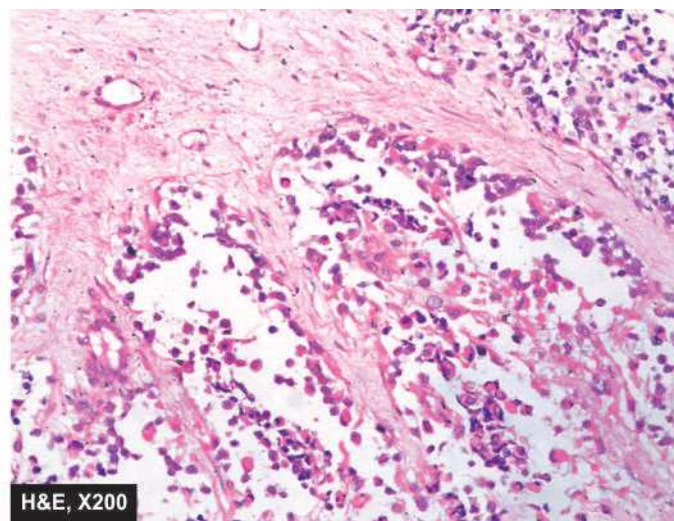

Histologically, the tumour shows characteristic alveolar pattern resembling pulmonary alveolar spaces. These spaces are formed by fine fibrocollagenous septa. The tumour cells lying in these spaces and lining the fibrous trabeculae are generally small, lymphocyte-like with frequent mitoses and some multinucleate tumour giant cells (**Fig. 27.10**). Cross-striation can be demonstrated in about a quarter of cases.

4. PLEOMORPHIC RHABDOMYOSARCOMA This less frequent variety of rhabdomyosarcoma occurs predominantly in older adults above the age of 40 years. They are most common in the extremities, most frequently in the lower limbs.

Grossly, the tumour forms a well-circumscribed, soft, whitish mass with areas of haemorrhages and necrosis.

Histologically, the tumour cells show considerable variation in size and shape. The tumour is generally composed of highly anaplastic cells having bizarre appearance and numerous multinucleate giant cells. Various shapes include racquet shape, tadpole appearance, large strap cells, and ribbon shapes containing several nuclei in a row.

Conventionally, the cross-striations can be demonstrated with PTAH stain in a few rhabdomyosarcomas. Immunohistochemical stains include: myogenin, Myo-D1, desmin, actin, myosin, myoglobin, and vimentin. Based on cytogenetic and molecular abnormalities, alveolar rhabdomyosarcoma with $t(1;13)(q36;q14)$ and *PAX3-FOXO1A* fusion gene have better prognosis, compared to cases having translocation $t(2;13)(p35;q14)$ and *PAX7-FOXO1A* fusion gene which have worse prognosis.

GIST BOX 27.5 Skeletal Muscle Tumours

- ▣ Rhabdomyoma is a rare benign soft tissue tumour.
- ▣ Rhabdomyosarcoma is a much more common soft tissue tumour than rhabdomyoma, arising from rhabdomyoblasts. It is the commonest soft tissue sarcoma in children and young adults.
- ▣ Four histologic types are distinguished: embryonal, botryoid, alveolar and pleomorphic. The last named is common in adults while others occur in children.

TUMOURS OF UNCERTAIN HISTOGENESIS

Some soft tissue tumours have a distinctive morphology but their exact histogenesis is unclear. A few examples are described below.

SYNOVIAL SARCOMA (MALIGNANT SYNOVIOMA)

Whether true benign tumours of synovial tissue exist is controversial. Pigmented villonodular synovitis and giant cell tumours of tendon sheaths, both of which are tumour-like lesions of synovial tissues have been discussed already on page 846. Synovial sarcoma or malignant synovioma, on the other hand, is a distinctive soft tissue sarcoma arising from synovial tissues close to the large joints, tendon sheaths, bursae and joint capsule but almost never arising within joint cavities. Most common locations are the extremities, frequently the lower extremity. However, synovial sarcoma is also found in regions where synovial tissue is not present such as in the anterior abdominal wall, parapharyngeal region and the pelvis. The tumour principally occurs in young adults, usually under 40 years of age. The tumour grows slowly as a painful mass but may metastasise via blood stream, chiefly to the lungs.

The *histogenesis* of tumour is, believed to be from multipotent mesenchymal cells which may differentiate along different cell lines.

Grossly, the tumour is of variable size and is grey-white, round to multilobulated and encapsulated. Cut surface shows fishflesh-like sarcomatous appearance with foci of calcification, cystic spaces and areas of haemorrhages and necrosis.

Microscopically, *classic synovial sarcoma* shows a characteristic *biphasic cellular pattern* composed of clefts or gland-like structures lined by cuboidal to columnar epithelial-like cells and plump to oval spindle cells (**Fig. 27.11**). Reticulin fibres are present around spindle cells but absent within the epithelial foci. The spindle cell areas form interlacing bands similar to those seen in fibrosarcoma. Myxoid matrix, calcification and hyalinisation are frequently present in the stroma. Mitoses and multinucleate giant cells are infrequent. Immunohistochemically, both types of tumour cells are positive for cytokeratin.

An uncommon variant of synovial sarcoma is *monophasic pattern* in which the epithelial component is exceedingly rare and thus the tumour may be difficult to distinguish from fibrosarcoma.

Translocation t(X;18)(p11;q11) and molecular profiling *SS18-SSX1* fusion gene helps in differentiating biphasic from monophasic form of synovial sarcoma.

ALVEOLAR SOFT PART SARCOMA

Alveolar soft part sarcoma is a histologically distinct, slow-growing malignant tumour of uncertain histogenesis. The tumour may occur at any age but affects children and young adults more often. Most alveolar soft part sarcomas occur in the deep tissues of the extremities, along the musculofascial planes, or within the skeletal muscles.

Grossly, the tumour is well-demarcated, yellowish and firm.

Microscopically, the tumour shows characteristic alveolar pattern. Organoid masses of tumour cells are separated by

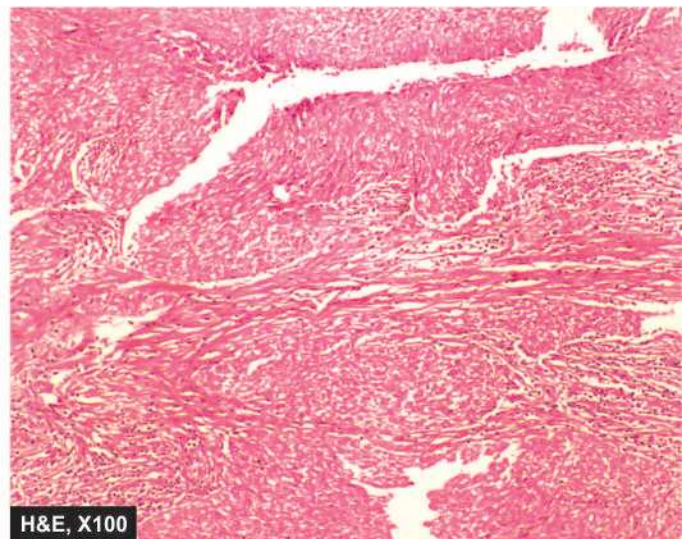

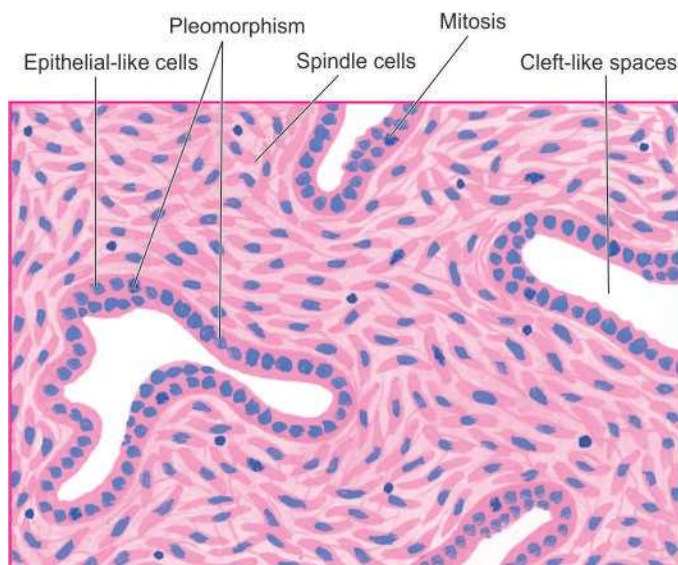

Figure 27.11 Classic synovial sarcoma, showing characteristic biphasic cellular pattern. The tumour is composed of epithelial-like cells lining cleft-like spaces and gland-like structures, and spindle cell areas forming fibrosarcoma-like growth pattern.

fibrovascular septa. The tumour cells are large and regular and contain abundant, eosinophilic, granular cytoplasm which contains diastase-resistant PAS-positive material. This feature distinguishes the tumour from paraganglioma, with which it closely resembles.

Translocation $t(X;17)(p11;q25)$ and genetic abnormality *TFE3-ASPL* fusion gene are seen in a large proportion of cases and are helpful in confirming the diagnosis.

GRANULAR CELL TUMOUR

Granular cell tumour is a benign tumour of unknown histogenesis. It may occur at any age but most often affected are young to middle-aged adults. The most frequent locations are the tongue and subcutaneous tissue of the trunk and extremities.

Grossly, the tumour is generally small, firm, grey-white to yellow-tan nodular mass.

Histologically, the tumour consists of nests or ribbons of large, round or polygonal, uniform cells having finely granular, acidophilic cytoplasm and small dense nuclei. The tumours located in the skin are frequently associated with pseudoepitheliomatous hyperplasia of the overlying skin.

EPITHELIOID SARCOMA

This soft tissue sarcoma occurring in young adults is peculiar in that it presents as an ulcer with sinuses, often located on the skin and subcutaneous tissues as a small swelling. The tumour is slow growing but metastasising.

Grossly, the tumour is somewhat circumscribed and has nodular appearance with central necrosis.

Microscopically, the tumour cells comprising the nodules have epithelioid appearance by having abundant pink cytoplasm and the centres of nodules show necrosis and thus can be mistaken for a granuloma.

CLEAR CELL SARCOMA

Clear cell sarcoma, first described by Enginzer, is seen in skin and subcutaneous tissues, especially of hands and feet.

Microscopically, it closely resembles malignant melanoma, and is therefore also called melanoma of the soft tissues.

Clear cell sarcoma can be further distinguished from cutaneous melanoma by translocation $t(12;22)(q13;q12)$ and *EWSR1-ATF1* fusion gene.

DESMOPLASTIC SMALL ROUND CELL TUMOUR

Desmoplastic small round cell tumour (DSRCT) is a rare and highly malignant tumour occurring more commonly in male

children and juveniles under 2nd decade of life. The cell of origin is not clear. Some of the common locations are the abdomen, paratesticular region, ovaries, parotid, brain and thorax.

Grossly, the tumour appears as multiple soft to firm masses.

Microscopically, characteristic small and round tumour cells having epithelial, mesenchymal and neural differentiation.

The tumour spreads rapidly to regional lymph nodes and other sites. DSRCT with translocation $t(11;22)(p13;q12)$ and *EWSR1-WT1* fusion gene have particularly poor prognosis.

GIST BOX 27.6

Tumours with Uncertain Histogenesis

- ▣ Synovial sarcoma arises from synovial tissues close to the large joints, tendon sheaths, bursae and joint capsule. Classic synovial sarcoma shows a biphasic cellular pattern: cuboidal to columnar epithelial-like cells and plump to oval spindle cells.
- ▣ Alveolar soft part sarcoma occurs in the deep tissues of the extremities, along the musculofascial planes, or within the skeletal muscles.
- ▣ Granular cell tumour is a benign tumour occurring in the tongue and subcutaneous tissue of the trunk and extremities.
- ▣ Clear cell sarcoma occurring in the subcutaneous soft tissues has some similarities with cutaneous melanoma.
- ▣ Desmoplastic small round cell tumour is a rare and highly malignant tumour occurring in male children and juveniles, most often in the abdomen.

CLINICAL CASE 29

A 55 years old male complains of a progressively increasing swelling on right upper arm for the last 2 months. It has been growing rapidly and lately he has noticed that he has started having tightness of shirt on this side due to increase in size of swelling.

On examination, the swelling is 6 x 4 cm size, firm to hard subcutaneous mass which is fixed to underlying soft tissues. It is not attached to the underlying bone, and has well-defined margins. The overlying skin is shining and stretched but not ulcerated. Multiple right axillary lymph nodes are palpable.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 914 (Appendix II)

The Nervous System

CENTRAL NERVOUS SYSTEM

NORMAL STRUCTURE

The skull and the vertebrae form a rigid compartment encasing the delicate brain and spinal cord. The average weight of the brain is about 1400 gm in men and 1250 gm in women. The two main divisions of the brain—the cerebrum and the cerebellum, are quite distinct in structure. The brain does not have lymphatic drainage. There are 2 types of tissues in the nervous system:

1. *Neuroectodermal tissues* which include neurons (nerve cells) and neuroglia, and together form the predominant constituent of the CNS.
2. *Mesodermal tissues* are microglia, dura mater, the leptomeninges (pia-arachnoid), blood vessels and their accompanying mesenchymal cells.

The predominant tissues comprising the nervous system and their general response to injury are briefly considered below:

1. NEURONS The neurons are highly specialised cells of the body which are incapable of dividing after the first few weeks of birth. Thus, brain damage involving the neurons is irreversible. Neurons vary considerably in size and shape. Their size may range from the small granular cells of the cerebellum to large Betz cells of the motor cortex. Some neurons are round, others oval or fusiform but the prototype of cortical neuron is pyramidal in shape. A neuron consists of 3 main parts: the cell body, an axon and numerous dendrites (Fig. 28.1,A). The *cell body* (or perikaryon) is the main constituent of the neuron from

which an axon and numerous dendritic processes extend. The cell bodies may be arranged in layers as in the cerebral cortex, or may be aggregated as in the basal ganglia. The cell body possesses a large, round, centrally-placed nucleus having finely granular nuclear chromatin and a prominent nucleolus. The cytoplasm contains polygonal, basophilic structures called Nissl substance. It consists of aggregates of RNA, sheaves of rough endoplasmic reticulum and intervening groups of free ribosomes. Besides Nissl substance, other special features of the cytoplasm of neuronal cell body are the presence of microtubules, synaptic vesicles and neurofilaments which are a form of intermediate filaments specific to neurons. Lipofuscin may be present due to ageing. Neuromelanin is found in neurons in the substantia nigra and pigmented nucleus of the pons.

Neurons respond to injury in a variety of ways depending upon the etiologic agent and the pathologic processes. These include central chromatolysis, atrophy and degeneration of neurons and axons, and intraneuronal storage of substances.

Neuropil is the term used for the fibrillar network formed by processes of all the neuronal cells.

2. NEUROGLIA The neuroglia provides supportive matrix and maintenance to the neurons. It includes 3 types of cells: astrocytes, oligodendrocytes and ependymal cells (Fig. 28.1,B). Neuroglia is generally referred to as *glia*; the tumours originating from it are termed *gliomas*, while reactive proliferation of the astrocytes is called *gliosis*.

i) Astrocytes The astrocytes are stellate cells with numerous fine branching processes. In routine haematoxylin and eosin stains, an astrocyte has round or oval vesicular nucleus, but

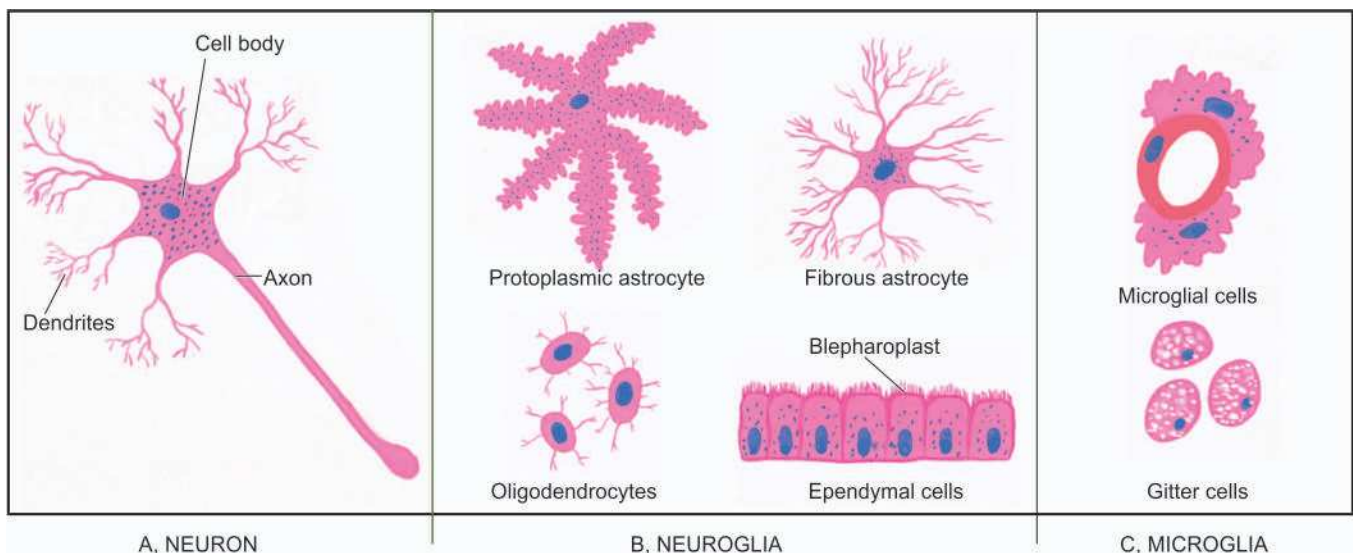

Figure 28.1 Cells comprising the nervous system.

unlike neuron, lacks a prominent nucleolus. The cytoplasm is generally scanty. The processes radiate from the cell body. Depending upon the type of processes, two types of astrocytes are distinguished:

- a) *Protoplasmic astrocytes* have branched processes and are found mostly in the grey matter.
- b) *Fibrous astrocytes* have long, thin processes and are present mainly in the white matter.

Some astrocytic processes are directed towards neurons and their processes, while others surround capillaries by terminal expansions called *foot processes*. The astrocytic processes may not be visible by routine stains but can be demonstrated by phosphotungstic acid haematoxylin (PTAH) stain. Ultrastructurally, these processes are composed of abundant intermediate filaments, mostly vimentin.

The main *functions* of astrocytes in health are physiological and biochemical support to the neurons and interactions with capillary endothelial cells which establishes blood brain barrier. In case of damage to the brain, astrocytes act like fibroblasts of other tissues. The astrocytes in response to injury undergo hyperplasia and hypertrophy termed 'gliosis' which is an equivalent of scar elsewhere in the body.

◆ *Gemistocytic astrocytes* are early reactive astrocytes having prominent pink cytoplasm. Long-standing progressive gliosis results in the development of *Rosenthal fibres* which are eosinophilic, elongated or globular bodies present on the astrocytic processes.

◆ *Corpora amylacea* are basophilic, rounded, sometimes laminated, bodies present in elderly people in the white matter and result from accumulation of starch-like material in the degenerating astrocytes.

ii) Oligodendrocytes Oligodendrocytes are so named because of their short and fewer processes when examined by light microscopy with special stains (*oligo*=short). In haematoxylin-eosin stained sections, these cells appear as small cells with a darkly-staining nucleus resembling that of small lymphocyte. The cytoplasm appears as a clear halo around the nucleus. Oligodendrocytes are present throughout the brain in grey as well as white matter and are most numerous of all other cells in the CNS. In grey matter, they are clustered around the neurons and are called *satellite cells*. In white matter, they are present along the myelinated nerve fibres and are termed *interfascicular oligodendroglia*.

The major *function* of oligodendrocytes is formation and maintenance of myelin. Thus, in this respect they are counterparts of Schwann cells of the peripheral nervous system. Diseases of oligodendrocytes are, therefore, disorders of myelin and myelination such as inherited leucodystrophies and acquired demyelinating diseases.

iii) Ependymal cells The ependymal cells are epithelium-like and form a single layer of cells lining the ventricular system, aqueduct, central canal of the spinal cord and cover the choroid plexus. They are cuboidal to columnar cells and have ciliated luminal surface, just beneath which are present small bodies termed *blepharoplasts*.

The ependymal cells influence the formation and composition of the cerebrospinal fluid (CSF) by processes of active secretion, diffusion, absorption and exchange. The function of cilia is not very clear but probably they play a role in the circulation of CSF. The ependymal cells respond to injury by

cell loss and the space left is filled by proliferation of underlying glial fibres.

3. MICROGLIA Microglia is the nervous system counterpart of the monocyte-macrophage system. Although the term 'microglia' is commonly used but it is inappropriate since these cells, unlike neuroglia, are not of neuroectodermal origin. Microglial cells (or Hortege cells) are not fixed but are mobile cells. These cells are found throughout the brain and are often present close to the blood vessels. Normally, microglial cells appear as small inconspicuous cells with bean-shaped vesicular nuclei, scanty cytoplasm and long cytoplasmic processes (**Fig. 28.1,C**). In response to injury or damage, however, these cells have capability to enlarge in size, proliferate and develop elongated nuclei, so called *rod cells*. Microglial cells may actually assume the shape and phagocytic function of macrophages and form *gitter cells*. The foci of necrosis and areas of selective hypoxic damage to the neurons are surrounded by microglial cells which perform phagocytosis of damaged and necrosed cells; this is known as *neuronophagia*.

4. DURA MATER The dura mater is a tough fibrous covering of the brain which is closely attached to the skull on its inner layer of endocranial periosteum. In the region of spinal canal, it encloses a potential space, the *epidural space*, between the bone and the dura. The dura is composed of dense collagen, fused with periosteum of the skull.

5. PIA-ARACHNOID (LEPTOMENINGES) The leptomeninges (*lepto*=thin, slender) consisting of the pia and arachnoid mater form the delicate vascular membranous covering of the central nervous system. The pia mater is closely applied to the brain and its convolutions, while the arachnoid mater lies between the pia mater and the dura mater without dipping into sulci. Thus, a space is left between the two layers of leptomeninges, known as *subarachnoid space*, which contains the CSF. The major arteries and veins run in the subarachnoid space and small nutrient arteries pass into the cortex. Extension of the subarachnoid space between the wall of blood vessels entering the brain and their pial sheaths form a circumvascular space called *Virchow-Robin space*. Another important potential space is enclosed between the dura and the arachnoid membrane known as *subdural space*.

GIST BOX 28.1

Normal Structure of CNS

- ☐ There are 2 types of tissues in the nervous system: *neuroectodermal tissues* (i.e. neurons or nerve cells and neuroglia), and *mesodermal tissues* (i.e. microglia, dura mater, the leptomeninges or pia-arachnoid, and blood vessels).
- ☐ Neuroglia is the supportive matrix of the neurons and includes astrocytes, oligodendrocytes and ependymal cells. Astrocytes are of 2 main types: protoplasmic and fibrous.
- ☐ Microglia is the nervous system counterpart of the monocyte-macrophage system.
- ☐ Ependymal cells line the ventricular system and central canal of spinal cord and form CSF.
- ☐ Dura mater is fibrous covering of the brain under the periosteum of skull. Pia mater is closely applied to the brain while arachnoid mater lies between dura and pia mater and encloses a space called subarachnoid space.

DEVELOPMENTAL ANOMALIES AND HYDROCEPHALUS

CNS malformations may be the result of various inherited and acquired factors. The acquired conditions include viral infections of the mother and foetus (e.g. rubella), intake of drugs (e.g. thalidomide), exposure to ionising radiation and foetal anoxia. There are a large number of developmental malformations of the CNS but only a few important and common ones are mentioned here. Congenital hydrocephalus is considered separately along with other types of hydrocephalus.

SPINAL CORD DEFECTS

Spina bifida is the term applied to the malformations of the vertebral column involving incomplete embryologic closure of one or more of the vertebral arches (rachischisis), most frequently in the lumbosacral region. The vertebral defect is frequently associated with defect in the neural tube structures and their coverings. The bony defect may be of varying degree. The least serious form is **spina bifida occulta** in which there is only vertebral defect but no abnormality of the spinal cord and its meninges. The site of bony defect is marked by a small dimple, or a hairy pigment mole in the overlying skin. The larger bony defect, however, appears as a distinct cystic swelling over the affected site called **spina bifida cystica**. This is associated with herniation of the meninges or the spinal cord, or both.

1. Herniation of the meninges alone through the bony defect is called **meningocele**. The herniated sac in meningocele consists of dura and arachnoid.
2. The commonest and more serious form is, however, **meningomyelocele** in which the spinal cord or its roots also herniate through the defect and are attached to the posterior wall of the sac. In this defect, the dura and the skin in the sac are deficient. A more serious variant of meningomyelocele is associated with hydrocephalus and Arnold-Chiari malformation.
3. A rare form of the defect is **myelocele** or **syringomyelocele** in which there is defective closure of the spinal canal so that the sac consists of an open flat neural tissue plate without skin covering and the CSF leaking through it.
4. Meningomyelocele and myelocele are frequently associated with neurologic defects of varying degree which include bladder and bowel dysfunction, motor and sensory defects, and paraplegia.
5. The existence of defect in bony closure in the region of occipital bone or fronto-ethmoid junction may result in **cranial meningocele** and **encephalocele**.

SYRINGOMYELIA AND SYRINGOBULBIA

These are congenital malformations which manifest clinically later in life and often develop in association with certain acquired lesions involving the CNS. Syringomyelia and syringobulbia are characterised by development of a *syrinx* or a tubular cavity in the spinal cord and medulla respectively. The cavity may be fusiform or irregular. It usually begins in the grey matter of the spinal cord dorsal to the central canal. The syrinx is usually surrounded by glial tissue. If the cavity communicates with the spinal canal, it is lined by ependymal cells. Since the fibres of lateral spinothalamic tract are frequently involved in the cavity, the clinical effects include loss of pain and temperature sensation in the affected region.

ARNOLD-CHIARI MALFORMATIONS

Arnold-Chiari malformation is the term used for a group of malformations of the brain involving the brainstem and cerebellum. The primary defect is elongation of the medulla and part of the vermis of the cerebellum resulting from failure to form the pontine flexure. Approximately 50% of children with hydrocephalus have Arnold-Chiari malformation. Four types are described, of which type II malformation is the most common and is most frequently associated with congenital hydrocephalus. Most patients of Arnold-Chiari malformation have, in addition, meningomyelocele. The major components of type II Arnold-Chiari malformation are as follows:

- i) Elongation of the medulla with part of fourth ventricle in the cervical canal.
- ii) Distortion of the medulla forming a characteristic S-shaped bend at the junction with the cervical spinal cord.
- iii) Lengthening and herniation of the cerebellar vermis and cerebellar tonsils through the foramen magnum resulting in formation of a mass over the upper cervical cord.

Combination of these abnormalities results in stenosis of the aqueduct or obstruction of the foramina of Luschka and Magendie causing internal hydrocephalus (discussed below).

HYDROCEPHALUS

Hydrocephalus is the term used for increased volume of CSF within the skull, accompanied by dilatation of the ventricles. In majority of cases of hydrocephalus, there is increased intracranial pressure. This type of hydrocephalus involving ventricular dilatation is termed *internal hydrocephalus*. A localised collection of CSF in the subarachnoid space is called *external hydrocephalus*. For better understanding of causes and mechanisms involved in the hydrocephalus, it is essential to briefly review the source and circulation of CSF.

Source and Circulation of CSF

CSF is mainly produced by choroid plexus in the lateral, third and fourth ventricle, and a small part is formed on the surface of the brain and spinal cord. The total volume of CSF is about 120-150 ml. CSF formed in the lateral ventricles flows through the foramina of Munro to the third ventricle and from there by the aqueduct of Sylvius to the fourth ventricle. The fluid then passes through the foramina of Magendie and Luschka of the fourth ventricle to reach the subarachnoid space of the brain. It then spreads through the subarachnoid space over the surface of the spinal cord. It is absorbed into the blood by the arachnoid villi present along the dural venous sinuses (**Fig. 28.2**).

Types and Etiopathogenesis

Hydrocephalus is classified into primary and secondary types, the former being much more common, both types have distinct etiology and pathogenesis.

PRIMARY HYDROCEPHALUS Primary hydrocephalus is defined as actual increase in the volume of CSF within the skull along with elevated intracranial pressure. There are 3 possible mechanisms of primary hydrocephalus:

1. Obstruction to the flow of CSF.
2. Overproduction of CSF.
3. Deficient reabsorption of CSF.

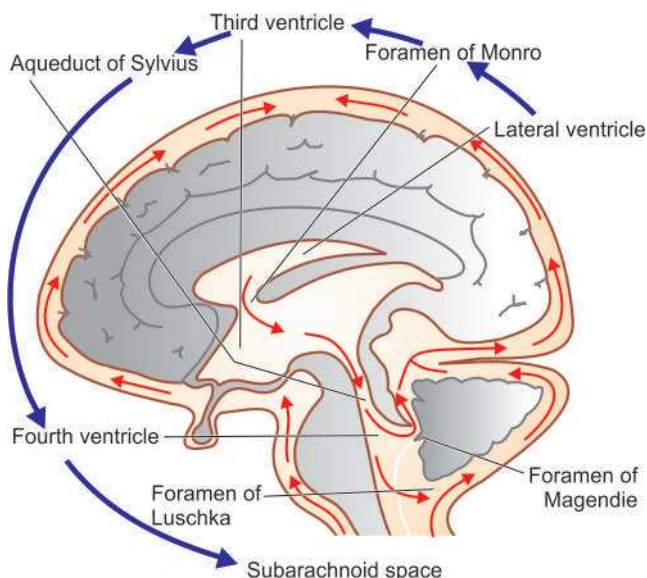

Figure 28.2 Normal circulation of CSF.

However, obstruction to the flow of CSF is by far the commonest cause and is termed *obstructive hydrocephalus*. The terms *non-communicating* and *communicating hydrocephalus* are used to denote the site of obstruction:

Non-communicating hydrocephalus When the site of obstruction of CSF pathway is in the third ventricle or at the exit foramina in the fourth ventricle, the ventricular system enlarges and CSF cannot pass into the subarachnoid space. This is termed as non-communicating hydrocephalus. Among the common causes are the following:

i) *Congenital non-communicating hydrocephalus* e.g. stenosis of the aqueduct, Arnold-Chiari malformation, progressive gliosis of the aqueduct and intra-uterine meningitis.

ii) *Acquired non-communicating hydrocephalus* may occur from expanding lesion within the skull. These conditions are as under:

- ◆ Tumours adjacent to the ventricular system e.g. ependymoma, choroid plexus papilloma, medulloblastoma and others.

- ◆ Inflammatory lesions e.g. cerebral abscess, meningitis.

- ◆ Haemorrhage e.g. parenchymal haemorrhage, intraventricular haemorrhage, and epidural and subdural haematoma.

Communicating hydrocephalus When obstruction to the flow of CSF is in the subarachnoid space at the base of the brain, it results in enlargement of the ventricular system but CSF flows freely between dilated ventricles and the spinal canal. This is called communicating hydrocephalus. The causes of communicating hydrocephalus are non-obstructive as follows:

i) *Overproduction of CSF* e.g. choroid plexus papilloma.

ii) *Deficient reabsorption of CSF* e.g. following meningitis, subarachnoid haemorrhage and dural sinus thrombosis.

SECONDARY HYDROCEPHALUS Secondary hydrocephalus is much less common and is defined as compensatory increase of CSF due to loss of neural tissue without associated rise in intracranial pressure (normal pressure hydrocephalus) e.g. from cerebral atrophy and infarction.

MORPHOLOGIC FEATURES *Grossly*, there is dilatation of the ventricles depending upon the site of obstruction. There is thinning and stretching of the brain. The scalp veins overlying the enlarged head are engorged and the fontanelle remain open.

Histologically, severe hydrocephalus may be associated with damage to ependymal lining of the ventricles and cause periventricular interstitial oedema.

GIST BOX 28.2

Developmental Anomalies and Hydrocephalus

- Spina bifida is incomplete embryologic closure of one or more of the vertebral arches, most frequently in the lumbosacral region. This is associated with herniation of the meninges (meningocele) or the spinal cord (myelocele), or both (meningomyelocele).
- Syringomyelia and syringobulbia are development of a syrinx or a tubular cavity in the spinal cord and medulla respectively.
- Arnold-Chiari malformation is a group of malformations of the brain involving the brainstem and cerebellum.
- Hydrocephalus is increased volume of CSF within the skull, accompanied by dilatation of the ventricles.
- Primary hydrocephalus is actual increase in the volume of CSF within the skull along with elevated intracranial pressure which may be due to obstruction, production or deficient reabsorption of CSF. It may be communicating or non-communicating type.
- Secondary hydrocephalus is much less common and is compensatory increase of CSF due to loss of neural tissue (normal pressure hydrocephalus).

INFECTIONS OF CNS

A large number of pathogens comprising various kinds of bacteria, fungi, viruses, rickettsiae and parasites can cause infections of the nervous system. The micro-organisms may gain entry into the nervous system by one of the following routes:

1. Via blood stream Spread of infection by the arterial route from another focus is the most common mode of spread of infection in the nervous system. Less often, the spread may occur by retrograde venous route and by lodgement of septic emboli in the brain.

2. Direct implantation Spread of infection by direct implantation occurs following skull fractures or through defects in the bony and meningeal coverings of the nervous system.

3. Local extension Extension of infection from contiguous focus such as otitis media and frontal or mastoid sinusitis may occur.

4. Along nerve Certain viruses such as herpes simplex, herpes zoster and rabies spread along cranial and peripheral nerves and ascend to the CNS.

In general, resultant lesions are in the form of either diffuse inflammation of the meninges (meningitis) and of brain parenchyma (encephalitis), or combination of both (meningoencephalitis). In addition, other inflammatory lesions of CNS include: brain abscess, epidural abscess, subdural empyema, septic thromboembolism of dural sinuses and

encephalomyelitis. Some of the morphologically significant lesions are described below.

MENINGITIS

Meningitis is inflammatory involvement of the meninges. Meningitis may involve the dura called *pachymeningitis*, or the leptomeninges (pia-arachnoid) termed *leptomeningitis*. The latter is far more common, and unless otherwise specified, meningitis would mean leptomeningitis.

Pachymeningitis is invariably an extension of the inflammation from chronic suppurative otitis media or from fracture of the skull. An *extradural abscess* may form by suppuration between the bone and dura. Further spread of infection may penetrate the dura and form a *subdural abscess*. Other effects of pachymeningitis are localised or generalised leptomeningitis and *cerebral abscess*.

Leptomeningitis, commonly called meningitis, is usually the result of infection but infrequently chemical meningitis and carcinomatous meningitis by infiltration of the subarachnoid space by cancer cells may occur. Infectious meningitis is broadly classified into 3 types: acute pyogenic, acute lymphocytic (viral, aseptic) and chronic (bacterial or fungal).

Acute Pyogenic Meningitis

Acute pyogenic or acute purulent meningitis is acute infection of the pia-arachnoid and of the CSF enclosed in the subarachnoid space. Since the subarachnoid space is continuous around the brain, spinal cord and the optic nerves, infection spreads immediately to whole of the cerebrospinal meninges as well as to the ventricles.

ETIOPATHOGENESIS The causative organisms vary with age of the patient:

1. *Escherichia coli* infection is common in neonates with neural tube defects.
2. *Haemophilus influenzae* is commonly responsible for infection in infants and children.
3. *Neisseria meningitidis* causes meningitis in adolescent and young adults and is causative for epidemic meningitis.
4. *Streptococcus pneumoniae* is causative for infection at extremes of age and following trauma.

The **routes** of infection in acute pyogenic meningitis are as follows:

1. Most commonly by the blood stream.
2. From an adjacent focus of infection.
3. By iatrogenic infection such as introduction of microorganisms at operation or during lumbar puncture.

MORPHOLOGIC FEATURES *Grossly*, pus accumulates in the subarachnoid space so that normally clear CSF becomes turbid or frankly purulent. The turbid fluid is particularly seen in the sulci and at the base of the brain where the space is wide. In fulminant cases, some degree of ventriculitis is also present having a fibrinous coating on their walls and containing turbid CSF. In addition, purulent material may interfere with CSF flow and result in obstructive hydrocephalus.

Microscopically, there is presence of numerous polymorphonuclear neutrophils in the subarachnoid space as well as in the meninges, particularly around the blood vessels (**Fig. 28.3**). Gram-staining reveals varying number of causative bacteria.

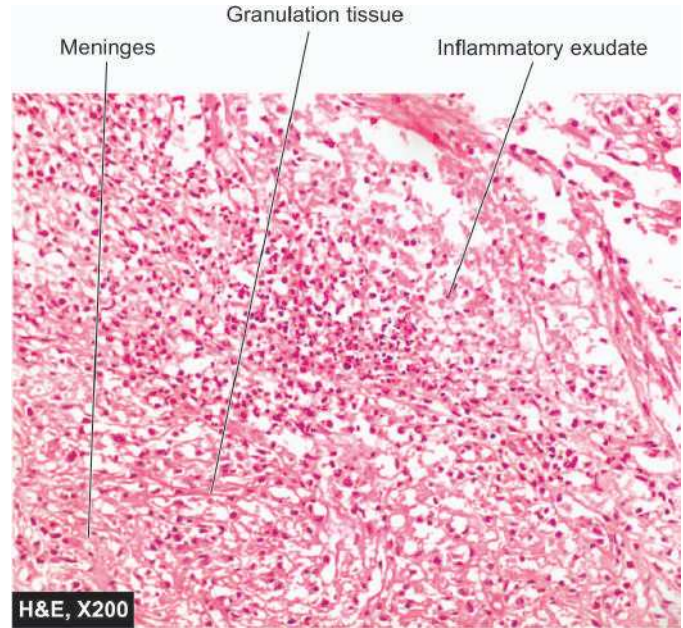

Figure 28.3 Acute suppurative meningitis.

CLINICAL FEATURES AND DIAGNOSIS Acute bacterial meningitis is a medical emergency. The immediate clinical manifestations are fever, severe headache, vomiting, drowsiness, stupor, coma, and occasionally, convulsions. The most important clinical sign is stiffness of the neck on forward bending.

The *diagnosis* is confirmed by examining CSF as soon as possible. The diagnostic alterations in the CSF in acute pyogenic meningitis are as under:

1. Naked eye appearance of cloudy or frankly purulent CSF.
2. Elevated CSF pressure (above 180 mm water).
3. Polymorphonuclear neutrophilic leucocytosis in CSF (between 10-10,000/ μ l).
4. Raised CSF protein level (higher than 50 mg/dl).
5. Decreased CSF sugar concentration (lower than 40 mg/dl).
6. Bacteriologic examination by Gram's stain or by CSF culture reveals causative organism.

Acute Lymphocytic (Viral, Aseptic) Meningitis

Acute lymphocytic meningitis is a viral or aseptic meningitis, especially common in children and young adults. Among the etiologic agents are numerous viruses such as enteroviruses, mumps, ECHO viruses, coxsackie virus, Epstein-Barr virus, herpes simplex virus-2, arthropod-borne viruses and HIV. However, evidence of viral infection may not be demonstrable in about a third of cases.

MORPHOLOGIC FEATURES *Grossly*, some cases show swelling of the brain while others show no distinctive change.

Microscopically, there is mild lymphocytic infiltrate in the leptomeninges.

CLINICAL FEATURES AND DIAGNOSIS The clinical manifestations of viral meningitis are much the same as in bacterial meningitis with features of acute onset meningeal

symptoms and fever. However, viral meningitis has a benign and self-limiting clinical course of short duration and is invariably followed by complete recovery without the life-threatening complications of bacterial meningitis.

The CSF findings in viral meningitis are as under:

1. Naked eye appearance of clear or slightly turbid CSF.
2. CSF pressure increased (above 250 mm water).
3. Lymphocytosis in CSF (10-100 cells/ μ l).
4. CSF protein usually normal or mildly raised.
5. CSF sugar concentration usually normal.
6. CSF bacteriologically sterile.

Chronic (Tuberculous and Cryptococcal) Meningitis

There are two principal types of chronic meningitis—one bacterial (tuberculous meningitis) and the other fungal (cryptococcal meningitis). Both types cause chronic granulomatous reaction and may produce parenchymal lesions.

◆ *Tuberculous meningitis* occurs in children and adults through haematogenous spread of infection from tuberculosis elsewhere in the body, or it may simply be a manifestation of miliary tuberculosis. Less commonly, the spread may occur directly from tuberculosis of a vertebral body.

◆ *Cryptococcal meningitis* develops particularly in debilitated or immunocompromised persons, usually as a result of haematogenous dissemination from a pulmonary lesion. Cryptococcal meningitis is especially an important cause of meningitis in patients with AIDS.

MORPHOLOGIC FEATURES *Grossly*, in tuberculous meningitis, the subarachnoid space contains thick exudate, particularly abundant in the sulci and the base of the brain. Tubercles, 1-2 mm in diameter, may be visible, especially adjacent to the blood vessels. The exudate in cryptococcal meningitis is scanty, translucent and gelatinous.

Microscopically, tuberculous meningitis shows exudate of acute and chronic inflammatory cells, and granulomas with or without caseation necrosis and giant cells. Acid-fast bacilli may be demonstrated. Late cases show dense fibrous adhesions in the subarachnoid space and consequent hydrocephalus. Cryptococcal meningitis is characterised by infiltration by lymphocytes, plasma cells, an occasional granuloma and abundant characteristic capsulated cryptococci.

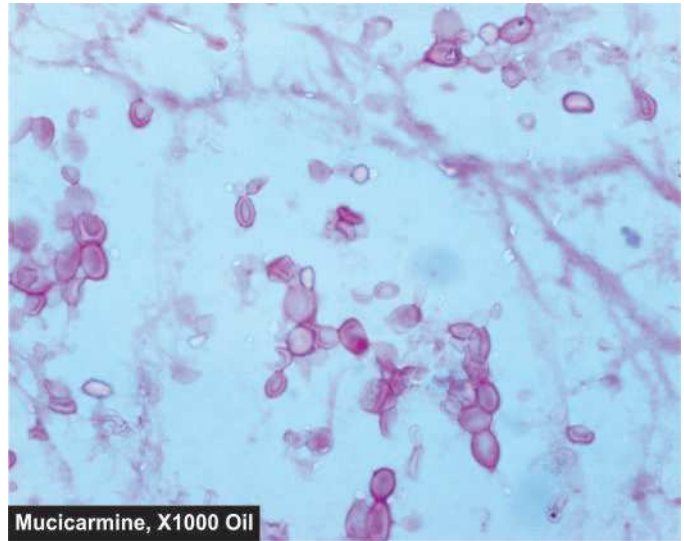

Figure 28.4 Cryptococci in CSF as seen in mucicarmine stain.

CLINICAL FEATURES AND DIAGNOSIS Tuberculous meningitis manifests clinically as headache, confusion, malaise and vomiting. The clinical course in cryptococcal meningitis may, however, be fulminant and fatal in a few weeks, or be indolent for months to years.

The CSF findings in chronic meningitis are as under:

1. Naked eye appearance of a clear or slightly turbid CSF which may form fibrin web on standing.
2. Raised CSF pressure (above 300 mm water).
3. Mononuclear leucocytosis consisting mostly of lymphocytes and some macrophages (100-1000 cells/ μ l).
4. Raised protein content.
5. Lowered glucose concentration.
6. Tubercle bacilli may be found on microscopy of centrifuged deposits by ZN staining in tuberculous meningitis. Pathognomonic capsulated cryptococci with a halo are appreciated in India ink preparation of CSF in cases of cryptococcal meningitis, while the capsule is better demonstrated by mucicarmine stain (Fig. 28.4).

Table 28.1 summarises the CSF findings in the three important types of meningitis in comparison with those in health.

Table 28.1 CSF findings in health and various types of meningitis.

| FEATURE | NORMAL | ACUTE PYOGENIC (BACTERIAL) MENINGITIS | ACUTE LYMPHOCYTIC (VIRAL) MENINGITIS | CHRONIC (TUBERCULOUS) MENINGITIS |
|-------------------------|--------------------------|---------------------------------------|--------------------------------------|---|
| 1. Naked eye appearance | Clear and colourless | Cloudy or frankly purulent | Clear or slightly turbid | Clear or slightly turbid, forms fibrin coagulum on standing |
| 2. CSF pressure | 60-150 mm water | Elevated (above 180 mm water) | Elevated (above 250 mm water) | Elevated (above 300 mm water) |
| 3. Cells | 0-4 lymphocytes/ μ l | 10-10,000 neutrophils/ μ l | 10-100 lymphocytes/ μ l | 100-1000 lymphocytes/ μ l |
| 4. Proteins | 15-45 mg/dl | Markedly raised | Mildly raised | Raised |
| 5. Glucose | 50-80 mg/dl | Markedly reduced | Normal | Reduced |
| 6. Bacteriology | Sterile | Causative organisms present | Sterile | Tubercle bacilli present |

ENCEPHALITIS

Parenchymal infection of the brain is termed encephalitis. Encephalitis may be the result of bacterial, viral, fungal and protozoal infections.

Bacterial Encephalitis

Bacterial infection of the brain substance is usually secondary to involvement of the meninges rather than a primary bacterial parenchymal infection. This results in bacterial cerebritis that progresses to form *brain abscess*. However, *tuberculosis* and *neurosyphilis* are the two primary bacterial involvements of the brain parenchyma.

BRAIN ABSCESS Brain abscesses may arise by one of the following routes:

1. By direct implantation of organisms e.g. following compound fractures of the skull.
2. By local extension of infection e.g. chronic suppurative otitis media, mastoiditis and sinusitis.
3. By haematogenous spread e.g. from primary infection in the heart such as acute bacterial endocarditis, and from lungs such as in bronchiectasis.

Clinically, there is usually evidence of reactivation of infection at the primary site preceding the onset of cerebral symptoms. The features of abscess are fever, headache, vomiting, seizures and focal neurological deficits depending upon the location of the abscess. Brain abscess is most common in cerebral hemispheres and less frequent in the cerebellum and basal ganglia.

Grossly, it appears as a localised area of inflammatory necrosis and oedema surrounded by fibrous capsule.

Microscopically, the changes consist of liquefactive necrosis in the centre of the abscess containing pus. It is surrounded by acute and chronic inflammatory cells, neovascularisation, oedema, septic thrombosis of vessels, fibrous encapsulation and zone of gliosis. The CSF and overlying meninges also show evidence of acute and chronic inflammation.

TUBERCULOMA Tuberculoma is an intracranial mass occurring secondary to dissemination of tuberculosis elsewhere in the body. Tuberculomas may be solitary or multiple.

Grossly, it has a central area of caseation necrosis surrounded by fibrous capsule.

Microscopically, there is typical tuberculous granulomatous reaction around the central caseation necrosis (Fig. 28.5). A zone of gliosis generally surrounds the tuberculoma. Advanced cases may show areas of calcification.

NEUROSYPHILIS Syphilitic lesions of the CNS used to be common and serious, but more recently there is evidence of atypical neurosyphilis in cases of HIV/AIDS. The lesions in syphilis may be in the form of *syphilitic meningitis* found in secondary syphilis, and *neurosyphilis* consisting of *tabes dorsalis* and generalised paralysis of the insane occurring in tertiary stage (page 152).

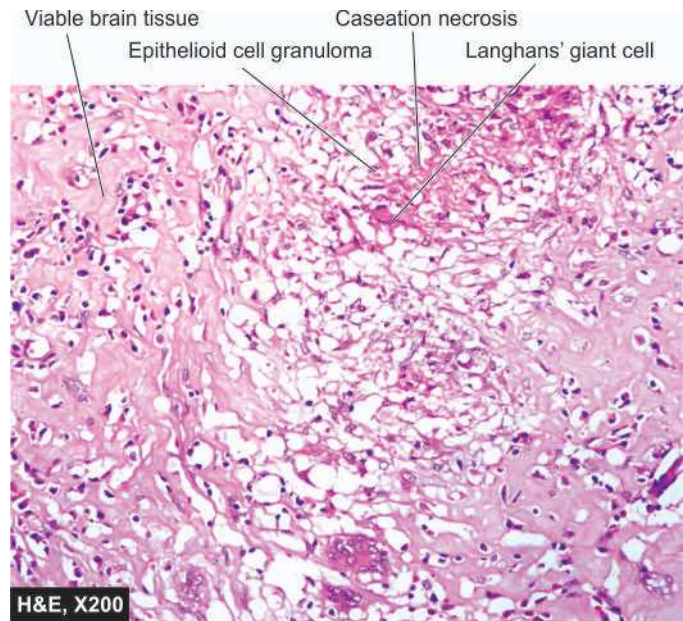

Figure 28.5 Tuberculous encephalitis of the brain.

Syphilitic meningitis This is a form of chronic meningitis characterised by distinctive perivascular inflammatory reaction of plasma cells and endarteritis obliterans.

Tabes dorsalis (Locomotor ataxia) There is slowly progressive degeneration of the posterior roots of the spinal nerves and the posterior columns of the spinal cord by the spirochaetes. These changes produce loss of coordination of muscles and joints resulting in locomotor ataxia. There is also loss of pain sensation and presence of Argyll-Robertson pupils which react to accommodation but not to light.

General paralysis of the insane This is the result of diffuse parenchymal involvement by the spirochaetes with widespread lesions in the nervous system. The symptoms consist of motor, sensory and psychiatric abnormalities.

Viral Encephalitis

A number of viruses can infect the CNS and produce either aseptic meningitis (described already) or viral encephalitis, but sometimes combination of both termed meningoencephalitis, is present. Most viral infections of the CNS are the end-result of preceding infection in other tissues and organs. There is usually a preceding phase of extraneural viral replication before involvement of the nervous system occurs.

Most of the viruses reach the nervous system via blood stream before which they enter the body by various routes e.g. infection of the skin and mucous membrane (in herpes simplex and herpes zoster-varicella), by the alimentary tract (in enteroviruses including polio virus), by arthropod bite (in arbovirus), by transplacental infection (in cytomegalovirus), and through body fluids in AIDS (in HIV infection). Rabies virus travels along the peripheral nerves to reach the CNS. Herpes zoster-varicella is a distinct primary disease (chickenpox) but the virus remains latent for a long time before it gets reactivated to cause severe hyperalgesia and pain along the distribution of nerve related to acutely inflamed posterior root ganglia (herpes zoster). All these viral infections enumerated so far cause *acute*

viral encephalitis. *Slow virus diseases* are another group of CNS infections in which the agents have not only a long latent period but the disease also develops slowly and may produce subacute sclerosing panencephalitis, progressive multifocal leucoencephalopathy, progressive rubella panencephalopathy and subacute spongiform encephalopathy.

MORPHOLOGIC FEATURES Although histologic changes vary from one viral infection of the CNS to the other but, in general, the characteristic features of viral diseases of the CNS are as under:

1. Parenchymal infiltrate, chiefly in perivascular location, of mononuclear cells consisting of lymphocytes, plasma cells and macrophages.
2. Microscopic clusters of microglial cells and presence of neuronophagia.
3. Intracellular inclusion bodies in most viral diseases and specific cytoplasmic inclusions of Negri bodies in rabies.

HIV Encephalopathy (AIDS-Dementia Complex)

Next to knocking off of the immune system, HIV has profound neurovirulence but unlike tropism for CD4+ T cells of the immune system, HIV does not have neurotropism. HIV has not been identified to infect the neuronal cells but instead infects the cells of monocyte-macrophage cell line including microglial cells. HIV infection then sets in a cascade of toxic mediators and cytokines—TNF- α , IL-1, IL-6, TGF- β , IFN- γ , platelet activating factor (PAF) and endothelin, all of which cause damage to the neuroglial tissues.

Important forms of CNS diseases in patients with AIDS are listed in **Table 28.2**. Late in the course of AIDS, a group of signs and symptoms of CNS disease appear termed HIV encephalopathy or *AIDS-dementia complex*. One major clinical feature of this entity is the occurrence of *dementia* i.e. fall in the cognitive ability of the individual compared to previous level. The condition is believed to be the result of direct effect of HIV on the CNS. Clinically, the disease develops in about 25% cases of AIDS while autopsy studies reveal presence of HIV-encephalopathy in 80-90% cases of AIDS.

Table 28.2 Major forms of CNS diseases in AIDS.

| DISEASE | INCIDENCE |
|--|-----------|
| 1. HIV-encephalopathy (<i>AIDS-dementia complex</i>) | 25% |
| 2. <i>Opportunistic infections</i> | |
| i) Toxoplasmosis | 15% |
| ii) Cryptococcal meningitis | 9% |
| iii) Progressive multifocal leucoencephalopathy | 4% |
| iv) Neurosyphilis | 1% |
| v) Tuberculous meningitis | 1% |
| 3. <i>Neoplasms</i> | |
| i) Primary CNS lymphoma | 4% |
| ii) Kaposi's sarcoma | <1% |
| 4. <i>Progressive multifocal leucoencephalopathy (PML)</i> | 1% |
| 5. <i>Peripheral neuropathies</i> | 70% |
| 6. <i>Myelopathy (Spinal cord disease)</i> | 20% |

Histologically, the changes are more in subcortical area of the brain and consist of gliosis, multinucleate giant cell encephalitis, and vacuolar myelopathy.

Progressive Multifocal Leucoencephalopathy

Progressive multifocal leucoencephalopathy (PML) is a slow viral infection of the CNS caused by a papovavirus called *JC virus* (not to be confused with CJ disease or mad-cow disease; JC virus here stands for the initials of the patient first infected). PML develops in immunocompromised individual like CMV and *Toxoplasma* encephalitis does, and is, therefore, an important form of encephalitis due to increasing number of cases of AIDS.

PML infects oligodendrocytes and causes progressive demyelination at multifocal areas scattered throughout the CNS.

Grossly, the lesions consist of focal, irregular gelatinous areas most prominent at the junction of grey and white matter. Main areas affected are cerebrum, brainstem, cerebellum, and sometimes spinal cord.

Microscopically, the features are as under:

- i) Focal areas of demyelination.
- ii) Many lipid-laden macrophages in the centre of foci.
- iii) Enlarged oligodendroglial nuclei containing purple viral inclusions at the periphery of the lesion.

Spongiform Encephalopathy (Creutzfeldt-Jakob Disease)

Spongiform encephalopathy, also called Creutzfeldt-Jakob disease (CJD) or mad-cow disease, though included under the group of viral encephalitis but is caused by accumulation of prion proteins. *Prion proteins* are a modified form of normal structural proteins present in the mammalian CNS and are peculiar in two respects: they lack nucleic acid (DNA or RNA), and they can be transmitted as an infectious proteinaceous particles (Dr Prusiner was awarded the Nobel Prize in medicine in 1997 for his discovery on prion proteins).

Majority of cases occur sporadically though familial predisposition with autosomal dominant inheritance has also been reported in 5-15% cases. Other methods of transmission are by iatrogenic route (e.g. by tissue transplantation from an infected individual) and by human consumption of BSE (bovine spongiform encephalopathy)-infected beef, hence called as mad-cow disease.

Clinically, CJD is characterised by rapidly progressive dementia with prominent association of myoclonus. CJD is invariably fatal with mean survival of about 7 months after diagnosis.

Grossly, the changes are too rapid to become noticeable but brain atrophy may be seen in long-standing cases.

Microscopically, the hallmark is spongiform change i.e. there are small round vacuoles in the neuronal cells. These changes are predominantly seen in the cortex and other grey matter areas. Spongiform changes result in neuronal loss and glial cell proliferation but significantly without any inflammation or white matter involvement.

Figure 28.6 Neurocysticercosis. The sliced surface of the cerebral hemisphere of the brain shows many tiny whitish nodules and cysts about 1 cm in diameter.

Fungal and Protozoal Encephalitis

Mycotic diseases of the CNS usually develop by blood stream from systemic deep mycoses elsewhere in the body. They are particularly more common in immunosuppressed individuals such as in AIDS, patients of lymphomas and other cancers. Some of the fungi which may disseminate to the CNS are *Candida albicans*, *Mucor*, *Aspergillus fumigatus*, *Cryptococcus neoformans*, *Histoplasma capsulatum* and *Blastomyces dermatitidis*. These fungal infections may produce one of the three patterns: fungal chronic meningitis, vasculitis and encephalitis.

Besides fungal infections, CNS may be involved in protozoal diseases such as in malaria, toxoplasmosis, amoebiasis, trypanosomiasis and cysticercosis (**Fig. 28.6**).

GIST BOX 28.3 Infections of CNS

- ☐ Infections in the CNS may occur via blood stream, direct implantation, local extension or along nerves.
- ☐ Meningitis is usually the result of infection which may be acute pyogenic, acute lymphocytic (viral, aseptic) and chronic (bacterial or fungal).
- ☐ Parenchymal infection of brain is termed encephalitis which may be the result of bacterial (brain abscess, tuberculoma, spirochetes (neurosyphilis), viral (including HIV-AIDS dementia complex and progressive multifocal leucoencephalopathy), prion proteins (spongiform encephalopathy), fungal and protozoal infections.

CEREBROVASCULAR DISEASES

Cerebrovascular diseases are all those diseases in which one or more of the blood vessels of the brain are involved in the pathologic processes. Various pathologic processes commonly implicated in cerebrovascular diseases are: thrombosis, embolism, rupture of a vessel, hypoxia, hypertensive arteriosclerosis, atherosclerosis, arteritis, trauma, aneurysm and developmental malformations. These processes can result in the following main types of parenchymal diseases of the brain:

A. Ischaemic brain damage:

- a) Generalised reduction in blood flow resulting in *global hypoxic-ischaemic encephalopathy*
- b) Local vascular obstruction causing *infarcts*.

B. Intracranial spontaneous (non-traumatic) haemorrhage:

- a) Haemorrhage in the brain parenchyma (*intracerebral haemorrhage*)
- b) Haemorrhage in the subarachnoid space (*subarachnoid haemorrhage*).

C. Traumatic brain haemorrhage:

- a) Epidural haematoma
- b) Subdural haematoma
- c) Parenchymal brain damage.

The *stroke syndrome* is the cardinal feature of cerebrovascular disease. The term stroke is used for sudden and dramatic development of focal neurologic deficit, varying from trivial neurologic disorder to hemiplegia and coma. Other less common effects of vascular disease include: transient ischaemic attacks (TIA), vascular headache (e.g. in migraine, hypertension and arteritis), local pressure of an aneurysm and increased intracranial pressure (e.g. in hypertensive encephalopathy and venous thrombosis).

A few important morphologic forms are discussed below.

A. ISCHAEMIC BRAIN DAMAGE

Ischaemic necrosis in the brain results from ischaemia caused by considerable reduction or complete interruption of blood supply to neural tissue which is insufficient to meet its metabolic needs. The brain requires sufficient quantities of oxygen and glucose so as to sustain its aerobic metabolism, mainly by citric acid (Krebs') cycle which requires oxygen. Moreover, neural tissue has limited stores of energy reserves so that cessation of continuous supply of oxygen and glucose for more than 3-4 minutes results in permanent damage to neurons and neuroglial cells.

Deprivation of oxygen (anoxia) to the brain may occur in 4 different ways:

- i. *Anoxic anoxia*, in which there is low inspired pO_2 .
- ii. *Anaemic anoxia*, in which the oxygen-carrying haemoglobin is reduced.
- iii. *Histotoxic anoxia*, in which there is direct toxic injury as occurs in cyanide poisoning.
- iv. *Stagnant (ischaemia) anoxia*, in which the damage is caused by cessation of blood with resultant local accumulation of metabolites and changes in pH.

In all these different forms of anoxia, the end-result is ischaemic brain damage which may have one of the following two patterns:

1. *Global hypoxic-ischaemic encephalopathy*, resulting from generalised cerebral hypoperfusion.
2. *Cerebral infarction*, resulting from severe localised reduction or cessation of blood supply.

Global Hypoxic-Ischaemic Encephalopathy

The brain receives 20% of cardiac output for maintaining its vital aerobic metabolism. A number of factors determine the maximum length of time the CNS can *survive irreversible ischaemic damage*. These are as under:

- i) Severity of the hypoxic episode.
- ii) Presence of pre-existing cerebrovascular disease.

- iii) Age of the patient.
- iv) Body temperature.

In normal individuals, the brain continues to be perfused adequately up to systolic arterial pressure of 50 mmHg by an auto-regulatory vascular control mechanism. However, fall of systemic arterial systolic pressure below this critical value results in rapid fall in cerebral perfusion pressure and eventual ischaemic encephalopathy. Such types of medical emergencies occur at the time of cardiac arrest followed by relatively delayed resuscitation, severe episode of hypotension, carbon monoxide intoxication and status epilepticus. Hypoxic encephalopathy may be followed by either a post-ischaemic confusional state and complete recovery, or a state of coma and even a persistent vegetative life and brain death.

Depending upon the proneness of different cells of the brain to the effects of ischaemia-hypoxia, three types of lesion may occur:

1. Selective neuronal damage Neurons are most vulnerable to damaging effect of ischaemia-hypoxia and irreversible injury. In particular, oligodendroglial cells are most susceptible, followed by astrocytes while microglial cells and vascular endothelium survive the longest. The reason for undue vulnerability of neurons to hypoxia can be explained by various factors:

- i) Different cerebral circulatory blood flow.
- ii) Presence of acidic excitatory neurotransmitters called *excitotoxins*.
- iii) Excessive metabolic requirement of these neurons.
- iv) Increased sensitivity of neurons to lactic acid.

2. Laminar necrosis Global ischaemia of cerebral cortex results in uneven damage because of different cerebral vasculature which is termed laminar or pseudolaminar necrosis. In this, superficial areas of cortical layers escape damage while deeper layers are necrosed.

3. Watershed infarcts Circulatory flow in the brain by anterior, middle and posterior cerebral arteries has overlapping circulations. In ischaemia-hypoxia, perfusion of overlapping zones, being farthest from the blood supply, suffers maximum damage. This results in wedge-shaped areas of coagulative necrosis called watershed or border zone infarcts. Particularly vulnerable is the border zone of the cerebral cortex between the anterior and middle cerebral arteries, producing parasagittal infarction.

MORPHOLOGIC FEATURES The pathologic appearance of the brain in hypoxic encephalopathy varies depending upon the duration and severity of hypoxic episode and the length of survival.

- ◆ **Survival for a few hours:** No pathologic changes are visible.
- ◆ **Survival 12-24 hours:** No macroscopic change is discernible but microscopic examination reveals early neuronal damage in the form of eosinophilic cytoplasm and pyknotic nuclei, so called *red neurons*.
- ◆ **After 2-7 days:** *Grossly*, there is focal softening. The area supplied by distal branches of the cerebral arteries suffers from the most severe ischaemic damage and may develop *border zone* or *watershed infarcts* in the junctional zones between the territories supplied by major arteries.

Microscopically, the nerve cells die and disappear and are replaced by reactive fibrillary gliosis. There are minor variations in the distribution of neuronal damage to the cortex; the loss of pyramidal cell layer is more severe than that of granular cell layer producing laminar necrosis.

- ◆ **Longer duration:** Use of modern ventilators has led to maintenance of cardiorespiratory function in the presence of total brain necrosis unassociated with vital reaction.

Cerebral Infarction

Cerebral infarction is a localised area of tissue necrosis caused by local vascular occlusion—arterial or venous. Occasionally, it may be the result of non-occlusive causes such as compression on the cerebral arteries from outside and from hypoxic encephalopathy. Clinically, the signs and symptoms associated with cerebral infarction depend upon the region infarcted. In general, the focal neurologic deficit termed stroke, is present. However, significant atherosclerotic cerebrovascular disease may produce transient ischaemic attacks (TIA).

1. Arterial occlusion Occlusion of the cerebral arteries by either thrombi or emboli is the most common cause of cerebral infarction. Thrombotic occlusion of the cerebral arteries is most frequently the result of atherosclerosis, and rarely, from arteritis of the cranial arteries. Embolic arterial occlusion is commonly derived from the heart, most often from mural thrombosis complicating myocardial infarction, from atrial fibrillation and endocarditis. The size and shape of an infarct are determined by the extent of anastomotic connections with adjacent arterial branches as under:

- ◆ Circle of Willis provides a complete collateral flow for internal carotid and vertebral arteries.
- ◆ Middle and anterior cerebral arteries have partial anastomosis of their distal branches. Their complete occlusion may cause infarcts.
- ◆ Small terminal cerebral arteries, on the contrary, are end-arteries and have no anastomosis. Hence, occlusion of these branches will invariably lead to an infarct.

2. Venous occlusion Venous infarction in the brain is an infrequent phenomenon due to good communications of the cerebral venous drainage. However in cancer, due to increased predisposition to thrombosis, superior sagittal thrombosis may occur leading to bilateral, parasagittal, multiple haemorrhagic infarcts.

3. Non-occlusive causes Compression of the cerebral arteries from outside such as occurs during herniation may cause cerebral infarction. Mechanism of watershed (border zone) cerebral infarction in hypoxic encephalopathy has already been explained above.

In any case, the extent of damage produced by any of the above causes depends upon:

- i) rate of reduction of blood flow;
- ii) type of blood vessel involved; and
- iii) extent of collateral circulation.

MORPHOLOGIC FEATURES *Grossly*, cerebral infarcts may be anaemic or haemorrhagic. An *anaemic infarct* becomes evident 6-12 hours after its occurrence. The affected area is soft and swollen and there is blurring

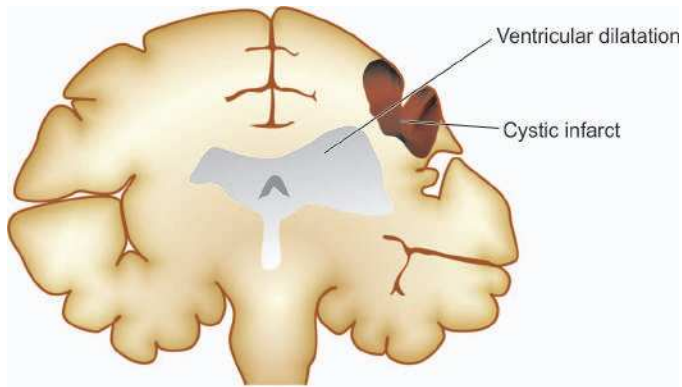

Figure 28.7 An old cystic infarct in the brain (coronal section). There is shrinkage of scarred area with ipsilateral ventricular dilatation.

of junction between grey and white matter. Within 2-3 days, the infarct undergoes softening and disintegration. Eventually, there is central liquefaction with peripheral firm glial reaction and thickened leptomeninges, forming a cystic infarct (**Fig. 28.7**). A *haemorrhagic infarct* is red and superficially resembles a haematoma. It is usually the result of fragmentation of occlusive arterial emboli or venous thrombosis.

Histologically, the sequential changes are as under:

1. Initially, there is eosinophilic neuronal necrosis and lipid vacuolisation produced by breakdown of myelin. Simultaneously, the infarcted area is infiltrated by neutrophils.
2. After the first 2-3 days, there is progressive invasion by macrophages and there is astrocytic and vascular proliferation.
3. In the following weeks to months, the macrophages clear away the necrotic debris by phagocytosis followed by reactive astrocytosis, often with little fine fibrosis (**Fig. 28.8**). A haemorrhagic infarct has some phagocytes containing haemosiderin.
4. Ultimately, after 3-4 months an old cystic infarct is formed which shows a cyst traversed by small blood vessels and has peripheral fibrillary gliosis. Small cavitory infarcts are called *lacunar infarcts* and are commonly found as a complication of systemic hypertension.

B. NON-TRAUMATIC INTRACRANIAL HAEMORRHAGE

Haemorrhage into the brain may be traumatic or non-traumatic, (or spontaneous). There are two main types of spontaneous intracranial haemorrhage (**Fig. 28.9**):

1. Intracerebral haemorrhage, which is usually of hypertensive origin.
2. Subarachnoid haemorrhage, which is commonly aneurysmal in origin.

In addition to hypertension and rupture of an aneurysm, other causes of spontaneous intracranial haemorrhage include haemorrhage into tumours, vascular malformations and haemorrhagic diathesis which produce mixed intracerebral and subarachnoid haemorrhage.

Intracerebral Haemorrhage

Spontaneous intracerebral haemorrhage occurs mostly in patients of hypertension. Most hypertensives over middle age have microaneurysms in very small cerebral arteries in the

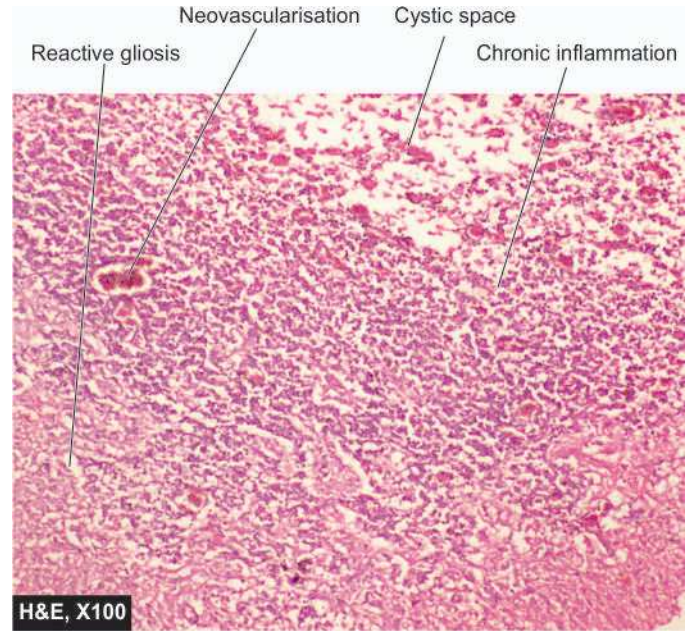

Figure 28.8 An anaemic infarct of a few days duration. The histologic changes are reactive astrocytosis, a few reactive macrophages and neovascularisation in the wall of the cystic lesion. The outer cortical layer is, however, intact.

brain tissue. Rupture of one of the numerous microaneurysms is believed to be the cause of intracerebral haemorrhage. Unlike subarachnoid haemorrhage, it is not common to have recurrent intracerebral haemorrhages.

The common sites of hypertensive intracerebral haemorrhage are the region of the basal ganglia (particularly the putamen and the internal capsule), pons and the cerebellar cortex. Clinically the onset is usually sudden with headache and loss of consciousness. Depending upon the location of the lesion, hemispheric, brainstem or cerebellar signs will be present. About 40% of patients die during the first 3-4 days of haemorrhage, mostly from haemorrhage into the ventricles. The survivors tend to have haematoma that separates the tissue planes which is followed by resolution and development of an *apoplectic cyst* accompanied by loss of function.

MORPHOLOGIC FEATURES *Grossly* and *microscopically*, the haemorrhage consists of dark mass of clotted blood replacing brain parenchyma. The borders of the lesion

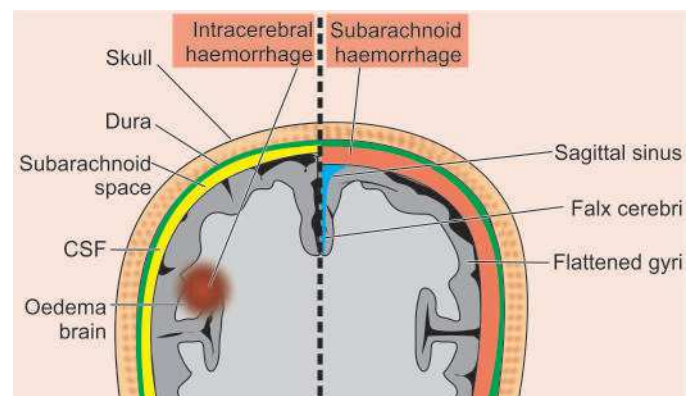

Figure 28.9 Two types of intracranial haemorrhage: intracerebral (left) and subarachnoid haemorrhage (right).

are sharply-defined and have a narrow rim of partially necrotic parenchyma. Small ring haemorrhages in the Virchow-Robin space in the border zone are commonly present. Ipsilateral ventricles are distorted and compressed and may contain blood in their lumina. Rarely, blood may rupture through the surface of the brain into the subarachnoid space. After a few weeks to months, the haematoma undergoes resolution with formation of a slit-like space called *apoplectic cyst* which contains yellowish fluid. Its margins are yellow-brown and have haemosiderin-laden macrophages and a reactive zone of fibrillary astrocytosis.

Subarachnoid Haemorrhage

Haemorrhage into the subarachnoid space is most commonly caused by rupture of an aneurysm, and rarely, rupture of a vascular malformation.

A general discussion of aneurysms is given on page 386. Of the three types of aneurysms affecting the larger intracranial arteries—berry, mycotic and fusiform, berry aneurysms are most important and most common.

Berry aneurysms are saccular in appearance with rounded or lobulated bulge arising at the bifurcation of intracranial arteries and varying in size from 2 mm to 2 cm or more. They account for 95% of aneurysms which are liable to rupture. Berry aneurysms are rare in childhood but increase in frequency in young adults and middle life. They are, therefore, not congenital anomalies but develop over the years from developmental defect of the media of the arterial wall at the bifurcation of arteries forming thin-walled saccular bulges. Although most berry aneurysms are sporadic in occurrence, there is an increased incidence of their presence in association with congenital polycystic kidney disease and coarctation of the aorta. About a quarter of berry aneurysms are multiple.

In more than 85% cases of subarachnoid haemorrhage, the cause is massive and sudden bleeding from a berry aneurysm on or near the circle of Willis. The four most common sites of such aneurysms are as under (**Fig. 28.10**):

1. In relation to anterior communicating artery.

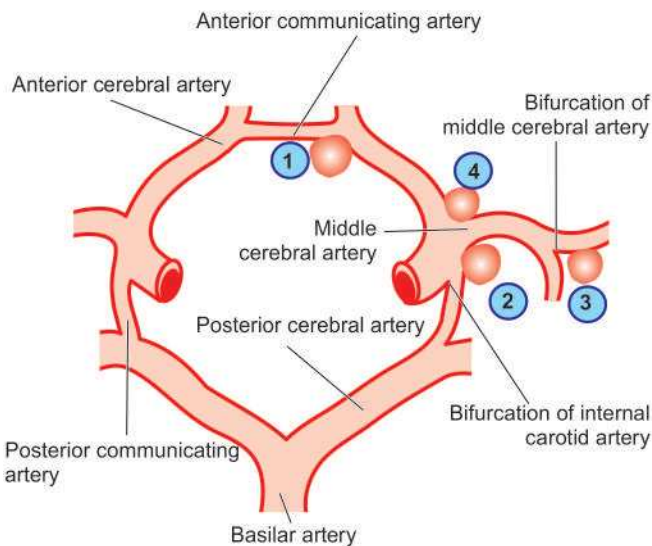

Figure 28.10 The circle of Willis showing principal sites of berry (saccular) aneurysms. The serial numbers indicate the frequency of involvement.

2. At the origin of the posterior communicating artery from the stem of the internal carotid artery.
3. At the first major bifurcation of the middle cerebral artery.
4. At the bifurcation of the internal carotid into the middle and anterior cerebral arteries.

The remaining 15% cases of subarachnoid haemorrhage are the result of rupture in the posterior circulation, vascular malformations and rupture of mycotic aneurysms that occurs in the setting of bacterial endocarditis. In all types of aneurysms, the rupture of thin-walled dilatation occurs in association with sudden rise in intravascular pressure but chronic hypertension does not appear to be a risk factor in their development or rupture.

Clinically, berry aneurysms remain asymptomatic prior to rupture. On rupture, they produce severe generalised headache of sudden onset which is frequently followed by unconsciousness and neurologic defects. Initial mortality from first rupture is about 20-25%. Survivors recover completely but frequently suffer from recurrent episodes of fresh bleeding.

MORPHOLOGIC FEATURES Rupture of a berry aneurysm frequently spreads haemorrhage throughout the subarachnoid space with rise in intracranial pressure and characteristic blood-stained CSF. An intracerebral haematoma may develop if the blood tracks into the brain parenchyma. The region of the brain supplied by the affected artery frequently shows infarction, partly attributed to vasospasm.

C. TRAUMA TO THE CNS

Trauma to the brain constitutes an important cause of death and permanent disability in the modern world. Important causes of head injuries are: motor vehicle accidents, accidental falls and violence. Traumatic injuries to the CNS may result in three consequences which may occur in isolation or in combination:

1. Epidural haematoma
2. Subdural haematoma
3. Parenchymal brain damage

Epidural Haematoma

Epidural haematoma is accumulation of blood between the dura and the skull following fracture of the skull, most commonly from rupture of middle meningeal artery. The haematoma expands rapidly since accumulating blood is arterial in origin and causes compression of the dura and flattening of underlying gyri (**Fig. 28.11**). The patient develops progressive loss of consciousness if haematoma is not drained early.

Subdural Haematoma

Subdural haematoma is accumulation of blood between the dura and subarachnoid and develops most often from rupture of veins which cross the surface convexities of the cerebral hemispheres. Subdural haematoma may be acute or chronic.

◆ **Acute subdural haematoma** develops following trauma and consists of clotted blood, often in the frontoparietal region. There is no significant compression of gyri (**Fig. 28.12**). Since the accumulated blood is of venous origin, symptoms appear slowly and may become chronic with passage of time if not fatal.

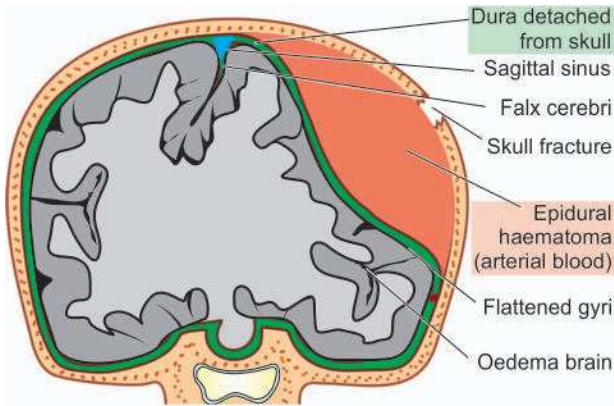

Figure 28.11 Epidural haematoma often results from rupture of artery following skull fracture resulting in accumulation of arterial blood between the skull and the dura.

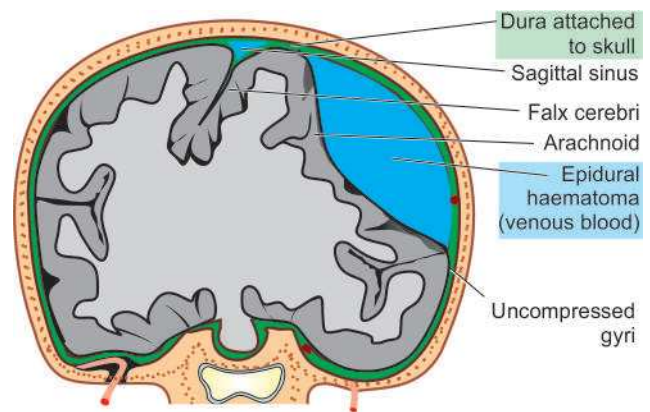

Figure 28.12 Subdural haematoma often results from rupture of veins crossing the cerebral convexities and is characterised by accumulation of venous blood between the dura and the arachnoid.

◆ **Chronic subdural haematoma** occurs often with brain atrophy and less commonly following trauma. Chronic subdural haematoma is composed of liquid blood. Separating the haematoma from underlying brain is a membrane composed of granulation tissue.

Parenchymal Brain Damage

Trauma to the CNS may result in damage to brain parenchyma and includes the following forms:

1. Concussion Concussion is caused by closed head injury and is characterised by transient neurologic dysfunction and loss of consciousness. Invariably, there is complete neurologic recovery after some hours to days.

No significant morphologic change is noticed but more severe concussion may cause diffuse axonal injury (discussed below).

2. Diffuse axonal injury Diffuse axonal injury is the most common cause of persistent coma or vegetative state following head injury. The underlying cause is sudden angular acceleration or deceleration resulting in widespread axonal shearing in the deep white matter of both the hemispheres.

Grossly, the changes are minimal to small multiple haemorrhages.

3. Contusions and lacerations Contusions and lacerations are the result of direct damage to the brain parenchyma, particularly cerebral hemispheres, as occurs in the soft tissues. Most often, they are the result of blunt trauma. The overlying skull may or may not be fractured. Traumatic subarachnoid haemorrhage invariably accompanies cerebral contusions.

Microscopically, brain parenchyma at the affected site is haemorrhagic, necrotic and fragmented. On healing, these lesions appear as shrunken areas with golden brown haemosiderin pigment on the surface.

4. Traumatic intracerebral haemorrhage On trauma to the CNS, the parenchymal vessels of the hemispheres may get torn and cause multiple intracerebral haemorrhages.

5. Brain swelling Head injury may be accompanied by localised or diffuse brain swelling.

GIST BOX 28.4 Cerebrovascular Diseases

- ▣ Cerebrovascular diseases are of 3 main types: ischaemic brain damage, spontaneous intracranial haemorrhage and trauma to the brain.
- ▣ Ischaemic necrosis of the brain may result from anoxia of various types (anoxic, anaemic, histotoxic and stagnant).
- ▣ Ischaemic brain damage may be either global hypoxic-ischaemic encephalopathy (generalised cerebral hypoperfusion) or cerebral infarction (from severe localised reduction or cessation of blood supply).
- ▣ Haemorrhage into the brain may be traumatic, non-traumatic, or spontaneous.
- ▣ There are two main types of spontaneous non-traumatic intracranial haemorrhage: intracerebral haemorrhage (usually of hypertensive origin) and subarachnoid haemorrhage (commonly aneurysmal in origin).
- ▣ Traumatic injuries to the brain may result in three consequences which may occur in isolation or in combination: epidural haematoma, subdural haematoma, and parenchymal brain damage (e.g. concussion, diffuse axonal injury, contusion and lacerations, intracerebral haemorrhage and brain swelling).

MISCELLANEOUS DISEASES

Miscellaneous diseases of the CNS include demyelinating, degenerative, metabolic and nutritional diseases. These groups along with the list of diseases included in each group are briefly outlined below but without going into the details of individual diseases for which the interested reader may consult pertinent text on neuropathology and neurology.

DEMYELINATING DISEASES

Demyelinating diseases are an important group of neurological disorders which have, in common, the pathologic features of focal or patchy destruction of myelin sheaths in the CNS accompanied by an inflammatory response. Demyelination may affect peripheral nervous system as well. Some degree of axonal damage may also occur but demyelination is the

predominant feature. The exact cause for demyelination is not known but currently viral infection and autoimmunity are implicated in its pathogenesis.

Loss of myelin may occur in certain other conditions as well, but without an inflammatory response. These conditions have known etiologies such as: genetically-determined defects in the myelin metabolism (leucodystrophies), slow virus diseases of oligodendrocytes (progressive multifocal leucoencephalopathy), and exposure to toxins (central pontine myelinolysis). All these entities are currently not classified as demyelinating diseases. Only those conditions in which the myelin sheath or the myelin-forming cells (i.e. oligodendrocytes and Schwann cells) are primarily injured and are associated with considerable inflammatory exudate are included under the term 'demyelinating diseases'. Pathologically and clinically, two demyelinating diseases are distinguished:

1. Multiple or disseminated sclerosis
2. Perivenous encephalomyelitis.

Multiple (Disseminated) Sclerosis

Multiple or disseminated sclerosis is the most common of the CNS demyelinating diseases. The usual age at onset is 20 to 40 years. The disease presents as recurrent attacks of focal neurologic disorder with predilection for involvement of the spinal cord, optic nerve and brain. The first attack usually begins with a single sign or symptom, most commonly optic neuritis, followed by recovery. As the disease becomes more progressive, remissions become infrequent and incomplete. The etiology of multiple sclerosis remains unknown but a role for genetic susceptibility, infectious agent and immunologic mechanism has been proposed.

MORPHOLOGIC FEATURES The pathologic hallmark is the presence of many scattered discrete areas of demyelination termed *plaques*.

Grossly, plaques appear as grey-pink, swollen, sharply defined, usually bilaterally symmetric areas in the white matter.

Microscopically, the features vary according to the age of the plaque:

◆ In *active enlarging plaques*, the histologic features are accumulation of lymphocytes and macrophages around venules and at the plaque margin where demyelination is occurring. In addition, there is loss of oligodendrocytes and presence of reactive astrocytosis with numerous lipid-laden macrophages (microglia) in the plaque. The axons in the plaque are generally intact.

◆ In *old inactive plaques*, there is no perivascular inflammatory cell infiltrate and nearly total absence of oligodendrocytes. Demyelination in the plaque area is complete as there is only limited regeneration of myelin. Gliosis is well-developed but astrocytes are less prominent. Some axonal loss may be present.

Perivenous Encephalomyelitis

Perivenous encephalomyelitis includes two uncommon diseases: *acute disseminated encephalomyelitis* and *acute necrotising haemorrhagic leucoencephalitis*. Both are monophasic diseases characterised by perivenous mononuclear inflammatory cell infiltration. Both diseases occur following

a viral infection, vaccination or a respiratory illness. Both these conditions are looked upon as human counterpart of experimental allergic encephalomyelitis (EAE) and are considered to be allergic reaction against myelin antigen.

◆ **Acute disseminated encephalomyelitis** occurs usually following viral infection (measles, mumps, rubella, chickenpox), whooping cough or vaccination. The disease begins abruptly with headache and delirium followed by lethargy and coma. Signs of meningeal irritation and fever may be present. Prognosis for recovery is generally good.

◆ **Acute necrotising haemorrhagic leucoencephalitis** is a rare disease occurring more often after a respiratory infection. The clinical course is similar to that of acute disseminated encephalomyelitis except for its suddenness of onset and rapidity of progression, sometimes leading to death within 48 hours.

DEGENERATIVE DISEASES

Degenerative diseases are disorders of unknown etiology and pathogenesis, characterised pathologically by progressive loss of CNS neurons and their processes accompanied by fibrillary astrocytosis. The identification of these diseases depends upon exclusion of diseases with known etiologies such as metabolic disturbances, vascular diseases, nutritional deficiencies or infection. A considerable proportion of degenerative disorders are genetic in origin, with either dominant or recessive inheritance; others occur sporadically. Family history is, of course, of great importance.

The degenerative disorders usually begin insidiously and have a gradual progressive course over many years. In virtually all cases, the lesions have characteristic bilaterally symmetric distribution. Another striking characteristic of the degenerative disorders is that particular anatomic or physiologic system of neurons may be selectively affected, leaving others entirely intact.

Classification of degenerative diseases into individual syndromes is based on clinical aspects and anatomic distribution of the lesions. Some of the more common degenerative diseases are listed in **Table 28.3**. Two of the important examples—Alzheimer's disease and parkinsonism, are considered below.

ALZHEIMER'S DISEASE Alzheimer's disease is the most common cause of dementia in the elderly. The condition occurs after 5th decade of life and its incidence progressively increases with advancing age. The exact cause is not known but a few factors are implicated in its etiology which includes positive family history and deposition of A β amyloid derived from amyloid precursor protein (APP) forming *neuritic 'senile' plaques* and *neurofibrillary tangles*. Its pathogenesis is discussed on page 68.

Grossly, the brain is often reduced in weight and bilaterally atrophic.

Microscopically, the main features are as under:

- i) *Senile neuritic plaque* is the most conspicuous lesion and consists of focal area which has a central core containing A β amyloid.
- ii) *Neurofibrillary tangle* is a filamentous collection of neurofilaments and neurotubules within the cytoplasm of neurons.

Table 28.3 Common degenerative diseases.

| REGION AFFECTED | DISEASE | MAIN FEATURES | PREDOMINANT PATHOLOGY |
|---------------------------------|--|---|--|
| I. Cerebral cortex | Alzheimer's disease | Progressive senile dementia | Cortical atrophy, senile plaques (neurites), neurofibrillary tangles, amyloid angiopathy |
| | Pick's disease | Pre-senile dementia | Lobar cortical atrophy, ballooning degeneration of neurons (Pick's cells) |
| II. Basal ganglia and brainstem | Huntington's disease | Progressive dementia with choreiform movements | Atrophy of frontal lobes, fibrillary astrocytosis |
| | Parkinson's disease | Abnormalities of posture and movement | Aggregates of melanin-containing nerve cells in brainstem, intracytoplasmic neuronal inclusions (Lewy bodies) |
| III. Spinal cord and cerebellum | Cerebellar cortical degeneration | Progressive cerebellar ataxia | Loss of Purkinje cells in cerebellar cortex |
| | Olivopontocerebellar atrophy | Cerebellar ataxia | Combination of atrophy of cerebellar cortex, inferior olivary nuclei and pontine nuclei |
| | Spinocerebellar atrophy (Friedreich's ataxia) | Gait ataxia, dysarthria | Degeneration of spinocerebellar tracts, peripheral axons and myelin sheaths |
| IV. Motor neurons (UMN and LMN) | Motor neuron disease (Amyotrophic lateral sclerosis) | Syndromes of muscular weakness and wasting without sensory loss | Progressive loss of motor neurons, both in the cerebellar cortex (UMN) and in the anterior horn of spinal cord (LMN) |
| | Werdnig-Hoffmann's disease | Spinal muscular atrophy in infants | Loss of lower motor neurons, denervation atrophy of muscles |

iii) *Amyloid angiopathy* is deposition of the same amyloid in the vessel wall which is deposited in the amyloid core of the plaque.

iv) *Granulovacuolar degeneration* is presence of multiple, small intraneuronal cytoplasmic vacuoles, some of which contain one or more dark granules called *Hirano bodies*.

PARKINSONISM Parkinsonism is a syndrome of chronic progressive disorder of motor function and is clinically characterised by tremors which are most conspicuous at rest and worsen with emotional stress; other features are rigidity and disordered gait and posture. Parkinsonism is caused by several degenerative diseases, the most important being Parkinson's disease; other causes of parkinsonism are trauma, toxic agents, and drugs (dopamine antagonists).

Grossly, the brain is atrophic or may be normal externally.

Microscopically, the hallmark is depigmentation of substantia nigra and locus ceruleus due to loss of neuromelanin pigment from neurons and accumulation of neuromelanin pigment in the glial cells. Some of the residual neurons in these areas contain intracytoplasmic, eosinophilic, elongated inclusions called *Lewy bodies*.

METABOLIC DISEASES

Metabolic diseases of the CNS result from neurochemical disturbances which are either inherited or acquired. *Hereditary metabolic disorders* predominantly manifest in infancy or childhood and include genetically-determined disorders of

carbohydrate, lipid, amino acid and mineral metabolism. *Acquired or secondary metabolic diseases* are the disturbances of cerebral function due to disease in some other organ system such as the heart and circulation, lungs and respiratory function, kidneys, liver, endocrine glands and pancreas. In addition, endogenous metabolic diseases may be caused by toxic injuries induced by metals, gases, chemicals, and drugs. The pathologic changes in each of these conditions are quite diverse and include oedema, neuronal storage, degenerative changes, and sometimes parenchymal necrosis.

The predominant types of hereditary and acquired metabolic disorders are as under:

A. HEREDITARY METABOLIC DISEASES

1. Neuronal storage diseases These are characterised by storage of a metabolic product in the neurons due to specific enzyme deficiency. Common examples are: gangliosidoses (e.g. Tay-Sachs disease or GM2 gangliosidosis), mucopolysaccharidoses, Gaucher's disease and Niemann-Pick disease). These conditions are described on page 256.

2. Leucodystrophies These are diseases of white matter characterised by diffuse demyelination and gliosis. They are caused by deficiency of one of the enzymes required for formation and maintenance of myelin. That is why these conditions are also called *dysmyelinating diseases*. Common types of leucodystrophies are: sudanophilic leucodystrophy, adrenoleucodystrophy, metachromatic leucodystrophy and globoid cell leucodystrophy (Krabbe's disease).

3. Other inborn errors of metabolism e.g. Wilson's disease (hepatolenticular degeneration), glycogen-storage diseases, phenylketonuria and galactosaemia.

B. ACQUIRED METABOLIC DISEASES

These include the following:

1. Anoxic-ischaemic encephalopathy
2. Hypoglycaemic encephalopathy
3. Hyperglycaemic coma
4. Acute hepatic encephalopathy (Reye's syndrome)
5. Chronic hepatic encephalopathy
6. Kernicterus
7. Uraemic encephalopathy
8. Encephalopathy due to electrolyte and endocrine disturbances.

All these conditions have already been discussed in the relevant chapters.

NUTRITIONAL DISEASES

Neurologic disorders may be caused by malnutrition from lack of adequate diet such as in many developing countries and many poor socio-economic groups. In the United States and Europe, however, nutritionally-induced disease is chiefly found in association with chronic alcoholism or due to defect in absorption, transport or metabolism of dietary nutrients.

The general aspects of deficiency diseases have been covered in Chapter 8. Some of the common neurologic diseases included in the category of deficiency diseases are as under:

1. Wernicke's encephalopathy and Korsakoff's psychosis (vitamin B₁ or thiamine deficiency).
2. Subacute combined degeneration of the spinal cord (vitamin B₁₂ deficiency).
3. Folic acid deficiency (page 280).
4. Spinocerebellar syndrome (vitamin E deficiency).
5. Pellagra (niacin deficiency).
6. Alcoholic cerebellar degeneration.

GIST BOX 28.5

Demyelinating, Degenerative, Metabolic, Nutritional Diseases

- ▣ Demyelinating diseases have focal or patchy destruction of myelin sheaths in the CNS accompanied by an inflammatory response. Clinically and pathologically, two main types are distinguished: multiple or disseminated sclerosis and perivenous encephalomyelitis.
- ▣ Degenerative diseases are disorders of unknown etiology and pathogenesis having progressive loss of CNS neurons and their processes accompanied by fibrillary astrocytosis. Important examples are Alzheimer's disease and parkinsonism.
- ▣ Metabolic diseases of the CNS result from neurochemical disturbances which are either inherited or acquired. *Hereditary metabolic disorders* are genetically-determined disorders of carbohydrate, lipid, amino acid and mineral metabolism. *Acquired or secondary metabolic diseases* are the disturbances of cerebral function due to disease in some other organ system.
- ▣ Nutritional disorders of CNS in many poor socio-economic groups are due to malnutrition while in the developed countries these are due to chronic alcoholism or due to defect in absorption, transport or metabolism of dietary nutrients.

TUMOURS OF THE CNS

Tumours of the CNS may originate in the brain or spinal cord (primary tumours), or may spread to the brain from another primary site of cancer (metastatic tumours). More than one-quarter of the CNS tumours are secondary metastases arising in patients undergoing treatment for systemic cancer. Primary CNS tumours are the second commonest form of cancer in infants and children under the age of 15 years, exceeded in frequency only by leukaemia. Both benign and malignant CNS tumours are capable of producing neurologic impairment depending upon their site.

Primary CNS tumours or intracranial tumours include: tumours arising from *constituent cells of the brain* (with the sole exception of microglial cells) and from *the supporting tissues*. Childhood brain tumours arise from more primitive cells (e.g. neuroblastoma, medulloblastoma).

A classification of intracranial tumours abbreviated from the WHO classification is given in **Table 28.4**. The anatomic distribution of common intracranial tumours is illustrated

Table 28.4 Classification of intracranial tumours.

in **Fig. 28.13**. Among the primary brain tumours, gliomas constitute 50-60%, meningiomas 25%, schwannomas 10%, while other primary tumours comprise the remainder.

Some of the important morphologic types are described below.

GLIOMAS

The term glioma is used for all tumours arising from neuroglia, or more precisely, from neuroectodermal epithelial tissue. Gliomas are the most common of the primary CNS tumours and collectively account for 40% of all intracranial tumours. They include tumours arising:

- i) from *astrocytes* (astrocytomas and glioblastoma multiforme);
- ii) from *oligodendrocytes* (oligodendroglioma);
- iii) from *ependyma* (ependymoma); and
- iv) from *choroid plexus* (choroid plexus papilloma).

Gliomas may be well-differentiated or poorly-differentiated. However, gliomas are never truly well-demarcated or encapsulated and thus all grades of gliomas infiltrate the adjacent brain tissue. Gliomas are disseminated to other parts of the CNS by CSF but they rarely ever metastasise beyond the CNS.

Astrocytomas (Including Glioblastoma Multiforme)

Astrocytomas are the most common type of gliomas. In general, they are found in the late middle life with a peak in 6th decade of life. They occur predominantly in the cerebral hemispheres, and occasionally in the spinal cord. In children and young adults, pilocytic astrocytomas arise in the optic nerves, cerebellum and brainstem. Astrocytomas have tendency to progress from low grade to higher grades of anaplasia. Low-grade astrocytomas evolve slowly over several years whereas higher grades (anaplastic astrocytoma and glioblastoma multiforme) bring about rapid clinical deterioration of the patient.

The diagnosis of various types of astrocytomas can be generally made by routine H & E morphology but in difficult situations and poorly differentiated cases, immunohistochemical staining with glial fibrillary protein (GFAP) or by electron microscopic demonstration of glial filaments can be done. Mitotic activity of astrocytomas can be assessed by proliferation markers, Ki67 and PCNA. At molecular genetic

level, low-grade astrocytomas overexpress platelet-derived growth factor- α (PDGF- α) and mutation of *p53* while high-grade astrocytomas show mutation of two tumour-suppressor genes, *RB* gene and *p16*.

MORPHOLOGIC FEATURES Astrocytomas have been conventionally divided into 3 progressive histologic grades: fibrillary (most common), gemistocytic and protoplasmic. However, currently WHO classification of astrocytomas is widely used which divides them into 4 grades from grade I (low grade) to grade IV (glioblastoma multiforme) as under.

WHO GRADE I ASTROCYTOMA Also called as diffuse astrocytoma, it is a low-grade tumour having good prognosis and includes special histologic entities which mainly occur in children as under:

i) Juvenile pilocytic astrocytoma It occur in children and young adults in the cerebellum, third ventricle and optic nerve pathway.

Grossly, it is usually cystic or solid and circumscribed.

Microscopically, it is predominantly composed of fusiform pilocytic astrocytes having unusually long, wavy fibrillary processes.

ii) Pleomorphic xanthoastrocytoma It looks histologically pleomorphic and alarming but has favourable prognosis.

WHO GRADE II (WELL-DIFFERENTIATED) ASTROCYTOMA It is also called as fibrillary astrocytoma and is the most common form of glioma occurring in 3rd to 4th decades of life.

Grossly, it is a poorly defined, grey-white tumour of variable size. The tumour distorts the underlying brain tissue and merges with the surrounding tissue.

Histologically, it is composed of well-differentiated astrocytes separated by variable amount of fibrillary background of astrocytic processes. Based on the type of astrocytes, three subtypes are distinguished: *fibrillary*, *protoplasmic* and *gemistocytic astrocytoma*.

WHO GRADE III (ANAPLASTIC) ASTROCYTOMA It generally evolves from lower grade of astrocytoma.

Grossly, it may not be distinguishable from the low-grade astrocytoma.

Histologically, it contains features of anaplasia such as hypercellularity, pleomorphism, nuclear hyperchromatism and mitoses. Another characteristic feature of anaplastic variety of astrocytoma is the proliferation of vascular endothelium (**Fig. 28.14**).

WHO GRADE IV ASTROCYTOMA (GLIOBLASTOMA MULTIFORME) Although its nomenclature means its origin from embryonal cells but now it is known that this tumour arises by neoplastic transformation of mature astrocytes. It is the most aggressive of astrocytomas.

Grossly, it shows variegated appearance, with some areas showing grey-white appearance while others are yellow and soft with foci of haemorrhages and necrosis. The surrounding normal brain tissue is distorted and infiltrated by yellow tumour tissue.

Histologically, the features are as under (**Fig. 28.15**):

i) It has highly anaplastic and cellular appearance. The cell types show marked variation consisting of fusiform cells,

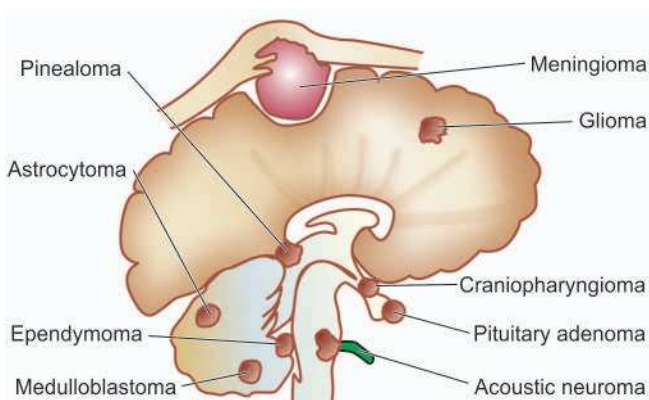

Figure 28.13 The anatomic distribution of common intracranial tumours.

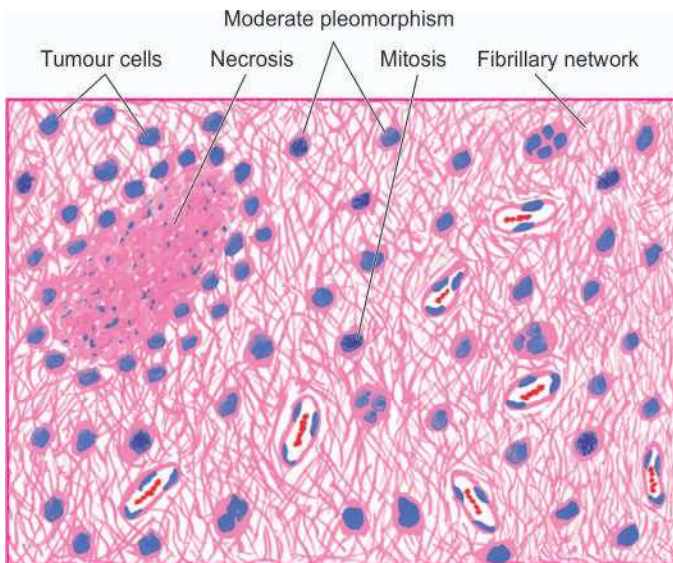

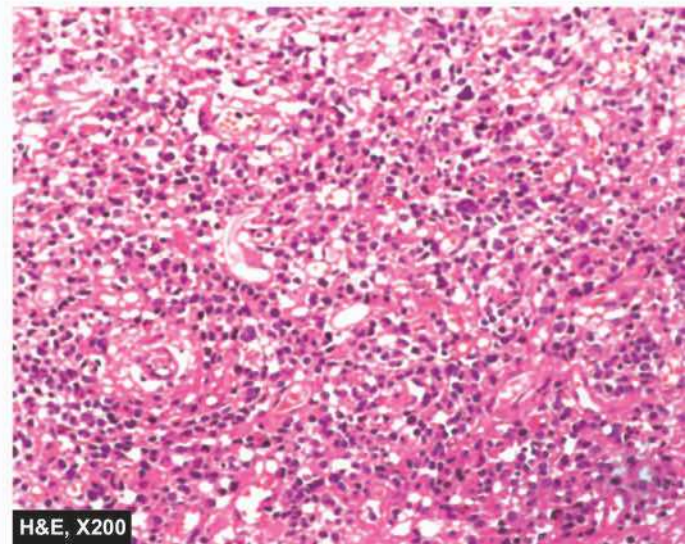

Figure 28.14 Anaplastic astrocytoma, showing hypercellularity of pleomorphic astrocytic cells, mitoses and vascular proliferation in fibrillary background. Areas of necrosis are also present.

small poorly-differentiated round cells, pleomorphic cells and giant cells. Mitoses are quite frequent and glial fibrils are scanty.

- ii) It shows areas of tumour necrosis around which tumour cells may form pseudopalisading.
- iii) Microvascular endothelial proliferation is marked.

Oligodendroglioma

Oligodendroglioma is an uncommon glioma of oligodendroglial origin and may develop in isolation or may be mixed with other glial cells. The tumour commonly presents in 3rd to 4th decades of life. It occurs in the cerebral hemispheres,

most commonly in the frontal lobes or within the ventricles. X-ray examination and CT scan reveal a well-defined mass with numerous small foci of calcification. The tumour is generally slow-growing. Oligodendrogliomas typically have deletions and translocations affecting chromosomes 1p and 19q, which have both diagnostic and prognostic value.

MORPHOLOGIC FEATURES *Grossly*, oligodendroglioma is well-circumscribed, grey-white and gelatinous mass having cystic areas, foci of haemorrhages and calcification.

Microscopically, the tumour is characterised by uniform cells with round to oval nuclei surrounded by a clear halo of cytoplasm and well-defined cell membranes. Tumour cells tend to cluster around the native neurons forming *satellitosis*. Typically, there are varying degree of endothelial cell hyperplasia and foci of calcification. Anaplastic change may occur as in other gliomas.

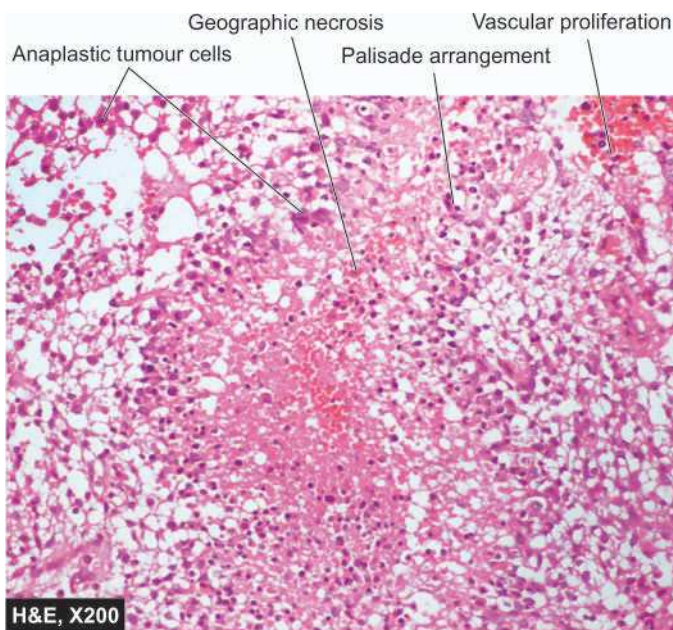

Figure 28.15 Glioblastoma multiforme (WHO grade IV astrocytoma). The tumour is densely cellular having marked pleomorphism. Characteristically, the tumour has areas of necrosis which are surrounded by a palisade layer of anaplastic tumour cells.

Ependymoma

Ependymoma is not an uncommon tumour, derived from the layer of epithelium that lines the ventricles and the central canal of the spinal cord. It occurs chiefly in children and young adults (below 20 years of age). Typically, it is encountered in the fourth ventricle (posterior fossa tumour). Other locations are the lateral ventricles, the third ventricle, and in the case of adults, the spinal cord in the region of lumbar spine. Clinically, by virtue of their frequent location in the floor of the fourth ventricle, ependymomas are associated with obstructive hydrocephalus. The usual biologic behaviour is of a slow-growing tumour over a period of years. Spinal ependymomas are associated with mutation of NF1 and NF2 genes.

MORPHOLOGIC FEATURES *Grossly*, ependymoma is a well-demarcated tumour but complete surgical removal may not be possible due to close proximity to vital structures in the medulla and pons.

Microscopically, the tumour is composed of uniform epithelial (ependymal) cells forming rosettes, canals and

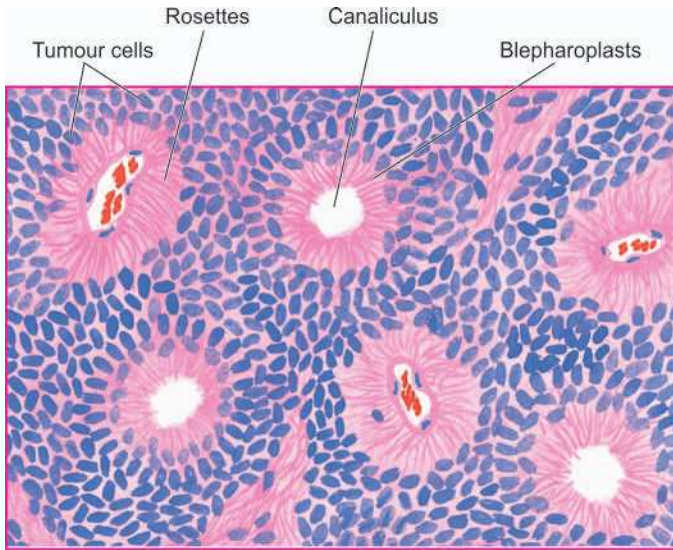

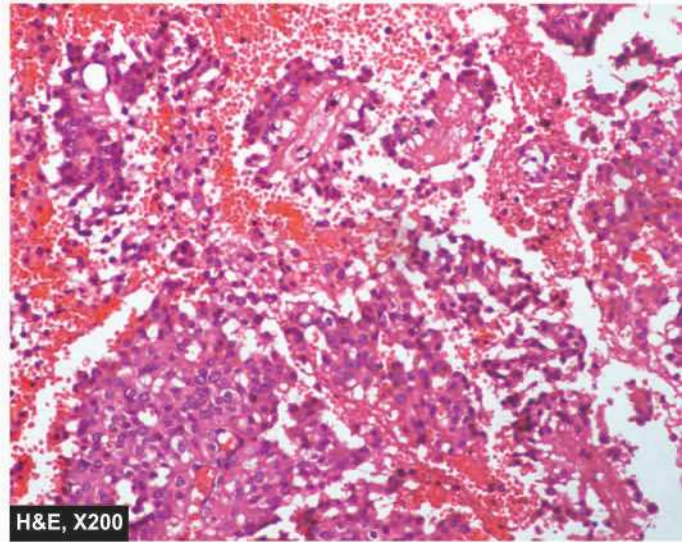

Figure 28.16 Ependymoma showing uniform ependymal tumour cells forming rosettes and canaliculi.

perivascular pseudorosettes. By light microscopy under high magnification, PTAH-positive structures, blepharoplasts, representing basal bodies of cilia may be demonstrated in the cytoplasm of tumour cells (Fig. 28.16). Most tumours are well-differentiated but anaplastic variants are also recognised.

Two variants of ependymoma deserve special mention: myxopapillary type and subependymoma.

Myxopapillary ependymoma It is a special variant of ependymoma which is common and occurs in adults. Characteristically, it occurs in the region of cauda equina and originates from the filum terminale. True to its name, it contains myxoid and papillary structures interspersed in the typical ependymal cells. It is a slow-growing tumour having a better prognosis.

Subependymoma It occurs as a small, asymptomatic, incidental solid nodule in the fourth and lateral ventricle of middle-aged or elderly patients. Areas of microcysts and calcification may be encountered.

Histologically, it is composed of nests of uniform ependymal cells in a stroma of very dense, acellular, finely fibrillar background. Subependymoma is typically a very slow-growing tumour.

Choroid Plexus Papilloma

Tumours derived from choroid plexus epithelium are uncommon intracranial tumours. They are found in the distribution of the choroid plexus. In children, they occur most frequently in the lateral ventricles, whereas in adults fourth ventricle is the most common site. They are invariably benign tumours and rarely ever undergo malignant transformation.

MORPHOLOGIC FEATURES *Grossly*, the tumour projects as rounded, papillary mass into one of the ventricles.

Histologically, choroid plexus papilloma is a papillary tumour resembling normal choroid plexus with a vascular connective tissue core covered by a single layer of cuboidal epithelium which lies upon a basement membrane.

POORLY-DIFFERENTIATED AND EMBRYONAL TUMOURS

CNS tumours composed of primitive undifferentiated cells include medulloblastoma and glioblastoma, and rarely, neuroblastoma (page 791) and retinoblastoma (page 493). Except for medulloblastoma, other examples of these tumours have been described elsewhere in the text.

Medulloblastoma

Medulloblastoma is the most common variety of primitive neuroectodermal tumour. It comprises 25% of all childhood brain tumours but a quarter of cases occur in patients over the age of 20 years. The most common location is the cerebellum in the region of roof of fourth ventricle, in the midline of cerebellum, in the vermis, and in the cerebellar hemispheres. The most common molecular genetic feature of medulloblastoma is deletion of 17p and isochromosome 17q.

Medulloblastoma is a highly malignant tumour and spreads to local as well as to distant sites. It invades locally and by the CSF to meninges, ventricles and subarachnoid space and has a tendency for widespread metastases to extraneural sites such as to lungs, liver, vertebrae and pelvis.

MORPHOLOGIC FEATURES *Grossly*, the tumour typically protrudes into the fourth ventricle as a soft, grey-white mass or invades the surface of the cerebellum.

Microscopically, medulloblastoma is composed of small, poorly-differentiated cells with ill-defined cytoplasmic processes and has a tendency to be arranged around blood vessels and occasionally forms pseudorosettes (Homer-Wright rosettes). Another characteristic of the tumour is differentiation into glial or neuronal elements.

OTHER PRIMARY INTRAPARENCHYMAL TUMOURS

Important examples of some other primary intraparenchymal are haemangioblastoma, CNS lymphoma and germ cell tumours.

Haemangioblastoma

Haemangioblastoma is a tumour of uncertain origin and constitutes about 2% of all intracranial tumours. It is seen more commonly in young adults and is commoner in males. It may occur sporadically or be a part of von Hippel-Lindau syndrome (along with cysts in the liver, kidney, and benign/malignant renal tumour). *VHL* gene located on chromosome 3p25-p26 has an important function of regulating hypoxia induced factor-1 (HIF-1) which is responsible for the release of erythropoietin. Thus, about a quarter haemangioblastomas secrete erythropoietin and cause polycythaemia.

MORPHOLOGIC FEATURES *Grossly*, the tumour is usually a circumscribed cystic mass with a mural nodule. The cyst contains haemorrhagic fluid.

Microscopically, the features are as under:

- i) Large number of thin-walled blood vessels lined by plump endothelium.
- ii) Vascular spaces are separated by groups of polygonal lipid-laden foamy stromal cells.

Primary CNS Lymphoma

Lymphomas in the brain may occur as a part of disseminated non-Hodgkin's lymphoma (Chapter 12) or may be a primary CNS lymphoma. The incidence of the primary CNS lymphoma has shown a rising trend in patients of AIDS and other immunosuppressed conditions. They occur in persons above 5th decade of life. Primary CNS lymphoma has a poor prognosis.

MORPHOLOGIC FEATURES *Grossly*, the tumour is frequently periventricular in location and may appear nodular or diffuse.

Microscopically, the features are as under:

- i) Characteristically, the tumour grows around blood vessels i.e. has an angiocentric growth pattern. Reticulin stain highlights this feature well.
- ii) Typically, CNS lymphomas are diffuse, large cell type with high mitotic activity.
- iii) They are generally B-cell type.

Germ Cell Tumours

Rarely, germ cell tumours may occur in the brain, especially in children. Common locations are suprasellar region and pineal area. Some common examples of such tumours are germinoma (seminoma/dysgerminoma), teratoma and embryonal carcinoma. Morphologically, they are similar to their counterparts elsewhere.

TUMOURS OF MENINGES

The most common tumour arising from the pia-arachnoid is meningioma accounting for 20% of intracranial tumours.

Meningioma

Meningiomas arise from the cap cell layer of the arachnoid. Their most common sites are in the front half of the head and

include: lateral cerebral convexities, midline along the falx cerebri adjacent to the major venous sinuses parasagittally, and olfactory groove. Less frequent sites are: within the cerebral ventricles, foramen magnum, cerebellopontine angle and the spinal cord. Meningiomas are generally solitary. They have an increased frequency in patients with neurofibromatosis 2 and are often multiple in these cases. They are usually found in 2nd to 6th decades of life, with slight female preponderance. Most meningiomas are benign and can be removed successfully. Rarely, a malignant meningioma may metastasise, mainly to the lungs.

The most frequent cytogenetic abnormality in meningiomas is deletion of 22q where *NF2* gene is located elaborating gene product, protein *merlin*. Thus, many cases of meningiomas may be associated with neurofibromatosis 2.

MORPHOLOGIC FEATURES *Grossly*, meningioma is well-circumscribed, solid, spherical or hemispherical mass of varying size (1-10 cm in diameter). The tumour is generally firmly attached to the dura and indents the surface of the brain but rarely ever invades it (**Fig. 28.17**). The overlying bone usually shows hyperostosis. Cut surface of the tumour is firm and fibrous, sometimes with foci of calcification.

Microscopically, meningiomas are divided into 5 subtypes: meningotheliomatous (syncytial), fibrous (fibroblastic), transitional (mixed), angioblastic and anaplastic (malignant).

1. Meningotheliomatous (syncytial) meningioma This pattern of meningioma resembles the normal arachnoid cap cells. The tumour consists of solid masses of polygonal cells with poorly-defined cell membranes (i.e. syncytial appearance). The cells have round to oval, central nuclei with abundant, finely granular cytoplasm. Some amount of collagenous stroma is present that divides the tumour into irregular lobules.

2. Fibrous (fibroblastic) meningioma A less frequent pattern is of a spindle-shaped fibroblastic tumour in which the tumour cells form parallel or interlacing bundles. Whorled pattern and psammoma bodies are less common features of this type.

3. Transitional (mixed) meningioma This pattern is characterised by a combination of cells with syncytial and fibroblastic features with conspicuous whorled pattern of tumour cells, often around central capillary-sized blood vessels. Some of the whorls contain psammoma bodies due to calcification of the central core of whorls (**Fig. 28.18**). Other forms of degenerative changes like xanthomatous and myxomatous degeneration may also be encountered, in transitional variety.

These first three histologic patterns constitute a spectrum of lesions rather than three distinct entities.

4. Angioblastic meningioma An angioblastic meningioma includes 2 patterns: *haemangioblastic pattern* resembling haemangioblastoma of the cerebellum, and *haemangiopericytic pattern* which is indistinguishable from haemangiopericytoma elsewhere in the body. Both types of angioblastic meningiomas have high rate of recurrences.

5. Anaplastic (malignant) meningioma Rarely, a meningioma may display features of anaplasia and invade the

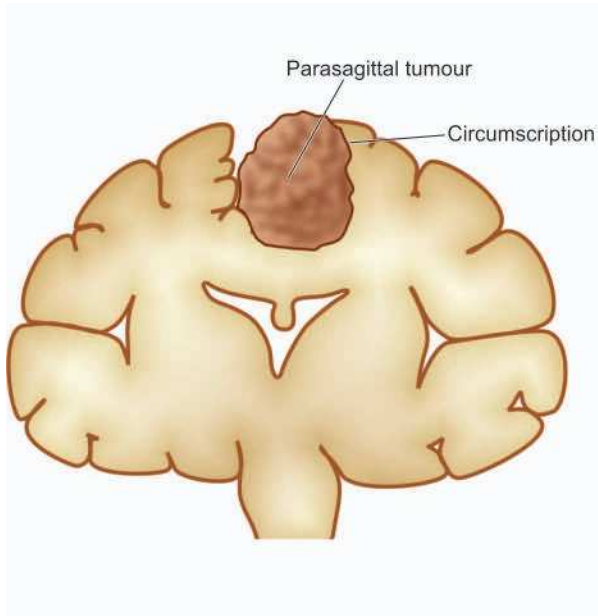

Figure 28.17 Meningioma, The tumour mass is circumscribed (arrow) with irregular surface convolutions and prominent blood vessels. It is firm in consistency with peripherally adherent thick firm dural tissue. Cut surface of the mass is firm and fibrous.

underlying brain or spinal cord. This pattern of meningioma is associated with extraneural metastases, mainly to the lungs.

METASTATIC TUMOURS

Approximately a quarter of intracranial tumours are metastatic tumours. The clinical features are like those of a primary brain tumour. Most common primary tumours metastasising to the brain are: carcinomas of the lung, breast, skin (malignant melanoma), kidney and the gastrointestinal tract and choriocarcinoma. Infiltration from lymphoma and leukaemias may also occur.

MORPHOLOGIC FEATURES *Grossly*, the metastatic deposits in the brain are usually multiple, sharply-defined masses at the junction of grey and white matter (**Fig. 28.19**). A less frequent pattern is carcinomatous meningitis or meningeal carcinomatosis in which there is presence of carcinomatous nodules on the surface of the brain and spinal cord, particularly encountered in carcinomas of the lung and breast.

Histologically, metastatic tumours in the brain recapitulate the appearance of the primary tumour of origin with sharp line of demarcation from adjoining brain tissue. It is usually surrounded by a zone of oedema.

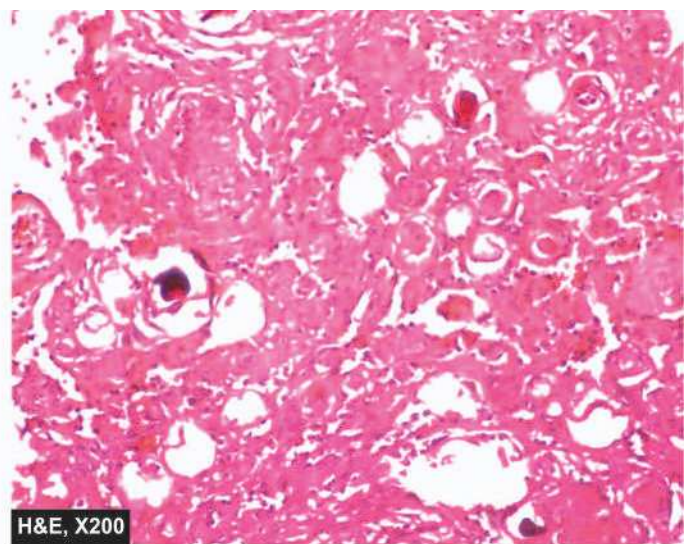

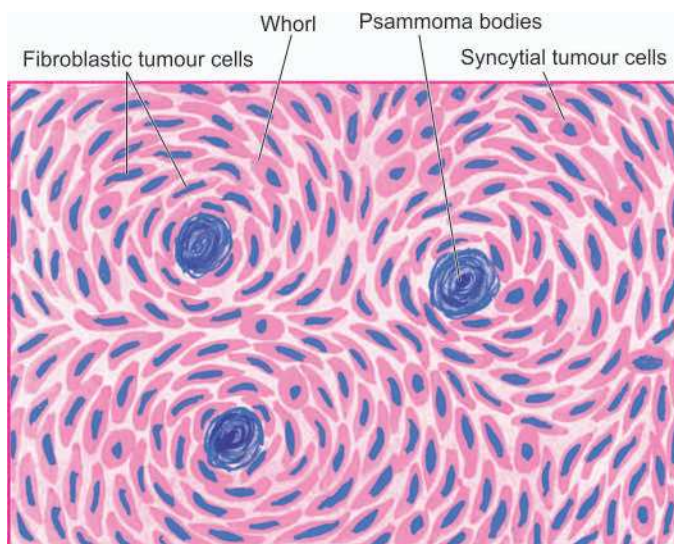

Figure 28.18 Meningioma, transitional type. The cells have features of both syncytial and fibroblastic type and form whorled appearance. Some of the whorls contain psammoma bodies.

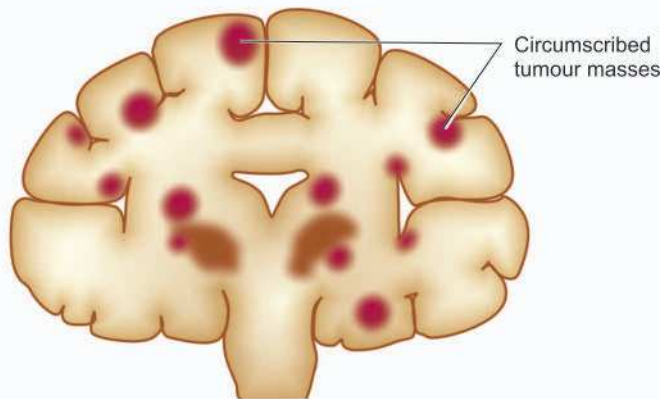

Figure 28.19 Metastatic tumour deposits in the brain. They are commonly multiple, well-defined and usually located at the grey and white matter junction.

GIST BOX 28.6

Tumours of CNS

- ▣ Glioma are tumours arising from neuroglia and are the most common of the primary CNS tumours.
- ▣ WHO classification of astrocytomas divides them into grade I (low grade), grade II (well-differentiated), grade III (anaplastic) and grade IV (glioblastoma multiforme).
- ▣ Oligodendroglioma is an uncommon glioma of oligodendroglial origin and may develop in isolation or may be mixed with other glial cells.
- ▣ Ependymoma is derived from the layer of epithelium that lines the ventricles and the central canal of the spinal cord. It has 2 variants: myxopapillary type and subependymoma.
- ▣ Medulloblastoma is the most common primitive neuroectodermal tumour occurring in children. The most common location is the cerebellum.
- ▣ Incidence of the primary CNS lymphoma has shown a rising trend in patients of AIDS and other immunosuppressed conditions.
- ▣ Meningiomas arise from the cap cell layer of the arachnoid. Their most common sites are in the front half of the head. (e.g. cerebral convexities, midline along the falx cerebri, olfactory groove).
- ▣ Approximately a quarter of intracranial tumours are metastatic tumours, often from carcinomas.

PERIPHERAL NERVOUS SYSTEM

NORMAL STRUCTURE

The peripheral nervous system (PNS) consists of cranial and spinal nerves, sympathetic and parasympathetic autonomic nervous system and the peripheral ganglia. The PNS is involved in electric transmission of sensory and motor impulses to and from the CNS. A peripheral nerve is surrounded by an outer layer of fibrous tissue, the *epineurium*. Each nerve is made of several fascicles enclosed in multilayered membrane of flattened cells, the *perineurium*. Each fascicle is composed of bundles of connective tissue, the *endoneurium*. There are 2 main types of nerve fibres or axons comprising a peripheral nerve—myelinated and non-myelinated. *Myelinated axons* are

thicker (diameter greater than $2\ \mu\text{m}$) and are surrounded by a chain of Schwann cells which produce myelin sheath. *Non-myelinated axons* have diameter of $0.2\text{--}3\ \mu\text{m}$ and about ten non-myelinated fibres may be enclosed by a Schwann cell. *Nodes of Ranvier* on myelinated fibres are the boundaries between each Schwann cell surrounding the fibre (Fig. 28.20,A). Myelinated axons have their origin from neurons in the posterior root ganglia and the anterior horn cell of the spinal cord, whereas non-myelinated axons arise from neurons in the posterior root ganglia and in the autonomic ganglia.

PATHOLOGIC REACTIONS TO INJURY

The peripheral nerves, unlike brain, have regenerative capacity as has been discussed on page 156. The pathologic reactions of the PNS in response to injury may be in the form of one of the types of degenerations causing *peripheral neuropathy* or formation of a *traumatic neuroma*. There are 3 main types of degenerative processes in the PNS—Wallerian degeneration, axonal degeneration and segmental demyelination (Fig. 28.20):

WALLERIAN DEGENERATION Wallerian degeneration occurs after transection of the axon which may be as a result of knife wounds, compression, traction and ischaemia. Following transection, initially there is accumulation of organelles in the proximal and distal ends of the transection sites. Subsequently, the axon and myelin sheath distal to the transection site undergo disintegration upto the next node of Ranvier, followed by phagocytosis. The process of regeneration occurs by sprouting of axons and proliferation of Schwann cells from the proximal end.

AXONAL DEGENERATION In axonal degeneration, degeneration of the axon begins at the peripheral terminal and proceeds backward towards the nerve cell body. The cell body often undergoes chromatolysis. There is Schwann cell proliferation in the region of axonal degeneration. The loss of axonal integrity occurs, probably as a result of some primary metabolic disturbance within the axon itself. Changes similar to those seen in Wallerian degeneration are present but regenerative reaction is limited or absent.

SEGMENTAL DEMYELINATION Segmental demyelination is similar to demyelination within the brain (page 875). Segmental demyelination is loss of myelin of the segment between two consecutive nodes of Ranvier, leaving a denuded axon segment. The axon, however, remains intact. Schwann cell proliferation generally accompanies demyelination. This results in remyelination of the affected axon. Repeated episodes of demyelination and remyelination are associated with concentric proliferation of Schwann cells around axons producing '*onion bulbs*' found in hypertrophic neuropathy.

TRAUMATIC NEUROMA Normally, the injured axon of a peripheral nerve regenerates at the rate of approximately 1 mm per day. However, if the process of regeneration is hampered due to an interposed haematoma or fibrous scar, the axonal sprouts together with Schwann cells and fibroblasts form a peripheral mass called as traumatic or stump neuroma.

PERIPHERAL NEUROPATHY

Peripheral neuropathy is the term used for disorders of the peripheral nerves of any cause. It may be polyneuropathy, mononeuropathy multiplex, and mononeuropathy.

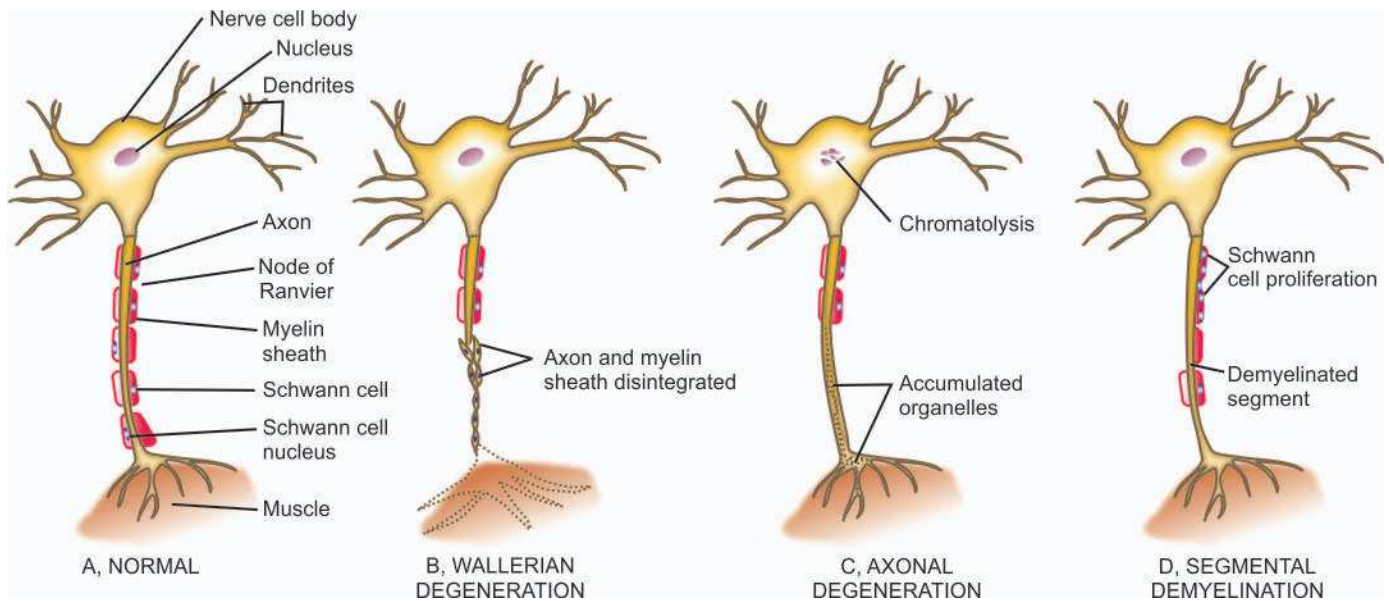

Figure 28.20 Pathologic reaction of peripheral nerve to injury.

POLYNEUROPATHY It is characteristically symmetrical with noticeable sensory features such as tingling, pricking, burning sensation or dysaesthesia in feet and toes. Motor features in the form of muscle weakness and loss of tendon reflexes may be present. Involvement of the autonomic nervous system may be associated. Most cases have origin in acquired metabolic and toxic causes such as thiamine deficiency, diabetes, amyloidosis, autoimmune demyelinating disease (Guillain-Barré syndrome), and administration of toxins and certain therapeutic agents (e.g. vincristine, isoniazid). Besides these, a number of hereditary polyneuropathies are described.

Pathologically, polyneuropathy may be the result of axonal degeneration (axonopathy) or segmental demyelination (demyelinating polyneuropathy). In each type, acute, subacute and chronic forms are distinguished. *Guillain-Barré syndrome* is the classical example of acute demyelinating polyneuropathy which has probably an autoimmune etiology.

MONONEUROPATHY MULTIPLEX (MULTIFOCAL NEUROPATHY) It is defined as simultaneous or sequential multifocal involvement of nerve trunks which are not in continuity. The involvement may be partial or complete and may evolve over days or years. Multifocal neuropathy represents part of spectrum of chronic acquired demyelinating neuropathy.

MONONEUROPATHY Mononeuropathy on the other hand, is focal involvement of a single nerve. It is generally the result of local causes such as direct trauma, compression and entrapment.

NERVE SHEATH TUMOURS

Tumours of the peripheral nerves are commonly benign and include schwannoma (neurilemmoma) and neurofibroma. Both of them arise from Schwann cells but neurofibroma contains large amount of collagen. Rarely, their malignant counterpart, malignant peripheral nerve sheath tumour, develops particularly in patients with von Recklinghausen's neurofibromatosis.

SCHWANNOMAS (NEURILEMMOMAS)

Schwannomas or neurilemmomas arise from cranial and spinal nerve roots. An *acoustic schwannoma* or *acoustic neuroma* is an intracranial schwannoma located within the internal auditory canal originating from vestibular portion of the acoustic nerve (page 496). *Intraspinal schwannomas* are found as intradural tumours in the thoracic region. In the peripheral nerves, they occur as solitary nodule on any sheathed sensory, motor, or autonomic nerve. Multiple schwannomas are uncommon and occur in von Recklinghausen's disease (see below). Schwannomas are tumours of adults except in von Recklinghausen's disease.

MORPHOLOGIC FEATURES **Grossly**, a schwannoma is an encapsulated, solid, sometimes cystic, tumour that produces eccentric enlargement of the nerve root from where it arises.

Microscopically, the tumour is composed of fibrocellular bundles forming whorled pattern. There are areas of dense and compact cellularity (*Antoni A pattern*) alternating with loose acellular areas (*Antoni B pattern*). Areas of Antoni A pattern show palisaded nuclei called *Verocay bodies* (Fig. 28.21). Nerve fibres are usually found stretched over the capsule but not within the tumour. Areas of degeneration contain haemosiderin and lipid-laden macrophages. Schwann cells characteristically express S-100 protein. A schwannoma rarely ever becomes malignant.

NEUROFIBROMAS AND VON RECKLINGHAUSEN'S DISEASE

Neurofibromas may occur as solitary, fusiform cutaneous tumour of a single nerve, but more often are multiple associated with von Recklinghausen's disease. Solitary neurofibroma is a tumour of adults but multiple neurofibromas or neurofibromatosis is a hereditary disorder with autosomal dominant inheritance. Solitary neurofibroma is generally asymptomatic but patients with von Recklinghausen's disease have a triad of features:

1. Multiple cutaneous neurofibromas.

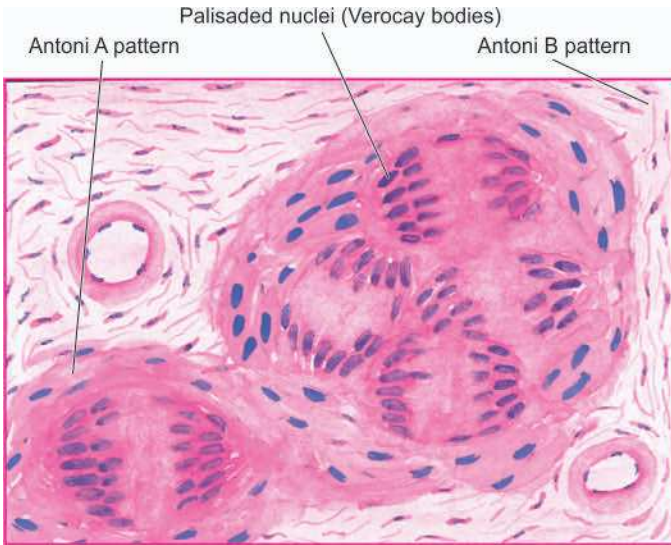

Figure 28.21 Schwannoma (neurilemmoma), showing whorls of densely cellular (Antoni A) and loosely cellular (Antoni B) areas with characteristic nuclear palisading (Verocay bodies).

2. Numerous pigmented skin lesions ('café au lait' spots).
3. Pigmented iris hamartomas.

Neurofibromatosis type 1 is a genetic disorder having mutation in chromosome 17 while type 2 has mutation in chromosome 22.

MORPHOLOGIC FEATURES *Grossly*, neurofibroma is an unencapsulated tumour producing fusiform enlargement of the affected nerve. Neurofibromatosis in von Recklinghausen's disease is characterised by numerous nodules of varying size, seen along the small cutaneous nerves but may also be found in visceral branches of sympathetic nerves. Neurofibromatosis may involve a group of nerves or may occur as multiple, oval and irregular swellings along the length of a nerve (plexiform neurofibroma) (**Fig. 28.22**).

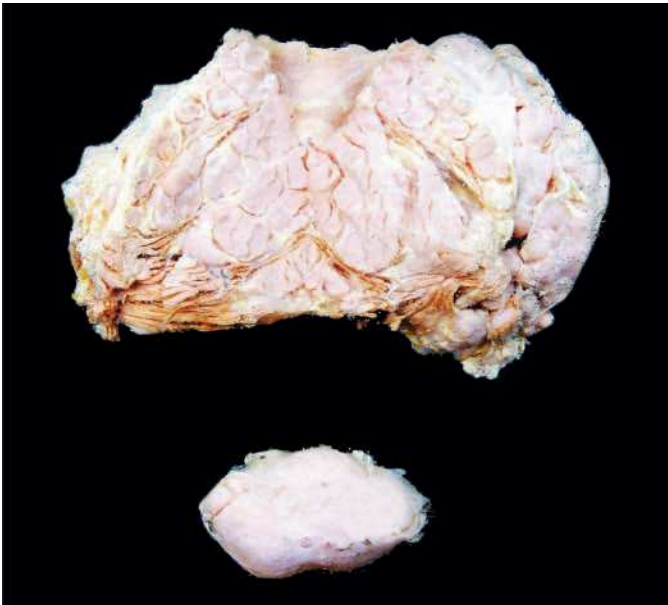

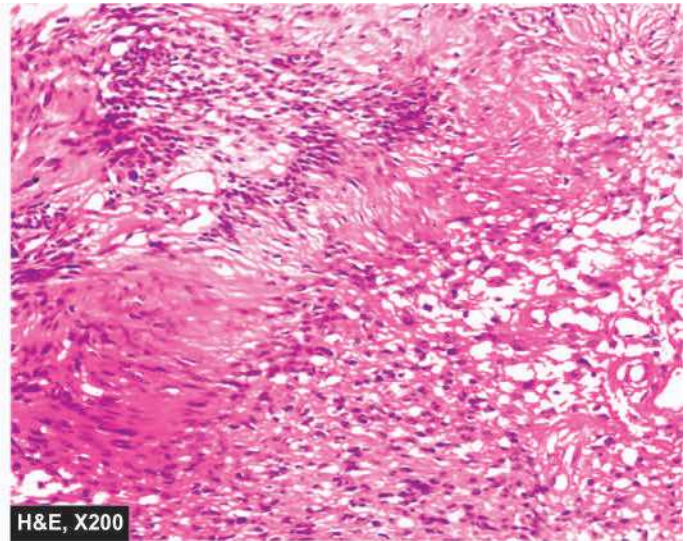

Figure 28.22 Plexiform neurofibromatosis. The main mass is multilobulated with increased fat while lower part of the image shows a separate encapsulated gelatinous mass. Cut surface of both the masses shows circumscribed, gelatinous, lobulated grey-white firm masses.

Microscopically, a neurofibroma is composed of bundles and interlacing fascicles of delicate and elongated spindle-shaped cells having wavy nuclei. The cellular area is separated by loose collagen and mucoid material. Residual nerve fibres (neurites) may be demonstrable (**Fig. 28.23**). Histologic appearance of Antoni B pattern of schwannoma may be seen in neurofibroma and cause diagnostic difficulty. Immunohistochemically, neurofibroma is positive for epithelial membrane antigen (EMA) and some tumours express S-100 protein as schwannomas do.

Neurofibromas have tendency for local recurrences after excision. Neurilemmoma virtually never turns malignant, while sarcomatous transformation in neurofibroma, particularly in neurofibromatosis, is not unusual. It is estimated that about 3% of patients with von Recklinghausen's neurofibromatosis develop malignant transformation of one of the nodules. Rarely, neurogenic sarcoma may develop spontaneously in the absence of pre-existing von Recklinghausen's disease.

The contrasting features to distinguish neurofibroma from schwannoma are listed in **Table 28.5**.

MALIGNANT PERIPHERAL NERVE SHEATH TUMOUR

Malignant peripheral nerve sheath tumour (MPNST) is a poorly differentiated spindle cell sarcoma of the peripheral nerves occurring most often in adults. The tumour may arise *de novo* or from malignant transformation of a pre-existing neurofibroma than a schwannoma, generally at an early age (20-40 years). About 50% of the tumours are seen in patients with neurofibromatosis type 1 with chromosomal deletion 17p and *p53* gene mutations, while some develop at sites of previous irradiation.

MORPHOLOGIC FEATURES *Grossly*, the tumour appears as an unencapsulated fusiform enlargement of a nerve.

Microscopically, the tumour has the general appearance of tumour cells resembling a fibrosarcoma. The tumour has frequent mitosis and areas of necrosis. *Triton tumour* is the name used for MPNST which has areas of poorly-differentiated rhabdomyosarcoma, cartilage and bone.

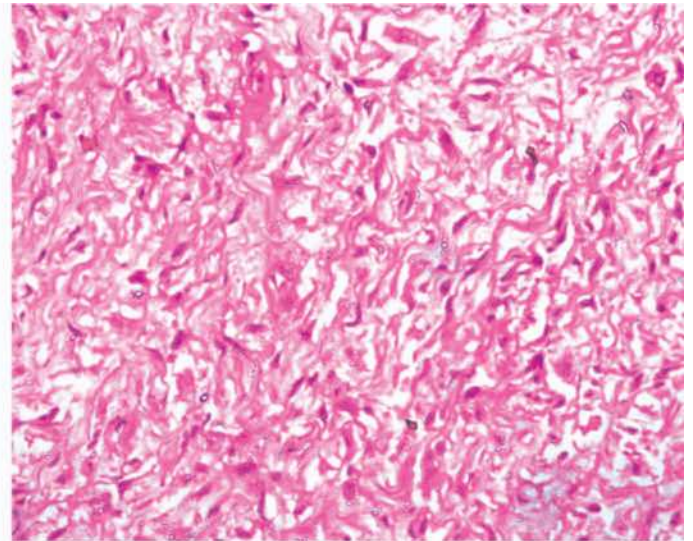

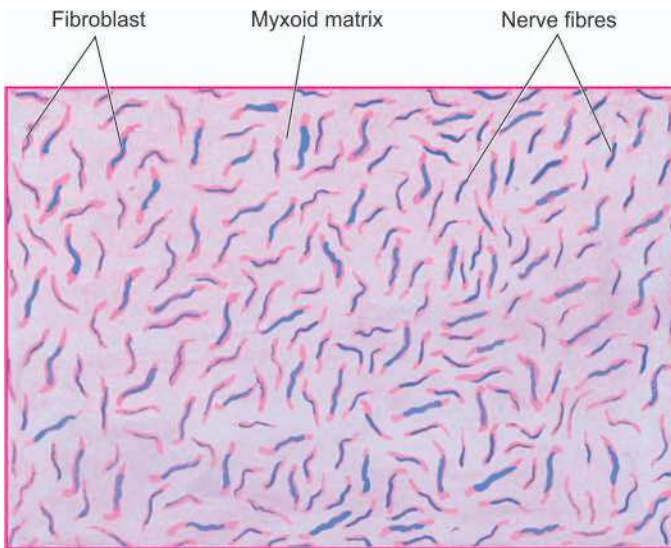

Figure 28.23 Neurofibroma, showing interlacing bundles of spindle-shaped cells separated by mucoïd matrix. The cells have wavy nuclei and a residual nerve fibre (neurite) is also identified.

Table 28.5 Contrasting features of neurilemmoma (schwannoma) and neurofibroma.

| FEATURE | NEURILEMMOMA | NEUROFIBROMA |
|--------------------------------|---|--|
| 1. <i>Location</i> | Cerebellopontine angle (vestibular branch of 8th nerve); extradural sites | Dermis; along the nerve trunk |
| 2. <i>Number</i> | Generally solitary | Solitary or multiple neurofibromatosis |
| 3. <i>Genetics</i> | Bilateral in association with type 2 neurofibromatosis having autosomal dominant inheritance (chromosome 22 disorder) | Multiple associated with type 1 neurofibromatosis having autosomal dominant inheritance (chromosome 17 disorder) |
| 4. <i>Gross appearance</i> | Firm, encapsulated, c/s tan, translucent | Soft, well demarcated but unencapsulated, c/s mucoïd, translucent |
| 5. <i>Microscopy</i> | Compact areas (Antoni A) and myxomatous areas (Antoni B), palisading tumour cells (Verocay bodies) | Dense collagen fibres and abundant extracellular mucoïd material |
| 6. <i>Infiltration</i> | Encapsulated along the edge of nerve without invading it | May infiltrate the peripheral nerve |
| 7. <i>Immunohistochemistry</i> | S-100 protein | EMA; sometimes S-100 protein |
| 8. <i>Behaviour</i> | Invariably benign | May turn malignant |

Epithelioid MPNST has plump cells resembling epithelioid cells and is positive for HMB-45 immunostain. Most of the recurrent forms of MPNST are of epithelioid type.

Although relatively slow-growing, MPNST has local recurrences and haematogenous metastasis occur commonly; histology thus appears to have little correlation with clinical behaviour of the tumour.

GIST BOX 28.7

Diseases of Peripheral Nervous System

- ▣ There are 3 main types of degenerative processes in the PNS—Wallerian degeneration, axonal degeneration and segmental demyelination.
- ▣ Peripheral neuropathy may be polyneuropathy, mononeuropathy multiplex, and mononeuropathy.
- ▣ Tumours of the peripheral nerves are commonly benign and include schwannoma (neurilemmoma) and neurofibroma.
- ▣ Malignant peripheral nerve sheath tumour develops particularly in patients with von Recklinghausen's neurofibromatosis.

CLINICAL CASE 30

A 62 years old man notices sudden onset of weakness and numbness of right side of his body and inability to walk or stand upright on his own. Earlier in the day, he had experienced severe headache.

He gives history of hypertension for 12 years, diabetes mellitus for 10 years and has been a smoker for 30 years before he quit smoking 10 years back. He has been well with treatment for hypertension and diabetes mellitus except for occasional episodes of angina which were relieved by rest.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

I

Basic Diagnostic Cytology

INTRODUCTION

Biopsy pathology has been the mainstay of diagnostic pathology at cellular level for over a century. This generated interest of workers towards obtaining cellular material by non-biopsy techniques to arrive at the diagnosis. As a result, diagnosis by cytopathologic technique was initially introduced in the 1920s by Dr. George N. Papanicolaou on cells naturally shed off (exfoliated) into cervical and vaginal secretion; subsequently its use was extended to cells shed off into other body cavities. Later, success of *bone marrow aspiration* for diagnosis of haematopoietic diseases created a parallel diagnostic cytopathologic technique of *fine needle aspiration cytology (FNAC)* for diagnosis of solid lesions. FNAC started in the 1930s from US without much encouragement but had resurgence in 1960s mainly from Scandinavian countries in Europe and later it spread to the rest of the world.

Thus, diagnostic cytology pertains to the interpretation of cells from the human body that either exfoliate (desquamate) spontaneously from epithelial surfaces (*Exfoliative Cytology*), or the cells are obtained from various organs/tissues by different clinical procedures (*Interventional Cytology*). While histopathologic diagnosis is based on interpretation of changes in tissue architecture, the cytopathologic diagnosis rests upon alterations in morphology observed in single cells or small groups of cells.

ROLE OF DIAGNOSTIC CYTOLOGY

Among the numerous applications of cytodagnostic techniques, the following are more important:

1. Diagnosis and management of cancer In the field of oncology, establishing a 'tissue diagnosis' (i.e. pathologic diagnosis based on microscopic evidence of malignancy) is an essential pre-requisite for proper management of a cancer patient.

i) Cytodiagnosis in its traditional role is a *valuable adjunct* to histopathology for establishing the vital tissue diagnosis e.g. diagnosis of lymphomas where imprint smears prove valuable, and in some respects superior to histopathology in typing the lymphoma.

ii) Cytologic techniques also provide a *preliminary diagnosis* of cancer for later confirmation by histopathology e.g. detection of ovarian cancer cells in ascitic fluid.

iii) In some fields, cytodagnosis has replaced histopathology as the *primary method* of establishing a tissue diagnosis e.g. in breast cancer, where positive cytologic report is considered sufficient for planning the management, obviating the need for diagnostic surgical biopsy.

iv) Cytodiagnosis has a major role in the detection and diagnosis of clinically silent *early cancer* e.g. carcinoma *in situ* of the uterine cervix.

v) In the management of cancer, cytodagnosis may help in assessing *response to therapy* e.g. cervical smears for response to radiotherapy in carcinoma cervix, and urinary cytology for response to chemotherapy in carcinoma of the urinary bladder.

vi) In the *follow-up* of previously diagnosed cases of cancer, it is of particular value in detecting dissemination (metastasis) or recurrence of tumour.

2. Identification of benign neoplasms This application is derived from its ability to distinguish between benign and malignant neoplasms e.g. fibroadenoma of the breast *versus* carcinoma.

3. Intraoperative cytopathologic consultation In this role, cytodagnosis complements histopathologic diagnosis e.g. imprint smears along with frozen section for breast lumps or for resection margin.

4. Diagnosis of non-neoplastic/inflammatory conditions Cytodiagnosis allows recognition of specific conditions which do not routinely require surgical intervention e.g. Hashimoto's thyroiditis.

5. Diagnosis of specific infections A variety of bacterial, viral, protozoal and fungal infections can be identified by cytologic methods e.g. tubercle bacilli in lymph node aspirates, herpetic inclusions and *Trichomonas* in cervico-vaginal smears, fungal hyphae in touch preparations from draining sinuses.

6. Cytogenetics Cytodiagnostic techniques can be employed for chromosomal studies including leucocyte and tissue cultures and for demonstrating sex-chromatin e.g. buccal smear for Barr body.

*Original contribution of this chapter by Dr Rohit Sharma, MD, to the second edition of this book (1994) is gratefully acknowledged.

Table A-I.1 Nuclear criteria of malignancy.

| | | |
|----|--|---|
| 1. | <i>Nuclear size</i> | : Usually larger than benign nuclei; variation in size (anisonucleosis) more significant. |
| 2. | <i>Nucleus-cytoplasmic (N:C) ratio</i> | : Increased. |
| 3. | <i>Nuclear shape</i> | : Moderate to marked variation. |
| 4. | <i>Nuclear membrane</i> | : Irregular thickening, angulation and indentations. |
| 5. | <i>Nuclear chromatin</i> | : Hyperchromatic (less significant), uneven distribution, coarse irregular angulated chromatin clumping, parachromatin clearing (more significant). |
| 6. | <i>Nucleoli</i> | : Increased size and number less significant; irregular angular outlines more significant. |
| 7. | <i>Number of nuclei</i> | : Multinucleation unreliable; nuclear character more important. |
| 8. | <i>Mitoses</i> | : Increased mitoses unreliable; abnormal mitoses significant. |

7. Assessment of hormonal status in women Vaginal smears accurately reflect changes in female sex hormonal levels e.g. to confirm the onset of menopause.

8. Identification of cell of origin For example, identification of spermatogenic elements in aspirates from the testes in cases of male infertility.

For cytomorphological recognition of cancer, nuclear characteristics are used to determine the presence or absence of malignancy (**Table A-I.1**). Cytoplasmic characteristics help in typing the malignancy e.g. keratinisation in squamous cell carcinoma, mucin droplets in adenocarcinoma, melanin pigment in melanomas.

BRANCHES OF DIAGNOSTIC CYTOLOGY

Broadly speaking, there are two branches of diagnostic cytology: exfoliative and interventional.

EXFOLIATIVE CYTOLOGY This is the older branch that essentially involves the study of cells spontaneously shed off (as a result of continuous growth of epithelial linings) from epithelial surfaces into body cavities or body fluids. Exfoliative cytology is facilitated by the fact that the rate of exfoliation is enhanced in disease-states, thereby yielding a larger number of cells for study. In addition, cells for study may also be obtained by scraping, brushing, or washing various mucosal surfaces (abrasive cytology).

Table A-I.2 Differences between exfoliative and interventional cytology.

| Feature | Exfoliative Cytology | Interventional Cytology |
|---|--|---|
| 1. <i>Cell samples</i> | Exfoliated from epithelial surfaces | Obtained by intervention/aspiration |
| 2. <i>Smears</i> | Require screening to locate suitable cells for study | Abundance of cells for study in most smears |
| 3. <i>Diagnostic basis</i> | Individual cell morphology | Cell patterns and morphology of groups of cells |
| 4. <i>Morphologic criteria of diagnostic significance</i> | Nuclear characteristics most important | Nuclear characteristics important; cytoplasmic character and background equally significant |

INTERVENTIONAL CYTOLOGY This branch is dominated by Fine Needle Aspiration (FNA) which is also known as Aspiration Biopsy Cytology (ABC). In FNAC, the cytopathologist often performs the clinical procedure and interacts with the patient in contrast to exfoliative cytology where the samples are prepared and forwarded by the clinician to the pathologist and the cytopathologist interprets them in isolation.

A brief account of both main branches of cytology is given below while their contrasting features are presented in **Table A-I.2**.

GIST BOX A-I.1

Introduction to Basic Diagnostic Cytology

- ☐ There are two main branches of diagnostic cytology: exfoliative and interventional.
- ☐ Exfoliative cytology is older branch and involves the study of cells spontaneously shed off from epithelial surfaces into body cavities or into body fluids.
- ☐ Fine Needle Aspiration Cytology (FNAC) is interventional cytology in which samples are obtained by clinical procedures.
- ☐ There are numerous applications of cytodiagnostic techniques e.g. diagnosis and management of tumours (benign and malignant tumours), non-neoplastic/inflammatory and infectious conditions, cytogenetics, assessment of hormonal status in women etc.

EXFOLIATIVE CYTOLOGY

Type of samples that can be obtained from different organ systems for exfoliative cytodagnosis (gynaecologic and non-gynaecologic) are listed in **Table A-I.3**. Apparently, a comprehensive review of each type of sample is beyond the scope of this text. Cytology of female genital tract is discussed in detail below while brief mention is made about other samples.

I. GYNAECOLOGIC EXFOLIATIVE CYTOLOGY

Smears from the female genital tract have traditionally been known as 'Pap smears'. These smears may be prepared by different methods depending upon the purpose for which they are intended:

- i) *Lateral vaginal smears (LVS)* obtained by scraping the upper third of the lateral walls of the vagina are ideal for cytohormonal assessment.
- ii) *Vaginal 'pool' or 'vault' smears* are obtained by scraping or aspirating material from the posterior fornix of the vagina and are recommended for detection of endometrial and ovarian cancer.

Table A-I.3 Types of samples for exfoliative cytology obtainable from different organ systems/body sites.

| I. GYNAECOLOGIC EXFOLIATIVE CYTOLOGY | |
|---|--|
| <i>Female genital tract</i> | i) Lateral vaginal smears (LVS) ii) Vaginal 'pool' smears iii) Cervical smears iv) Combined (fast) smears v) Triple smears (CVE) vi) Endocervical/Endometrial aspiration |
| II. NON-GYNAECOLOGIC EXFOLIATIVE CYTOLOGY | |
| 1. <i>Respiratory tract</i> | i) Sputum ii) Bronchial washings/brushing/ bronchioalveolar lavage (BAL) |
| 2. <i>Gastrointestinal tract</i> | Endoscopic lavage/brushing |
| 3. <i>Urinary tract</i> | i) Urinary sediment ii) Bladder washings iii) Retrograde catheterisation iv) Prostatic massage (secretions) |
| 4. <i>Body fluids</i> | i) Effusions ii) Fluids of small volume <ol style="list-style-type: none"> Cerebrospinal fluid (CSF) Synovial fluid Amniotic fluid Hydrocele fluid Seminal fluid (semen) Nipple discharge |
| 5. <i>Other samples</i> | — Buccal smears (for sex chromatin) |

iii) *Cervical smears* obtained by Ayre's spatula from the portio of the cervix are ideal for detection of cervical carcinoma.

iv) *Combined (Fast) smears* are a combination of vaginal pool and cervical scrapings. They offer the advantages of both and are recommended for routine population screening as they allow detection of up to 97% of cervical cancers and about 90% of endometrial cancers when properly prepared.

v) *Triple (cervical-vaginal-endocervical or CVE) smears* contain three distinct samples representing the ectocervix, vagina and endocervix on three separate areas of the same slide. These smears are also recommended for routine screening as they allow localisation of lesions but are difficult to prepare.

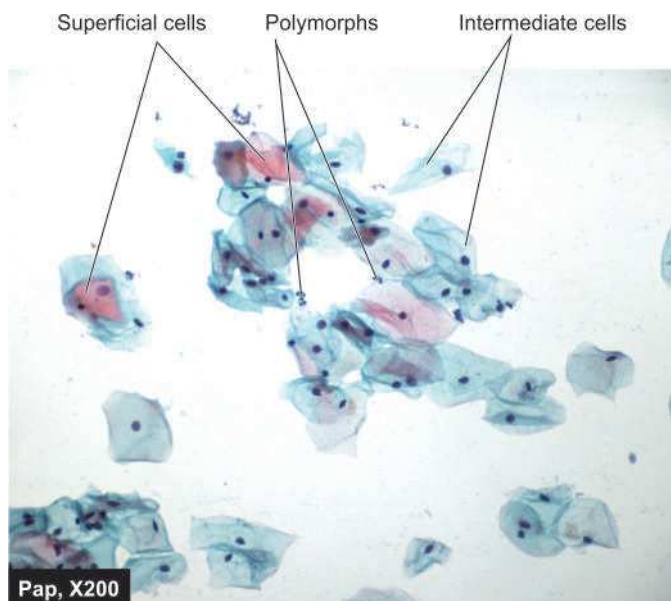

Figure A-I.1 Various types of epithelial cells seen in normal Pap smear.

vi) *Endocervical and endometrial smears* may also be prepared by aspirating the contents of the endocervical canal and endometrial cavity respectively.

CELLS IN NORMAL COMBINED SMEARS

Combined smears normally contain epithelial cells (normal and variants) and other cells (**Fig. A-I.1**):

Epithelial cells There are 4 types of squamous epithelial cells in the cervical smear: *superficial*, *intermediate*, *parabasal* and *basal cells*. Morphological features of these cells are summed up in **Table A-I.4**. A few variants of morphological forms and other epithelial cells are as under:

1. *Navicular cells* are boat-shaped intermediate cells with folded cell borders. These cells appear in latter half of the menstrual cycle, during pregnancy and menopause.
2. *Lactation cells* are parabasal cells with strongly acidophilic cytoplasm. These cells are seen so long as lactation persists.
3. *Endocervical cells* appear either as single dispersed nuclei due to degeneration, or as clusters of columnar cells giving it

Table A-I.4 Squamous epithelial cells found in normal combined (fast) smears.

| Cell Type | Size | Nuclei | Cytoplasm | Morphology |
|---------------------|---------------------|---|--|---|
| <i>Superficial</i> | 30-60 μm | < 6 μm dark, pyknotic | Polyhedral, thin, broad, acidophilic or cyanophilic with keratohyaline granules. |  |
| <i>Intermediate</i> | 20-40 μm | 6-9 μm vesicular | Polyhedral or elongated, thin, cyanophilic with folded edges. |  |
| <i>Parabasal</i> | 15-25 μm | 6-11 μm vesicular | Round to oval, thick, well-defined, basophilic with occasional small vacuoles. |  |
| <i>Basal</i> | 13-20 μm | Large, (> one-half of cell volume), hyperchromatic, may have small nucleoli | Round to oval, deeply basophilic. |  |

honey-combed appearance. Nuclei of endocervical cells are vesicular, with fine granular chromatin and contain 1-2 nucleoli, while the cytoplasm is slightly basophilic or vacuolated.

4. *Endometrial cells* are seen up to 12th day of menstrual cycle. They are slightly smaller than endocervical cells, appear as tight rounded clusters of overlapping cells with moderately dark oval nuclei and scanty basophilic, vacuolated cytoplasm.

5. *Trophoblastic cells* are seen following abortion or after delivery.

Other cells Besides epithelial cells, other cells in cervical smears are leucocytes and Döderlein bacilli:

1. *Leucocytes* in cervical smear include polymorphonuclear neutrophils (in large numbers normally), lymphocytes (isolated and entrapped in mucus normally), plasma cells (in chronic cervicitis), macrophages (normally in first 10 days of the menstrual cycle) and multinucleate cells (in specific inflammation).

2. *Döderlein bacilli* (*Bacillus vaginalis/Lactobacillus acidophilus*), which belong to the group of lactobacilli, are the predominant organisms of the normal vaginal flora. It is a slender, gram-positive, rod-like organism staining pale blue with the Papanicolaou technique. These organisms utilise the glycogen contained in the cytoplasm of intermediate and parabasal cells resulting in their disintegration (cytolysis). They are most numerous in the luteal phase and during pregnancy.

APPLICATIONS OF PAP SMEAR

It includes application of Pap smears for hormonal evaluation and for categorising their abnormalities into non-neoplastic, benign, and malignant types.

Cytohormonal Evaluation

Assessment of hormonal status is best carried out from lateral vaginal smears although vaginal 'pool' or fast smears may also be used. Ideally, at least 3 smears obtained on alternate days should be scrutinised and cytologic indices determined for each smear for accurate assessment.

Several indices are available for description of cyto-hormonal patterns. The most commonly used are as under:

i) *Acidophilic index (AI)*: The relative proportion of cells containing acidophilic (pink) and basophilic (blue) cytoplasm are determined by AI.

ii) *Pyknotic index (PI)*: The percentage of cells having small, dark, shrunken nuclei (less than 6 µm in size) is determined by PI. The PI is more reliable than AI as it is not influenced by many of the cytoplasmic artefacts e.g. acidophilia caused by drying of smears prior to fixation that affects the latter.

iii) *Maturation index (MI)*: MI is the most widely used method. One hundred squamous cells are counted and grouped according to their type—parabasal, intermediate, or superficial (basal cells are virtually absent from normal vaginal smears). Their proportions are expressed as a percentage; for example 10/80/10 represents parabasal, intermediate and superficial cells respectively. Some representative MIs at different stages of life are listed in **Table A-I.5**.

Abnormal Combined Smears

In order to evolve a system acceptable to clinicians and cytopathologists, National Cancer Institute Workshop in 1988 developed the *Bethesda System (TBS)* for uniformity in evaluation as well as limitations of reporting in cervicovaginal cytopathology; this was subsequently modified in 1991 and

Table A-I.5 Representative maturation indices at different stages of life.

| Stage | Maturation Index* (%) | Comment |
|--------------------|-----------------------|-------------------------------------|
| Neonatal | 0/90/10 | As in pregnancy |
| Infancy | 90/10/0 | With infections shows midzone shift |
| Preovulatory | 0/40/60 | Shift-to-right |
| Post-ovulatory | 0/70/30 | Midzone shift |
| Pregnancy | 0/95/5 | Midzone shift |
| Postpartum | 90/10/0 | Shift-to-left |
| Menopausal (early) | 0/80/10 | Estatrophy |
| Menopausal (late) | 95/5/0 | Teleatrophy |

*MI = Parabasal/intermediate/superficial

further updated in 2001. Criteria followed in the Bethesda system are given in Chapter 22 (page 716). Briefly, it has three basic components in recommendations:

1. Specimen adequacy It is an important component of quality assurance and provides feedback regarding sampling technique. It implies properly labelled, adequately fixed smears having sufficient number of evenly spread, well preserved cells as evaluated microscopically.

2. General categorisation It includes categorising the smear in one of the three broad categories: within normal limits, benign cellular changes, and epithelial cell abnormalities.

3. Descriptive diagnosis Final aspect of the Bethesda system includes detailed description of the benign cellular changes or epithelial cell abnormalities in the smear.

Based on it, the cellular changes in cervical smears are described under 2 headings: non-neoplastic (or benign) and neoplastic epithelial cell abnormalities.

NON-NEOPLASTIC (BENIGN) CELLULAR CHANGES:

i) NON-SPECIFIC INFLAMMATORY CHANGES Inflammatory changes not associated with any specific infection or identifiable infectious agent (i.e. non-specific inflammation) are commonly seen in smears of the female genital tract as under:

◆ *Acute inflammatory changes* are characterised by an increase in the number of parabasal cells (due to disruption of superficial layers of the epithelium resulting in exposure of deeper layers), cytoplasmic acidophilia and vacuolisation, leucocytic migration into cytoplasm, and perinuclear halos with nuclear pyknosis or enlargement.

◆ *Chronic inflammatory changes (Reactive changes)* manifest in squamous cells as nuclear enlargement, hyperchromatism, and nucleolar prominence, with multinucleation in some instances. Endocervical cells may show reparative hyperplasia and/or squamous metaplasia.

ii) SPECIFIC INFLAMMATORY CHANGES Specific inflammatory changes may be associated with a variety of infectious agents, the common among which are listed in **Table A-I.6**.

a) Bacterial agents:

◆ *N. gonorrhoeae* (the gonococcus) is a gram-negative diplococcus which is an intracellular micro-organism. It may

Table A-I.6 Common infections detectable on Pap smears.

BACTERIAL AGENTS

Neisseria gonorrhoeae
Gardnerella vaginalis
Mycobacterium tuberculosis

VIRAL AGENTS

Herpes simplex virus (HSV)
 Human papillomavirus (HPV)

FUNGAL AGENTS

Candida albicans
Torulopsis glabrata

PARASITIC AGENTS

Trichomonas vaginalis
Entamoeba histolytica

be observed under oil-immersion within intermediate or parabasal squamous cells and polymorphonuclear leucocytes as tiny paired coffee-bean organisms. However, a definitive diagnosis requires bacterial culture.

◆ *Gardnerella vaginalis*, a gram-negative rod, is a frequent cause of bacterial vaginitis. It manifests in smears as blue stained cocco-bacillary organism covering and imparting a grainy appearance to affected squamous cells (so called 'clue cells') against a clean background devoid of *Döderlein bacilli*.

◆ Tuberculosis of the female genital tract usually manifests as tuberculous salpingitis or endometritis, but may involve the uterine cervix. While *Mycobacterium tuberculosis* cannot be identified in Papanicolaou stained smears, tuberculous granulomas composed of epithelioid macrophages with accompanying Langhans' giant cells may occasionally be identified.

b) Viral agents:

◆ *Human papillomavirus (HPV)* is one of the commonest sexually-transmitted infections. There are 2 types of HPVs: low-risk and high-risk types. Low-risk HPV, most commonly types 6 and 11, are involved in causation of anogenital wart

or condyloma acuminatum. High-risk HPV, most often types 16 and 18, are strongly implicated in precancerous lesions of ectocervical epithelium leading to cervical cancer. Morphologically, smears from HPV-infected subjects show aggregates of rounded to oval squamous cells with blunted cell margins, peripheral cytoplasmic condensation and crisply outlined perinuclear halos, with dysplastic or degenerative changes of nuclei; these changes are collectively termed 'koilocytotic changes.' (see Fig. A-I.4). HPV can be identified in these cells by Southern blot, PCR, *in situ* hybridisation and by hybrid capture.

◆ Genital infection by *herpes simplex virus (HSV)* commonly affects the squamous epithelium of the vulva, vagina and cervix, but may ascend to involve endocervical and endometrial epithelium. Infected cells show enlarged nuclei with watery, 'ground-glass' chromatin, multinucleation with internuclear moulding, and intranuclear acidophilic inclusions.

c) Fungal agents:

◆ Moniliasis (infection by *Candida albicans*) is the commonest fungal infection of the female genital tract and is particularly associated with diabetes, pregnancy and use of antibacterial agents (which alter the vaginal flora). *Candida* appears in smears in two forms—the *yeast form* (unicellular) appears as round to oval budding organisms with inconspicuous capsules, and the *fungal form* (pseudohyphae) as thin, elongated, pseudoseptate, bamboo-like filaments (Fig. A-I.2).

◆ *Torulopsis glabrata* causes less than 10% of mycotic vaginal infections. It is related to *Candida*, appears in smears as round budding organisms with thick capsule-like halos, and does not form pseudohyphae *in vivo*.

d) Parasitic agents:

◆ Up to 25% of adult women are estimated to harbour *Trichomonas vaginalis* in their lower genital tract. Smears from infected women may not show any cytomorphological changes or may show non-specific acute inflammatory changes. The protozoan appears in the background as a fuzzy, grey-green, round or elliptical structure 8 to 20 μm in size, containing a small vesicular nucleus (Fig. A-I.3).

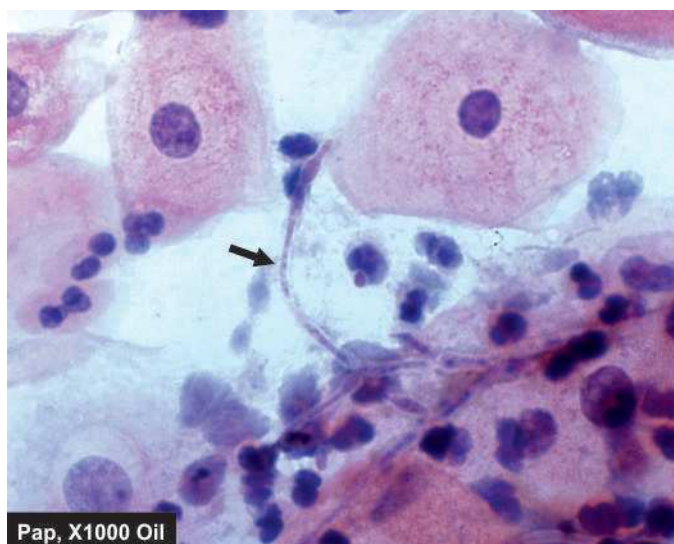

Figure A-I.2 Inflammatory smear with *Candida* (candidiasis, moniliasis) (arrow).

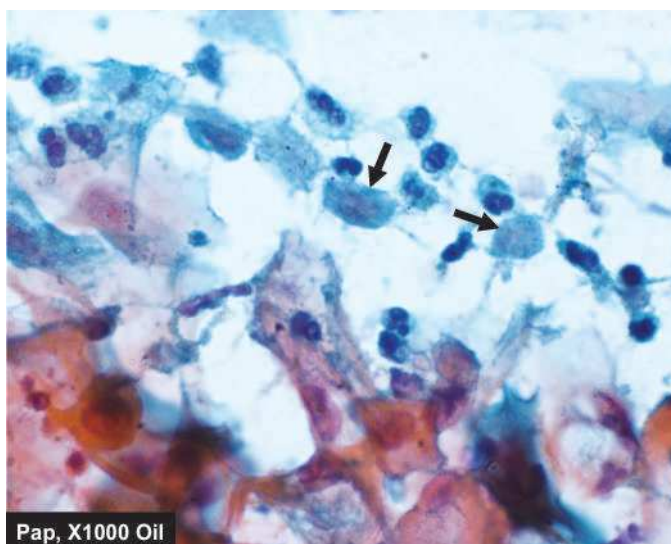

Figure A-I.3 *Trichomonas* in inflammatory smear (arrow).

Figure A-I.4 L-SIL. The smear shows koilocytes having nuclear enlargement and perinuclear halo (arrow).

◆ *Entamoeba histolytica* in trophozoite form appears in Pap smears as basophilic, round to oval structures, 15 to 20 µm in size, with ingested erythrocytes and a round eccentric nucleus with a central karyosome.

NEOPLASTIC EPITHELIAL CELL ABNORMALITIES:

Carcinoma of the uterine cervix still ranks high in the list as the most frequent cancer in developing countries of the world and is the leading cause of cancer morbidity and mortality. Vast majority of cervical cancers are of the squamous cell type, and the diagnosis of squamous cell carcinoma of the cervix and its precursor lesions is considered as the most important application of exfoliative cytology.

Neoplastic epithelial changes are described below under 2 headings: squamous cell abnormalities and glandular cell abnormalities.

1. SQUAMOUS CELL ABNORMALITIES The fully-developed invasive squamous cell carcinoma of the uterine cervix is preceded by a pre-invasive intraepithelial neoplastic process that is recognisable on histologic and cytologic examination.

Morphogenesis and nomenclature The earliest recognisable change is *hyperplasia* of basal or reserve cells which normally constitute a single layer at the deepest part of the epithelium. The proliferating reserve cells next develop certain atypical features i.e. hyperchromasia and increased nuclear size. The continued proliferation of these atypical cells with loss of polarity, a concomitant increase in mitotic activity, and progressive involvement of more and more layers of the epithelium is known as *dysplasia* (disordered growth). When dysplasia involves the full thickness of the epithelium and the lesion morphologically resembles squamous cell carcinoma without invasion of underlying stroma, it is termed *carcinoma in situ* (CIS). CIS further progresses through the stage of *microinvasive carcinoma* (with depth of stromal invasion not exceeding 3 mm) into full-blown *invasive squamous cell carcinoma*.

Previously, depending on the degree of epithelial involvement, three grades of dysplasia were recognised: mild, moderate and severe. As the stages of dysplasia and CIS represented a continuous spectrum of lesions seen in the

precancerous state, they were collectively termed 'cervical intraepithelial neoplasia' (CIN) and categorised as under:

| | | |
|----------------|--|---|
| CIN I | Mild dysplasia | Primitive (atypical) cells, proliferating in lower third of epithelium. |
| CIN II | Moderate dysplasia | Involvement up to middle-third of epithelium. |
| CIN III | Severe dysplasia Carcinoma <i>in situ</i> (CIS) | Involvement of upper-third of epithelium. Involvement of full thickness of epithelium. |

Presently, the *Bethesda system* (TBS) divides squamous cell abnormalities into four categories:

- Atypical squamous cells of undetermined significance* (ASCUS) which represents cellular changes falling short of intraepithelial lesion.
- Low-grade squamous intraepithelial lesion* (L-SIL) that includes CIN-I and cellular changes associated with HPV infection.
- High-grade squamous intraepithelial lesion* (H-SIL) includes CIN grade II, III and CIS.
- Squamous cell carcinoma*.

Cytomorphology Precancerous states can be distinguished from invasive carcinoma on the basis of cytomorphological features observed in smears. In dysplastic epithelium, stratification and maturation of cytoplasm occurs above the layers of proliferating primitive cells while the nuclear abnormalities persist. Cells exfoliating from the surface, thus, display cytoplasmic maturation and differentiation with nuclear atypia and are known as *dyskaryotic cells*.

The character and type of dyskaryotic cells observed in smears reflect the severity of dysplasia:

- In mild dysplasia (CIN-I or L-SIL), maturation occurs in the upper two-thirds of the epithelium and exfoliated dyskaryotic cells are of the superficial type. These cells show cytoplasmic vacuolation as perinuclear halo (koilocytosis) and nuclear enlargement (**Fig. A-I.4**).
- With increasing dysplasia (CIN-II and CIN-III, or H-SIL), the proliferating primitive cells reach closer to the epithelial surface, less cytoplasmic maturation/differentiation occurs, and dyskaryotic intermediate and parabasal cells are observed in smears (**Fig. A-I.5**).
- Progression to CIS (CIN-III or H-SIL) manifests as subtle alterations in cell arrangement and morphology (with predominantly basal and parabasal cells in smears).
- Onset of invasive carcinoma is heralded by the appearance of macronucleoli, cytoplasmic orangeophilia and presence of tumour diathesis (dirty, necrotic background) (**Fig. A-I.6**).

2. GLANDULAR CELL ABNORMALITIES The *Bethesda system* categorises glandular abnormalities as under:

- Atypical glandular cells of undetermined significance* (AGUS) which represent nuclear atypia of endocervical and endometrial cells exceeding reparative changes.
- Endocervical* and *endometrial adenocarcinoma*, both of which can be detected from Pap smears; cytomorphological features allowing distinction between these two types of malignancies are summed up in **Table A-I.7**.
- Cells from *extrauterine cancers* may also be present in Pap smears, majority originating from the ovaries. Clues to the

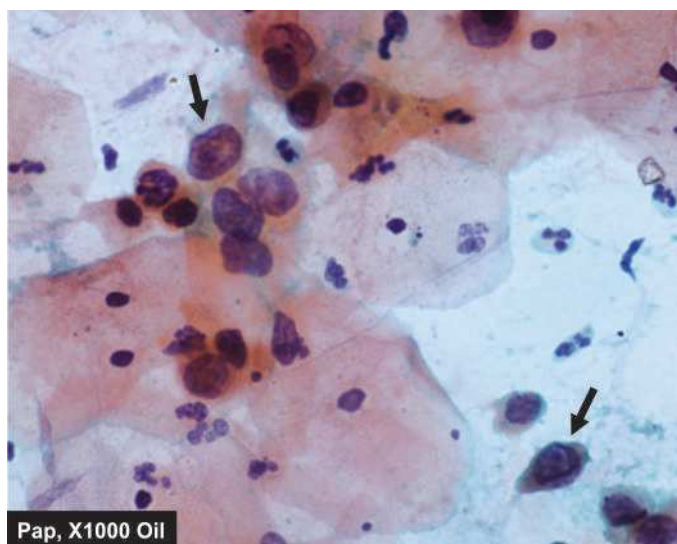

Figure A-I.5 H-SIL. The squamous cells have scanty cytoplasm and markedly hyperchromatic nuclei having irregular nuclear outlines. The background shows numerous PMNs.

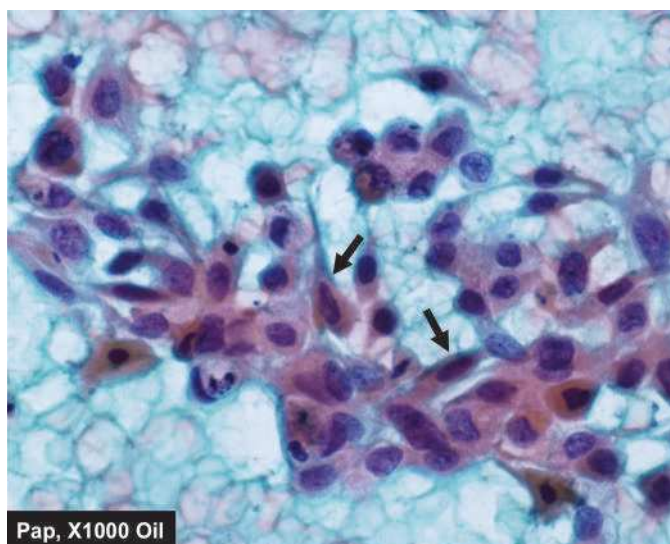

Figure A-I.6 Invasive squamous cell carcinoma. The malignant epithelial cells have anisonucleosis with irregular nuclear chromatin with prominent nucleoli. A few fibre cells and caudate cells are also seen (arrow). The background shows abundant haemorrhage and some necrotic debris.

extrauterine origin of cancer cells include: the absence of a tumour diathesis, arrangement of cancer cells in glandular and papillary configuration (accompanied by psammoma bodies in some instances), and absence of dysplastic changes in coexistent cervico-endometrial cells.

Automation in Cervical Cytology

Introduction of automated devices like PapNet for primary screening is a major technologic achievement in recent times. Automation offers routine pre-screening of hundreds of Pap smears, decreasing the workload of cytopathologists and at the same time providing quality assurance. It can be applied to conventional Pap smears or to *Thin-Preps* (discussed later).

II. NON-GYNAECOLOGIC EXFOLIATIVE CYTOLOGY

RESPIRATORY TRACT

Cellular material from the respiratory tract may be obtained as a result of spontaneous expectoration (sputum), aspiration or brushing during bronchoscopic procedures.

1. SPUTUM EXAMINATION Sputum is produced by a spontaneous deep cough bringing up material from small airways and alveoli. The cough reflex may also be triggered artificially by aerosol-inhalation of cough-stimulating substances (e.g. propylene glycol with hypertonic saline). Sputum examination is advantageous as samples are easily obtained and the cellular content is representative of the entire respiratory tract (satisfactory specimens allow diagnosis of over 80% of lung cancers). However, a large number of cells have to be scrutinised and the specimen does not allow localisation of the lesion within the respiratory tract.

2. BRONCHIAL ASPIRATION (WASHINGS) AND BRONCHIAL BRUSHING Cellular material obtained by aspiration brushing (BB) or bronchial washing (BW), or by bronchio-alveolar lavage (BAL) during bronchoscopy allows localisation of lesions to specific areas of the respiratory tract. Moreover, specimens are easier to study as the cellularity is less than that of sputum. However, bronchoscopic procedures are unpleasant for patients, time-consuming and require considerable expertise.

Table A-I.7 Cytomorphological features of endocervical and endometrial adenocarcinoma.

| Feature | Endocervical Carcinoma | Endometrial Carcinoma |
|---------------------|---|--|
| 1. Background | Clean | Dirty, bloody |
| 2. Cell yield | High (found mainly on cervical smears) | Low (found mainly on vaginal smears) |
| 3. Cell arrangement | Clusters or sheets with 'side-by-side' grouping | Three-dimensional 'cell ball' or grape-like clusters |
| 4. Cytoplasm | | |
| i) Amount | Moderate (often in columnar configuration) | Small |
| ii) Character | Granular, well-stained, often producing mucin | Finely vacuolated, translucent, with ingested leucocytes |
| 5. Nuclei | | |
| i) Size | Large | Fairly small |
| ii) Character | Finely granular chromatin (mild hyperchromasia) | Coarse chromatin (marked hyperchromasia) |
| iii) Nucleoli | Macronucleoli | Micronucleoli |

GASTROINTESTINAL TRACT

Lesions in the oral cavity may be sampled by scraping the surface with wooden and metal tongue-depressors. For the oesophagus, stomach and duodenum, cytologic samples are obtained under direct vision by brushing or lavage through fiberoptic endoscopes by direct mucosal visualisation by the endoscopist and collection of cytologic sample while doing a biopsy. Cytology samples from the colon may also be obtained by brushing during colonoscopy or lavage following enema to clean the colon.

URINARY TRACT

1. URINARY SEDIMENT CYTOLOGY Cytological evaluation of the urinary tract is most often carried out by examining the sediment of voided or catheterised specimens of urine. It is convenient for the patient and a useful method for study of both the upper and lower urinary tracts, provided the samples are collected and processed in the correct manner. While voided specimens are satisfactory in men, catheterisation is often preferred in women to avoid contamination by vaginal cells and menstrual blood.

2. BLADDER IRRIGATION (WASHINGS) Washings of the urinary bladder obtained at cystoscopy are preferred in symptomatic patients when bladder tumours are suspected. The procedure provides excellent cytological preparations.

3. RETROGRADE CATHETERISATION For suspected lesions of the upper urinary tract, voided urine is usually satisfactory. While renal parenchymal cells are infrequent in urine, material obtained from the renal pelvis and ureter contains adequate quantity of these cells. In some instances, retrograde catheterisation and brushing of the ureter and renal pelvis are utilised for localisation of lesions.

4. PROSTATIC MASSAGE Prostatic secretions are obtained by prostatic massage and the sample is collected directly onto a glass slide and smeared. The procedure is rarely used nowadays with the advent of direct sampling of the prostate by FNAC.

Diagnostic Utility of Urinary Cytology

While evaluating the utility of urinary cytology in the diagnosis of urothelial tumours, following aspects need to be kept in mind:

1. *Papillary tumours of low-grade* are lined by urothelium showing no morphological abnormalities or only slight cellular and nuclear abnormalities. Such tumours cannot be diagnosed on cytologic material with any degree of certainty.
2. *High-grade papillary tumours*, sessile tumours and carcinoma *in situ* where urothelial cells exhibit cytomorphological abnormalities, are readily diagnosed by urinary cytology.
3. Urothelial tumours are often synchronous or metachronous and may involve *different regions of the urinary tract*. Urinary cytology is, thus, of immense value in the follow-up of patients with previously diagnosed urothelial tumours.

BODY FLUIDS

Body fluids may be divided into 2 types:

- A. Effusions in body cavities
- B. Body fluids of small volume.

A. EFFUSIONS

Effusion refers to the accumulation of fluid in any of the three body cavities (pleural, pericardial and peritoneal). An effusion in the peritoneal cavity is also known as ascites. Effusions have traditionally been classed as transudates or exudates. This distinction is important in diagnostic cytology as malignant effusions are invariably exudates with a protein content greater than 3 gm/dl (see Table 4.1, page 81).

Diagnostic cytology of effusions on samples obtained by paracentesis is mainly related to the identification of malignancy, and wherever possible, its classification. In benign effusions, cytological findings are mostly non-specific.

Cellular Components in Effusions

Two main primary component cells of effusions are mesothelial cells and macrophages or histiocytes. Effusion causes disruption of the mesothelial lining and these cells collect in the fluid individually or as small groups. Macrophages appear as mononuclear cells of the size of mesothelial cells distributed singly or as loose clusters. However, macrophages have ill-defined cell border compared to mesothelial and may have cytoplasmic vacuoles. Moreover, the nuclei in the macrophages are eccentric and kidney-shaped while those of mesothelial cells are central and round.

In addition, the effusion may have the following cellular components:

CELLS IN BENIGN EFFUSIONS These include reactive proliferations of mesothelial cells in inflammation, polymorphonuclear neutrophils in acute suppurative inflammation, and lymphocytes in chronic fluid collections. When lymphocytes are dominant cells in the effusion fluid in fibrin-rich background, the possibility of tuberculosis is considered. In tuberculous effusions, granulomas, epithelioid cells or Langhans' giant cells may not be seen; stain for tubercle bacilli may sometimes be of value.

CELLS IN MALIGNANT EFFUSIONS Malignant cells in effusion may of origin from primary tumour (e.g. mesothelioma) or from secondary/metastatic tumour; the latter being more common.

1. Mesothelioma It is an uncommon tumour and the cell yield is more often epithelial type since fibrous mesothelioma does not exfoliate cells in the effusion. Epithelial cells of mesothelioma require to be distinguished from adenocarcinoma cells.

2. Adenocarcinomas These are the most common malignant cellular component in the effusions. They mostly represent metastasis from primary adenocarcinomas such as from the stomach, lung, breast, colon, and ovary. Less frequent sources are adenocarcinoma of the biliary system, pancreas and liver. Most adenocarcinomas show similar morphologic appearance and thus it may not be possible to comment on the possible primary site of origin of the adenocarcinoma on morphology alone (**Fig. A-1.7**).

3. Squamous cell carcinoma Effusion may rarely have malignant squamous cells in it and represent metastasis from carcinoma lung, oesophagus or uterine cervix.

4. Small cell carcinoma Cytologic features of small cell carcinoma of the lung are quite characteristic—hyperchromatic moulded nuclei and scanty or no cytoplasm.

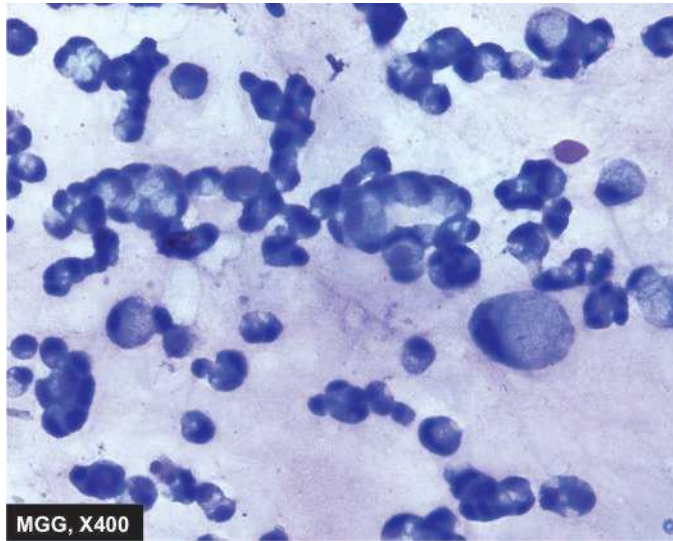

Figure A-1.7 Pleural fluid positive for signet ring cells (adenocarcinoma stomach). There are large number of malignant cells scattered singly or in small clusters having characteristic cytoplasmic vacuoles, nuclear hyperchromasia and prominent nucleoli.

5. Lymphomas-leukaemias Effusions may sometimes have malignant cells of leukaemia and lymphoma in line with primary disease in the body.

B. BODY FLUIDS OF SMALL VOLUME

Of the miscellaneous fluids included in this category, the most common samples submitted for cytological evaluation are cerebrospinal fluid (CSF) and seminal fluid (semen).

Cerebrospinal Fluid (CSF)

CSF examination is an important part of complete neurologic evaluation, both in non-neoplastic and neoplastic diseases of the central nervous system. Samples are usually obtained by lumbar puncture. Factors that are critical to the successful cytological evaluation of CSF are as under:

- i) Speed of delivery to the laboratory and immediate processing, as diagnostic material may disintegrate within an hour resulting in false-negative diagnosis.
- ii) Correct cytological processing and technique, since the cell yield of CSF is generally low and faulty technique may result in loss of cellular material or poor morphology.

Normal CSF CSF is an ultrafiltrate of plasma with a total volume of about 150 ml (in the adult). Cell content is low (0-4/ μ l) comprising mainly lymphocytes or monocytes.

CSF in non-neoplastic diseases Changes in CSF in various non-neoplastic diseases are discussed in Chapter 28 (see Table 28.1).

CSF in neoplastic disease Neoplasms that are in direct contact with the CSF are most likely to shed cells which are recoverable for scrutiny. Metastatic cancers (leukaemia, lymphoma and adenocarcinoma), medulloblastomas, and ependymomas shed the greatest amount of material. Though meningioma occurs in the subarachnoid space, it rarely exfoliates sufficient material for diagnosis. Low-grade gliomas

do not generally shed sufficient cells although high-grade gliomas may yield adequate cellular material for diagnosis.

Seminal Fluid (Semen)

Examination of seminal fluid (semen analysis) is one of the tests for investigating infertile couples, and is also used to check the adequacy of vasectomy. Samples are obtained by masturbation or coitus interruptus after observing at least 4 days of sexual abstinence and assessed on the following lines:

- 1. Volume** Normal volume is between 2.5 and 5 ml.
- 2. Viscosity and pH** When ejaculated, semen is fairly viscous but liquefies in about 10 to 30 minutes. It is usually alkaline (pH about 8).
- 3. Motility** Normally, within 2 hours of ejaculation, at least 60% of the spermatozoa are vigorously motile; in 6 to 8 hours 25 to 40% are still motile.
- 4. Count** Counting is done in a Neubauer chamber after suitable dilution. Normally, 60 million or more spermatozoa are present per ml. Currently, automated counters for semen are also available.
- 5. Morphology** Stained smears are used to assess morphology. Normally, not more than 20% of spermatozoa are morphologically abnormal (e.g. double-head, pointed-head, or swollen).
- 6. Fructose** Seminal fructose estimation (normal levels 150-600 mg/dl) complements cytological analysis. Low levels of seminal fructose indicate obstruction at the level of ejaculatory ducts.

Results of semen analysis need to be interpreted with caution as infertility is caused by several factors in the couple. As discussed in Chapter 21, other causes of infertility need to be evaluated before it is assigned to abnormalities in semen. Even specimens with several abnormal features need not necessarily be the cause of infertility.

BUCCAL SMEARS FOR SEX CHROMATIN BODIES

Sex-specific chromatin bodies are observed in interphase nuclei and comprise the Barr body (X chromatin) and the fluorescent or F body (Y chromatin). The number of Barr bodies observed in interphase nuclei is one less than the number of X chromosome ($n-1$), whereas the number of F bodies observed is equal to the number of Y chromosomes present (n). In effect, the Barr body is specific for females and the F body for males (page 252).

DEMONSTRATION OF BARR BODY (X CHROMATIN) In buccal smears, the Barr body appears as a plano-convex mass about 1 μ m in diameter applied to the inner surface of the nuclear membrane. The interphase nuclei of one hundred intermediate squamous epithelial cells are scrutinised. In normal females, Barr bodies are present in at least 20% of nuclei (**Fig. A-1.8, A**). Males have a Barr body count of less than 2%. Vaginal smears may also be used for Barr body counts (page 889).

DEMONSTRATION OF F BODY (Y CHROMATIN) Demonstration of the F body requires fluorescent staining in contrast to the Barr body which may be observed on routine Papanicolaou-stained smears. On staining buccal smears with quinacrine

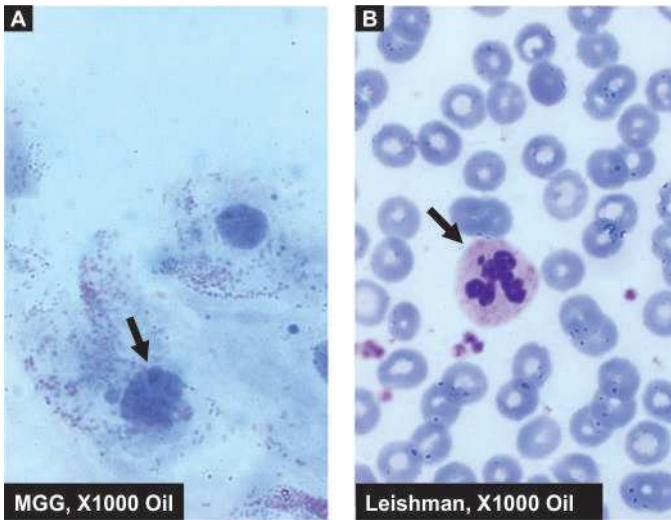

Figure A-1.8 Sex chromatin. A, Buccal smear showing condensation of chromatin under the nuclear membrane. B, Blood film showing presence of drumstick appendage attached to a nuclear lobe of the neutrophil.

mustard, the intensely fluorescent F body is observed in about 60% of interphase nuclei in males and in less than 8% of nuclei in females. The F body is also demonstrable in the nuclei of lymphocytes in a peripheral blood film stained with quinacrine mustard.

COUNTING OF DRUMSTICK APPENDAGE The presence and frequency of drumstick appendages attached to nuclei of polymorphonuclear leucocytes on a peripheral blood film may also be used for determining sex. At least 500 neutrophilic leucocytes are scrutinised in a Romanowsky-stained blood film. Genetic females show drumsticks in 3-6% of neutrophils (Fig. A-1.8, B). In males, the frequency of drumsticks is less than 0.3%.

GIST BOX A-1.2 Exfoliative Cytology

- ☐ Exfoliative cytologic material may be gynaecologic (i.e. Pap smear) or non-gynaecologic (e.g. respiratory tract, alimentary tract, body fluid and buccal smear).
- ☐ Pap smears are the smears obtained from the female genital tract.
- ☐ Combined smears contain normal epithelial cells (superficial, intermediate, parabasal and basal cell), variants (e.g. navicular cells, endocervical and endometrial cells) and other cells (e.g. leucocytes, Döderlein bacilli).
- ☐ Pap smears are applied for hormonal evaluation and for categorising their abnormalities into non-neoplastic (non-specific and specific infections) and benign and malignant neoplastic types (squamous cell and glandular cell abnormalities).
- ☐ Cellular material from the respiratory tract may be obtained by sputum, washing or brushing during bronchoscopic procedures (e.g. BB, BW, BAL).
- ☐ Alimentary tract material is obtained by direct vision by brushing or lavage through fiberoptic endoscope.
- ☐ Urinary sediment is used for cytological evaluation of the urinary tract.
- ☐ Body fluids studied in cytology are effusions in body cavities and fluids of small volume such as CSF and seminal fluid.

- ☐ Buccal smears may be used for demonstration of Barr bodies (for X-chromatin), bodies (for Y chromatin) and by counting drumstick appendages in neutrophils.

TECHNIQUES IN EXFOLIATIVE CYTOLOGY

A brief review of methods for collection of specimens and processing of samples for exfoliative cytodagnosis is outlined below under 4 headings: collection, fixation and fixatives, processing in the laboratory, and staining.

A. COLLECTION OF SAMPLES

1. PREPARATION OF PAP SMEARS Smears should not be taken during menstrual bleeding. The patient should not douche for at least 24 hours before the smear is obtained.

- i) Smears are obtained under *direct vision* after introducing a Cusco's speculum with the patient in lithotomy position.
- ii) Ideally, *lubricants* and medical jellies should not be used for introducing the speculum since use of lubricants results in contamination of the smear. If required, the speculum may be moistened with a few drops of normal saline.
- iii) The posterior fornix of the vagina is aspirated with a *blunt-ended glass pipette* fitted with a rubber bulb. A drop of the aspirate is placed at the unlabelled end of a glass slide.
- iv) The ectocervix is sampled with the *Ayre's spatula* (Fig. A-1.9). The longer limb of the spatula is fitted into the external os and the spatula rotated through 360° to sample the entire cervix. The scraped material on the spatula is then placed on the drop aspirated from the vaginal pool and the smear prepared with the spatula itself or with the tip of the gloved finger.
- v) Thin uniform smears should be prepared and the slide immediately *immersed in fixative* to avoid artefacts in cells caused by drying.
- vi) Smears should be *transported* to the laboratory in the fixative in a Coplin's jar (discussed later).

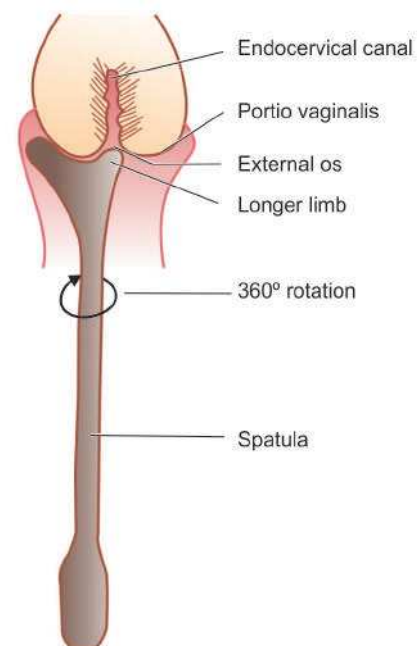

Figure A-1.9 Method of obtaining cervical smear with Ayre spatula (fast smear).

Slides should ideally be labelled by using a diamond pencil. If sticking labels are used, the labels must not come into contact with the fixative.

2. LIQUID-BASED CYTOLOGY (LBC) PREPARATIONS LBC is a special technique for preparation of gynaecologic and non-gynaecologic samples which provides uniform monolayered dispersion of cells on smears, without overlapping or clump formation and does not contain background material or debris. It is a pre-requisite for quantitative analysis and automated devices. Two types of LBC systems are commercially available—ThinPrep and SurePath, each with its own advantages.

3. PREPARATION OF LATERAL VAGINAL SMEARS (LVS) The LVS is obtained by scraping the lateral walls of the upper third of the vagina (at the level of the cervical external os) with the flat surface of a wooden tongue depressor and smearing the material directly onto labelled slides. The patient is prepared and positioned as described for the combined (fast) smear.

4. COLLECTION OF SPUTUM Fresh, unfixed, early morning specimens resulting from overnight accumulation of secretions are best for diagnostic purposes. A minimum of at least three specimens collected on three successive days should be examined. The patient is instructed to cough deeply on waking up and to expectorate all sputum into a clean, dry, wide-mouthed glass container or a petridish. Care should be taken to avoid spitting into the container. The container is capped or covered, labelled and transported to the laboratory where smears are prepared.

5. BRONCHIAL MATERIALS All aspirated bronchial secretions, lavage (BAL), washings (BW) and brushings (BB) must be dispatched to the laboratory without delay. If immediate dispatch is not possible, the sample should be collected in fixative (50% ethanol in volumes equal to that of the sample).

6. BUCCAL SMEARS The mouth is rinsed with water or normal saline and the buccal mucosa scraped vigorously with a wooden or metal tongue depressor. The material is smeared directly onto labelled glass slides which are placed in fixative.

7. G.I. CYTOLOGY In a case of suspected malignancy or specific infections of GI tract, or for screening for Barrett's oesophagus, cytologic examination is indicated. The cytology specimen is collected during fiberoptic endoscopy of the part being visualised.

8. URINE Fresh catheterised specimens are preferred in female patients while voided urine is satisfactory in males. After initial morning voiding (which is discarded), samples of about 50 to 100 ml are collected on three consecutive days. Hydration by forced intake of fluids (1 glass of water every 30 minutes over 3 hour period) is recommended by some workers for production of high volume specimens. If delay is anticipated in despatch to the laboratory, the sample should be collected in an equal volume of 50% ethanol.

The initial morning specimen is discarded as cells deteriorate extremely quickly in acidic urine, and the morphology of cells accumulating overnight in bladder urine is distorted to an extreme degree. For the same reason, 24-hour collections of urine are useless for cytodiagnostic purposes.

9. EFFUSIONS Pericardial, pleural and peritoneal fluids are obtained by paracentesis. As these fluids are often exudative in character, they may clot after removal from respective cavities. Anticoagulants may be used to prevent coagulation—heparin

(3-5 units per ml), 3.8% sodium citrate (1 ml per 10 ml), or EDTA (1 mg per ml) may be used for this purpose.

If the fluids cannot be processed within 12 hours of collection, an equal volume of 50% ethanol or 10% formalin should be added.

10. CEREBROSPINAL FLUID (CSF) CSF samples should be dispatched without delay to the laboratory for immediate processing as the cells contained are extremely fragile. A gap of even 1 hour between removal and processing may result in loss of diagnostic cellular material.

11. SEMEN Samples of seminal fluid obtained by masturbation are best collected at the laboratory. Samples obtained by coitus interruptus are collected in clean, dry test tubes (or vials) and transported to the laboratory within 30 minutes. The patient is instructed to note the time of ejaculation.

B. FIXATION AND FIXATIVES

All material for cytological examination must be properly fixed to ensure preservation of cytomorphological details. Methods of fixation vary depending upon the type of staining employed:

◆ Material for exfoliative cytodiagnosis is usually *wet-fixed* i.e. smears are immersed in fixative without allowing them to dry. These smears are then stained with Papanicolaou (Pap) or haematoxylin and eosin (H & E) stains.

◆ Sometimes, exfoliative cytology smears are *air-dried* for use with the Romanowsky stains as are used in haematologic studies. In Romanowsky staining, fixation is effected during the staining procedure.

1. ROUTINE FIXATIVES The ideal fixative for routine use is Papanicolaou's fixative comprising a solution of equal parts of ether and 95% ethanol. However, the flammability of ether makes it hazardous. Most laboratories use 95% ethanol alone with excellent results. Where ethanol is not available, 100% methanol, 95% denatured alcohol, or 85% isopropyl alcohol (isopropanolol) may be used.

Smears prepared at the bedside as well as those prepared in the laboratory from fluid samples are immediately placed in 95% ethanol *without allowing them to dry prior to fixation*. Drying causes distortion of cells and induces cytoplasmic staining artefacts. Fixation time of 10 to 15 minutes at room temperature is adequate. Smears may also be left in the fixative for 24 hours or more without any detrimental effect as regards cytomorphological detail. Smears should be transported to the laboratory in the fixative; screw-capped Coplin jars are best for this purpose.

2. COATING FIXATIVES Coating fixatives are applied as aerosol-sprays or with a dropper to the surface of freshly prepared smears. While commercial preparations (e.g. cytospray) are available, a standard hairspray with a high alcohol content is also a suitable alternative. Smears while still wet, are placed face-up on a table and sprayed with the nozzle held at a distance of 10 to 12 inches. A period of 10 minutes is sufficient for drying of coated smears, which may then be wrapped or put in a box for transport to the laboratory. Coating fixatives are ideal when unstained smears are to be transported over long distances.

3. SPECIAL PURPOSE FIXATIVES Buffered neutral formalin, Bouin's fluid and picric acid are used for specific purposes when required. Formalin vapour fixation is also employed for some staining procedures.

4. PRESERVATION OF FLUID SAMPLES Samples of fluids are best submitted to the laboratory in a fresh state for immediate processing. Where a delay is anticipated in despatch to the laboratory or in processing, the sample is collected in a suitable preservative for 'refixation' so that cellular morphology is preserved. When the samples have been processed and smears prepared, 'fixation' is effected as described earlier.

Fluid samples with a high protein content (e.g. pericardial, pleural and peritoneal fluids) may be preserved under refrigeration for up to 12 hours without prefixation. However, fluids with a low protein content (e.g. urine and cerebrospinal fluid) deteriorate in 1 to 2 hours even if refrigerated. Fluids with low pH (e.g. gastric lavage samples) must be collected in pre-cooled preservative since cells deteriorate extremely rapidly in such specimens.

The best *preservative for general use* is 50% ethanol in volumes equal to that of the fluid sample. Ninety-five per cent ethanol precipitates proteins and hardens the sediment making smear preparation difficult; it is used only for gastric aspirates. Pericardial, pleural and peritoneal fluids may be pre-fixed with an equal volume of 10% formalin if ethanol is not available. Solutions containing ether and acetone are not used as preservatives as they cause extreme hardening of the sediment making smear preparation virtually impossible.

C. PROCESSING OF SAMPLES IN THE LABORATORY

1. PREPARED SMEARS Smears prepared at the bedside and wet-fixed in ethanol need no further processing in the laboratory prior to staining.

2. SPUTUM The sample is prepared as under:

- i) The sample is placed in a petridish and inspected against a dark background.
- ii) Bloody, discoloured or solid particles are removed with wooden applicator sticks and placed on glass slides. Strands of ropy mucus are also selected (exfoliated cells adhere to mucus strands).
- iii) Clean glass slides are used to crush the particles/mucus and spread the material evenly.
- iv) Four such smears are prepared and immediately placed in 95% ethanol for fixation.

3. FLUID SPECIMENS Large volumes of fluid received are allowed to stand in the refrigerator for half to one hour. After that, all except the bottom 200 ml is discarded. The retained fluid is then processed. In specimens containing excessive amounts of blood, erythrocytes may be lysed by the addition of 1 ml of glacial acetic acid for every 50 ml of specimen.

Commonly employed techniques for processing of fluids are as under:

Sediment smears The sample is poured into 50 ml centrifuge tubes and centrifuged at 600 g for 10 minutes (To achieve a relative centrifugal force of 600 g, the speed of the centrifuge in revolutions per minute varies with the rotating radius of the centrifuge. With a rotating radius of 25 cm the required speed is 1500 rpm).

Following centrifugation, the supernatant is decanted and smears prepared from the sediment or cell button by recovering the material with a glass pipette or a platinum wire loop. Smear preparation from samples collected in a preservative require albuminised slides as cell adhesiveness is reduced by

refixation. Smears are wet-fixed in 95% ethanol (or air-dried in some instances).

Cytocentrifuge and membrane filter preparations These methods are most useful for small volume fluids of low cell content. The interested reader is referred to specialised texts for descriptions of these methods.

D. STAINING OF SMEARS

Three staining procedures are commonly employed: Papanicolaou and H&E stains are used for *wet-fixed smears* while Romanowsky stains are used for *air-dried smears*.

1. PAPANICOLAOU STAIN Papanicolaou staining is the best method for routine cytodiagnostics studies. Three solutions are used comprising a nuclear stain (Harris' haematoxylin) and two cytoplasmic counter-stains (Orange G or OG-6, and eosin-azure or EA-65 or EA-50). Nuclear stain gives basophilic colour to the nucleus while the two cytoplasmic stains impart the orange and cyanophilic tints to cytoplasm respectively.

2. H & E STAIN The stain is essentially the same that is used for histological sections. Harris' haematoxylin is the nuclear stain, and eosin is the cytoplasmic counterstain.

3. ROMANOWSKY STAINS Romanowsky stains used in haematological preparations may also be used for cytological smear preparations. Leishman's, May-Grünwald-Giemsa (MGG) and Wright's stains are most commonly used.

GIST BOX A-1.3

Techniques of Exfoliative Cytology

- ☐ Ayre's spatula is used for preparation of Pap smears. LVS is prepared by scraping the lateral vaginal wall.
- ☐ For sputum, a minimum of three specimens collected on three successive days should be examined. All bronchoscopic material (lavage, washings and brushings) must be dispatched to the laboratory without delay.
- ☐ Specimens of effusion, CSF and semen should be sent to laboratory unfixed immediately for examination.
- ☐ Material for exfoliative cytodiagnostics is usually wet-fixed. Sometimes, exfoliative cytology smears are air-dried like blood smears.
- ☐ The ideal fixative for routine use is Papanicolaou's fixative comprising a solution of equal parts of ether and 95% ethanol.
- ☐ Some cytologic material may require preparation and processing in the laboratory e.g. sputum and fluids. It includes centrifugation.
- ☐ Papanicolaou and H&E stains are used for wet-fixed smears while Romanowsky stains (e.g. Leishman's, MGG, Wright's) are used for air-dried smears.

INTERVENTIONAL CYTOLOGY

In interventional cytology, samples are obtained by aspiration or surgical biopsy. This branch includes fine needle aspiration cytology, imprint cytology, crush smear cytology and biopsy sediment cytology.

I. FINE NEEDLE ASPIRATION CYTOLOGY

Interventional cytology is virtually synonymous with Fine Needle Aspiration Cytology (FNAC). The technique has gained

wide acceptance in the last four decades and is increasingly being used to sample a wide variety of body tissues. Almost all organ systems are accessible to the fine needle and versatility of the technique has enormously increased the scope of diagnostic cytology. The applications and advantages of FNAC, its procedure, complications and limitations are briefly outlined here.

A. APPLICATIONS OF FNAC

In routine practice, FNAC is most often used for diagnosis of palpable mass lesions. Palpable lesions commonly sampled are: breast masses, enlarged lymph nodes, enlarged thyroid and superficial soft tissue masses. The salivary glands, palpable abdominal lesions and the testicles are also frequently sampled for FNAC. Other sites and lesions accessible to FNAC are the prostate, pelvic organs, bone and joint spaces, lungs, retroperitoneum and orbit.

B. ADVANTAGES OF FNAC

- i) FNAC is an OPD procedure and requires *no hospitalisation* while surgical biopsies are obtained in the operation theatre and hospitalisation is often required.
- ii) *No anaesthesia* is required (except in specific circumstances), while surgical biopsy is performed under local or general anaesthesia.
- iii) The procedure is *quick, safe and least painful*.
- iv) *Multiple attempts* (or repeating the procedure) are possible without inconvenience, whereas repeating a surgical biopsy is uncomfortable and inconvenient for the patient.
- v) Results are obtained *rapidly* with reports being available in a matter of hours (turn-around time of 2 to 24 hours depending on the urgency), while histopathological reports are available after a longer duration (turn-around time of 2 to 4 days on account of time required for processing and sectioning of tissues).
- vi) It is a *cost-effective* procedure and no major equipment is required.
- vii) As the cytopathologist performs the procedure himself, *first-hand knowledge* of the clinical findings is gained which facilitates interpretation of slides and enhances diagnostic accuracy.

C. GENERAL PROCEDURE FOR FNAC

Materials

For performing FNAC, a syringe with a well-fitting needle, syringe holder, some microscopic glass slides and a suitable fixative are the only material required in most instances (**Fig. A-I.10**):

NEEDLES Fine needles range from 25 to 20 gauge (0.6 mm to 0.9 mm outer diameter). The standard 21 gauge disposable needle of 38 mm length is suitable for routine transcutaneous FNAC of palpable masses; 25 or 24 gauge disposable needles of 25 mm length are used for lymph nodes and in children. Larger needles, 80 to 160 mm in length, are required for sampling the lung and abdominal viscera; 22 to 20 gauge Chiba spinal puncture needles may be profitably employed for this purpose. Needles of up to 200 mm length are used for transrectal FNAC of the prostate and for transvaginal FNAC of the ovary. Aspiration of bony lesions may require 18 gauge (1 mm outer diameter) needles although superficial lytic lesions are adequately sampled with a 21 gauge needle.

SYRINGES Syringes of 10 to 20 ml capacity are suitable. Syringe holders such as the Franzen handle permit a single-hand grip during aspiration, employing disposable syringes. For needles with metal hubs (e.g. spinal puncture needles), disposable syringes should be used to ensure a proper fit between the needle hub and syringe nozzle.

GLASS SLIDES AND FIXATIVE Four or six standard microscopic glass slides and a Coplin jar containing 95% ethyl alcohol (as a fixative) are the only other material required for routine FNAC.

Method of Aspiration

Transcutaneous FNAC of palpable masses is routinely performed without anaesthesia as per the following procedure; aspiration of sites/lesions requiring anaesthesia or special technique are discussed separately (**Fig. A-I.11**):

- i) The patient is asked to *lie down* in a position that best exposes the target area.
- ii) The target area is thoroughly *palpated* and the firmest portion of the lesion or mass delineated.

Figure A-I.10 Equipments required for transcutaneous FNAC.

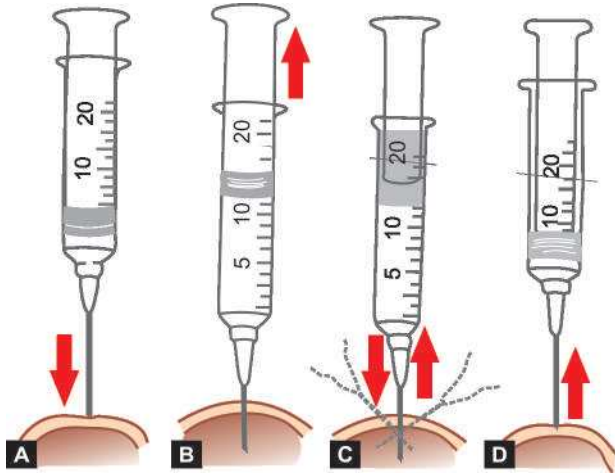

Figure A-I.11 Procedure for FNAC of palpable masses. Needle is introduced into the mass (A). Plunger is retracted after needle enters the mass (B). Suction is maintained while needle is moved back and forth within the mass (C). Suction is released and plunger returned to original position before needle is withdrawn (D).

- iii) The skin is *cleaned* with an alcohol pad.
- iv) The mass is *fixed* by the palpating hand of the operator or by an assistant; gloves may be used for protection of the operator and the assistant.
- v) The needle is *inserted* into the target area. On reaching the lesion, the plunger of the syringe is retracted and at least 10 ml of suction applied while moving the needle back and forth within the lesion; the direction or angle of the needle may be changed to access different areas of the lesion.
- vi) Aspiration is *terminated* when aspirated material or blood becomes visible at the base or hub of the needle. For diagnostic purposes, cellular material contained within the needle is more than adequate; material drawn into the barrel of the syringe is not recovered since it is of no use for cytologic diagnosis.
- vii) On completion of aspiration, suction is *released* and pressure within the syringe allowed to equalise before withdrawing the needle. Withdrawing the needle with negative pressure or suction results in blood being aspirated and cellular material being sucked into the barrel of the syringe, thus lost to interpretation.
- viii) Following withdrawal of the needle from the lesion, *pressure* is applied to the site of puncture by the assistant or patient himself for 2 to 3 minutes in order to arrest bleeding and prevent haematoma formation.

ix) Aspirated material is *recovered* by detaching the needle from the syringe and filling the syringe with air; the syringe and needle are then reconnected and the aspirate expressed onto one end of a glass slide.

Preparation of Smears

Preparation of smears is crucial to the success of FNAC. Poorly-prepared smears with distorted cellular morphology will frustrate the best efforts of the most competent cytopathologist, and often result in errors of interpretation or in failure to arrive at any specific diagnosis. The procedure consists of the following steps (**Fig. A-I.12**):

- i) Aspirates deposited on the slide are *inspected* with the naked eye.
- ii) Semisolid particulate aspirates are *crush-smear*ed by flat pressure with a glass slide or a thick coverslip. Even and gentle pressure is required to avoid traumatising cells. Droplets of fluid or bloody material are gathered under the edge of the angled smearing slide or coverslip and pulled like a blood smear. Particulate material, which collects along the edges and at the end of the smear, is then crush-smear-ed by flattening the smearing slide.
- iii) Prepared smears are either *wet-fixed* or *air-dried*. Half the number of smears are immediately immersed in 95% ethanol, transported to the laboratory in the fixative (wet-fixed), and used for Papanicolaou or H&E staining. The remaining smears are air-dried, wrapped in tissue paper for transport to the laboratory, and stained by Romanowsky stains (e.g. Leishman's, May-Grünwald-Giemsa). Most cytopathologists use both wet-fixed and air-dried smears—the wet-fixed smears provide excellent nuclear detail while the air-dried smears yield information about the cytoplasm and the background. The general properties of wet-fixed and air-dried smears outlined in **Table A-I. 8**.

Special and Ancillary Studies

Aspirates may also be studied by special stains and techniques for specific purposes as under:

1. **SPECIAL STAINS** Wet-fixed smears are used for a variety of special stains such as Alcian blue, mucicarmine and PAS (for mucin and carbohydrates); methyl violet or congo red (for amyloid); and bacterial and fungal stains (for microbial agents).
2. **MICROBIOLOGICAL STUDIES** Aspirates may also be submitted for viral, fungal, mycobacterial and bacterial culture.

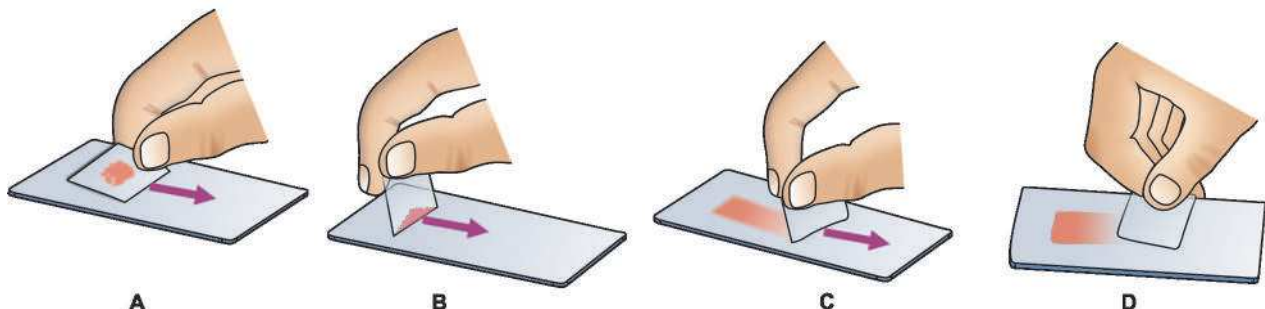

Figure A-I.12 Preparation of smears. Semisolid aspirates are crush-smear-ed by flat pressure with cover slip or glass slide (A). Fluid or blood droplet is collected along edge of spreader (B), and pulled as for peripheral blood films (C). Particles at the end of the smear are crush-smear-ed (D).

Table A-I.8 General properties of wet-fixed and air-dried smears.

| Feature | Wet-fixed | Air-dried |
|--------------------------------|-----------------------------------|-------------------------------|
| 1. Staining | Papanicolaou, H&E | Leishman, May-Grünwald-Giemsa |
| 2. Cell size | Comparable to tissue sections | Exaggerated |
| 3. Nuclear detail | Excellent | Fair |
| 4. Nucleoli | Well demonstrated | Not always discernible |
| 5. Cytoplasmic details | Poorly demonstrated | Well demonstrated |
| 6. Stromal components | Poorly demonstrated | Well demonstrated |
| 7. Partially necrotic material | Single intact cells, well defined | Cell details poorly defined |

When infection is suspected, an additional aspirate is obtained and expressed into a sterile culture tube. If additional aspiration is not feasible, the needle is flushed with sterile isotonic saline and the rinsed fluid submitted for microbial culture.

3. CELL BLOCK Aspirated material may be processed as surgical pathology material by preparing paraffin blocks from cell button of the centrifuged deposit. Sections provide recognition of histologic patterns and can also be used for ancillary techniques.

4. IMMUNOCYTOCHEMICAL STUDIES The smears or cell block sections can be further evaluated by immunocytochemical stains by employing panel of antibodies selected on the basis of differential diagnosis made after routine morphologic examination of smears.

5. IMAGE ANALYSIS AND MORPHOMETRY These techniques when applied to cytological smears bring quantitation and objectivity to cytodagnosis. They determine the cellular parameters like N/C ratio, nuclear area, shape and size of nuclei and nucleoli etc.

6. FLOW CYTOMETRY Determination of ploidy status and S phase fraction of tumour cells using flow cytometry enhances the diagnostic and prognostic information available on routine cytology.

7. ULTRASTRUCTURAL STUDIES Aspirates obtained by FNAC are also suitable for electron microscopy (both TEM and SEM).

8. MOLECULAR BIOLOGIC TECHNIQUES These techniques are now being widely applied to cytopathology also. Detection of oncogenes like *ERBB-2* in breast cancer, *BCL-2* in lymphomas, DNA sequence analysis, gene expression profiling and fluorescence *in situ* hybridisation (FISH) can all be used for aspiration samples.

Aspiration of Specific Lesions/Body Sites

In addition to the general procedure for FNAC described above, aspiration from certain specific sites/lesions require greater expertise and additional material as outlined below.

1. CYSTS Cysts of the neck, thyroid, breast and other sites are often encountered during FNAC. During aspiration, the entire fluid content is evacuated by drawing into the syringe and collected in test tube for centrifugation and smear preparation. If a residual mass is palpable after removal of fluid, a fresh syringe is used for additional aspiration of the mass in the usual manner.

2. THYROID Lesions of the thyroid are aspirated with the patient either sitting up or lying supine with the neck extended. Solitary nodules are fixed between two palpating fingers, while a diffusely enlarged lobe is fixed by asking the patient to swallow and applying two fingers to the base of the lobe to hold it against the trachea. The patient is asked to avoid swallowing during aspiration. Subsequently, firm pressure is applied to the puncture site for about 3 minutes to prevent haematoma formation.

3. LUNG AND RETROPERITONEUM FNAC of these two sites is usually carried out under the guidance of radiological imaging techniques. Local anaesthesia (1% xylocaine) is advisable with infiltration of skin and deeper tissues. Spinal puncture needles (22 or 20 gauge) are used. Since these long needles are flexible they are rotated during insertion to enable an accurate approach to the target lesion.

4. PROSTATE The prostate is sampled transrectally during per-rectal examination with the patient in lithotomy position. A custom-made or commercially available needle guide (such as the Franzen needle guide) may be used. Alternatively, a 16 gauge blunt-tipped venous cannula may serve as a needle guide. The cannula is taped to the index finger of the gloved hand with its tip just proximal to the pulp of the index-finger, and a fingercot drawn over it. The prostatic lesion is palpated with the pulp of the finger and sampled by puncturing through the fingercot with a long 22 gauge needle introduced through the cannula.

5. TESTIS Local anaesthesia is advisable when FNAC of the testis is carried out for infertility as pain may be considerable when suction is applied. Spermatic cord block is employed for the purpose. Infiltration of scrotal skin is not required. For suspected testicular tumours, local anaesthesia is not required; however, thinner needles (25 or 24 gauge) are advocated by some workers to avoid seeding of tumour along the needle track.

6. ABDOMINAL FAT ASPIRATION FNA of the para-umbilical abdominal adipose tissue is currently accepted method for diagnosis of secondary systemic amyloidosis. Amyloid is demonstrated as rings around fat cells by the conventional Congo red staining (congophilia) and apple-green birefringence when viewed under polarising microscopy.

Radiological Imaging Aids for FNAC

Non-palpable lesions require some form of localisation by radiological aids for FNAC to be carried out. *Plain X-ray films* are usually adequate for lesions within bones and for

some lesions within the chest. FNAC of the chest may also be attempted under *image amplified fluoroscopy* which allows visualisation of needle placement on the television monitor. *Computerised tomographic-(CT) guidance* is also used for lesions within the chest and abdomen. The most versatile radiological aid is *ultrasonographic (US)-guidance* which allows direct visualisation of needle placement in real time and is free from radiation hazards. It is an extremely valuable aid for FNAC of thyroid nodules, soft tissue masses, intra-abdominal lesions and for intrathoracic lesions which abut the chest wall, but is of no help in deep intrathoracic lesions or in bony lesions.

D. COMPLICATIONS AND HAZARDS OF FNAC

FNAC is associated with relatively few complications. Possible hazards and more commonly encountered complications are as follows:

1. Haematomas Bleeding from the puncture site and haematoma formation are the commonest complications of the procedure, particularly in the breast and the thyroid. Firm finger pressure for 2 to 3 minutes immediately after the procedure greatly reduces the frequency of these complications.

2. Infection Introduction of infection is not a significant hazard; even transabdominal aspiration does not result in peritoneal contamination despite puncture of bowel walls. Transrectal aspiration in cases of acute prostatitis may, however, result in bacteraemia and septicaemia.

3. Pneumothorax Transcutaneous aspiration of the lung causes pneumothorax in about 20% of cases; most resolve spontaneously although intercostal intubation may be required in some instances. Transient haemoptysis may also be associated with lung aspiration.

4. Dissemination of tumour Generalised dissemination of malignant cells via lymphatics and blood vessels following FNAC is a theoretical possibility but no definite instances have been recorded. Local dissemination by seeding of malignant cells along the needle tract is a rare complication and has been reported in cancers of the lung, prostate and pancreas.

Aspiration of malignant ovarian cysts may result in release of cyst contents into the peritoneal cavity with peritoneal implants.

E. PRECAUTIONS AND CONTRAINDICATIONS OF FNAC

While FNAC is generally a safe procedure, precautions have to be taken when aspiration is contemplated of some sites under certain circumstances:

1. Bleeding disorders Thrombocytopenia *per se* is not a contraindication to FNAC. In patients with coagulopathies such as haemophilia, aspiration of joint spaces, chest and abdominal viscera is contraindicated; superficial lesions may be aspirated and pressure applied to the puncture site for at least 5 minutes following the procedure.

2. Liver Estimation of prothrombin time is an essential prerequisite for aspiration of the liver. FNAC is not advisable if prothrombin index (PTI) is less than 80%. Obstructive jaundice is a relative contraindication for FNAC on account of the risk of bile peritonitis.

3. Lung FNAC of the lung should not be undertaken in elderly patients with emphysema or pulmonary hypertension because of the enhanced risk of pneumothorax and haemoptysis respectively.

4. Pancreas FNAC is contraindicated in acute pancreatitis as it aggravates the inflammatory process.

5. Prostate Transrectal aspiration in acute prostatitis may cause bacteraemia/septicaemia and is contraindicated.

6. Testis Aspiration is extremely painful in acute epididymo-orchitis and should be deferred till such time the acute inflammatory process subsides. The patient is treated with anti-inflammatory agents and antibiotics and FNAC undertaken at a later date.

7. Adrenal FNAC of a suspected pheochromocytoma is inadvisable as it may sometimes provoke extreme fluctuations in blood pressure.

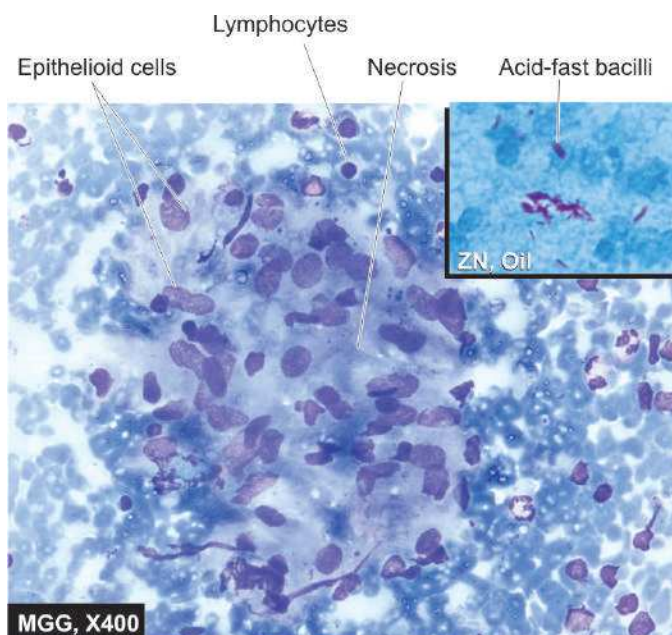

Figure A-I.13 FNA lymph node showing tuberculous lymphadenitis. Inset shows Ziehl-Neelsen staining having many tubercle bacilli.

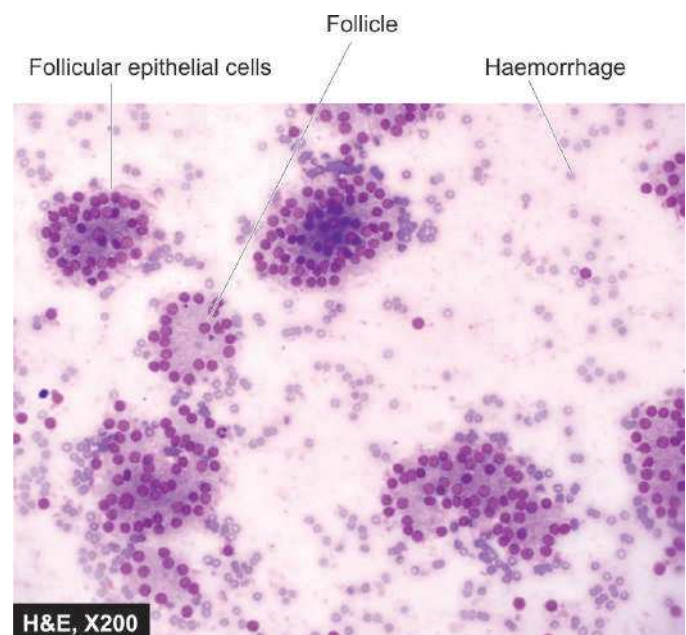

Figure A-I.14 FNA thyroid showing follicular neoplasm.

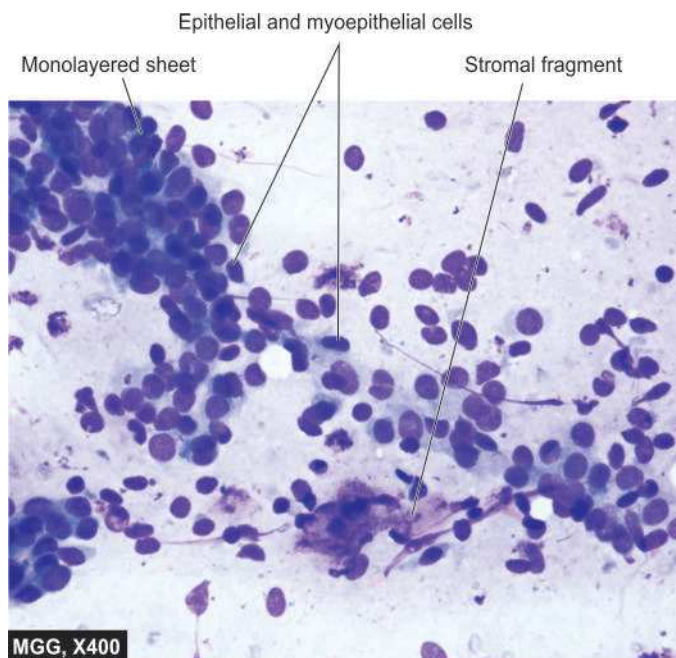

Figure A-I.15 FNA breast lump showing features of fibroadenoma.

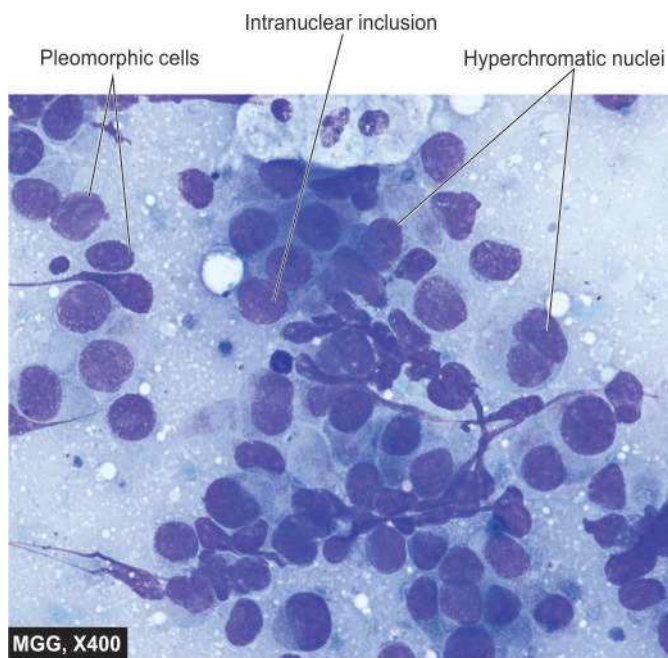

Figure A-I.16 FNA breast showing features of infiltrating ductal carcinoma.

F. CYTOLOGIC DIAGNOSIS

The cytopathologist can render a preliminary diagnosis within one hour after the FNAC procedure when urgently required. Basic cytologic features in FNAC are similar to those in histopathology but smear cytology depends upon the technique for smear and stains employed. Emphasis in FNA cytology is on pattern recognition or arrangement of cells, nuclear and cytoplasmic features of individual cells or groups of cells, and comment on the background morphology.

Understandably, it is beyond the scope of this book to delve into morphological details of various lesions which can be sampled by FNAC; interested readers in this subject are referred

to the specialised texts listed at the end of the book. However, a few common and classical examples of FNAC applications in lymph node (tuberculous lymphadenitis, **Fig. A-I.13**), thyroid (follicular neoplasm, **Fig. A-I.14**), breast (fibroadenoma and infiltrating carcinoma, **Figs. A-I.15 and A-I.16**), abdominal fat (for amyloid, **Fig. A-I.17**) and cell-block preparation along with immunocytochemistry (**Fig. A-I.18**) are illustrated.

G. LIMITATIONS OF FNAC

The main limitation of FNAC lies in the fact that only a small population of cells is sampled by the procedure. The reliability of the test, thus, depends upon the adequacy of the sample

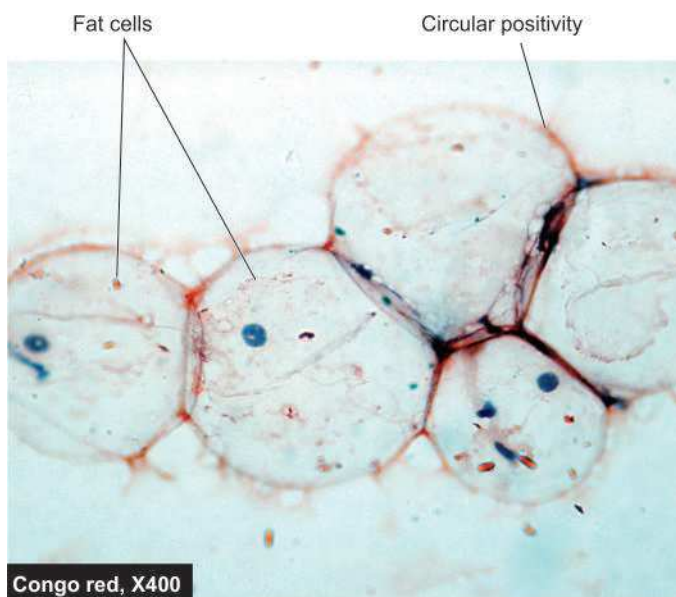

Figure A-I.17 Abdominal fat aspirate stained with Congo red stain for amyloid.

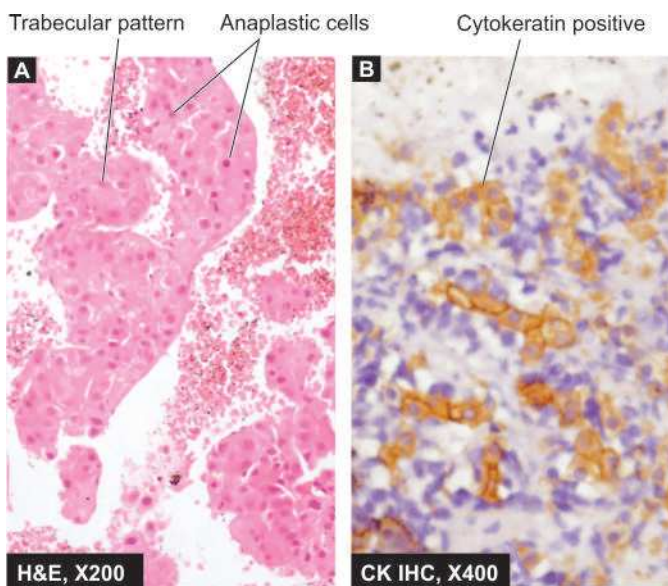

Figure A-I.18 A, Section of cellblock preparation showing hepatocellular carcinoma. B, Same cellblock, stained with cytokeratin for epithelial cells.

and its representative character. An inadequate sample which is not representative of the true lesion results in a 'false-negative' diagnosis. If the FNAC report is 'negative' despite a strong clinical suspicion of malignancy, the patient should be investigated further. FNAC may be repeated or a surgical biopsy performed to obtain a tissue diagnosis in such instances.

Lack of requisite clinical information (e.g. size, site and character of mass) or relevant investigative results (e.g. X-ray findings, reports of haematologic and biochemical tests etc.) further limit the utility of FNAC. Knowledge of the exact site from where the aspirate has been obtained is crucial to the accurate interpretation of FNAC smears and lack of this information severely compromises the ability of the cytopathologist to provide a diagnosis.

II. IMPRINT CYTOLOGY

In imprint cytology, touch preparations from cut surfaces of fresh unfixed surgically excised mass lesions are examined. Imprints may also be obtained from draining sinuses or ulcerated areas.

For surgically resected specimens (e.g. lymph nodes), smears are prepared by bisecting or slicing the specimen and lightly touching or pressing a glass slide onto the freshly exposed surface without smearing it. Smears cannot be prepared from fixed specimens. Imprint smears are wet-fixed or air-dried and stained as per routine.

The main advantage of the imprint smear is that the cell distribution reflects, and to some extent, recapitulates tissue architecture thus aiding in interpretation. The technique is used in the intraoperative diagnosis of malignancy as a complement to frozen-section, and is also valuable as an adjunct to histopathology in the typing of lymphomas.

III. CRUSH SMEAR CYTOLOGY

Crush smear preparations of tissue particles obtained by craniotomy have been used in the diagnosis of brain tumours. These smears are preferred by many workers as they allow recognition of tissue architecture to some degree, in addition to better cytological details.

IV. BIOPSY SEDIMENT CYTOLOGY

Biopsy sediment cytology entails the examination of sediment obtained by centrifugation of fixatives/fluids in which surgical

biopsy specimens are dispatched to the laboratory. The method may be useful in the rapid diagnosis of bone tumours as histological sections are usually obtained after many days on account of the delay necessitated by decalcification. For soft tissue specimens, the technique offers no particular advantage.

In conclusion, both exfoliative cytology and FNA cytology have now become a part of diagnostic pathology. It is imperative for the student in pathology as well as the clinician to be familiar with the advantages and limitations of cytologic diagnosis. It is acknowledged that a marked decline in incidence of cervical cancer in developed countries is attributable to highly successful preventive Pap smear screening programme. Similarly, large number of surgical diagnostic procedures are now avoided by rational use of FNAC. However, in view of unique responsibility of pathologist in patient management, reporting cytopathologist should be adequately trained in the skill and should not hesitate to ask for ancillary diagnostic techniques, or advise the use of core biopsy or open biopsy, wherever appropriate.

GIST BOX A-I.4

Interventional Cytology

- ☐ FNAC is a versatile procedure and almost all organ systems are accessible to the fine needle aspiration.
- ☐ For performing FNAC, a syringe with a well-fitting needle, syringe holder, some microscopic glass slides and a suitable fixative are the only material required in most instances.
- ☐ Half the prepared smears are wet-fixed and used for Papanicolaou or H&E staining. The remaining smears are air-dried and stained by Romanowsky stains such as MGG.
- ☐ Major advantages of FNAC are that it is as an OPD procedure, no anaesthesia is required, it is quick, safe, least painful and cost-effective, and allows multiple attempts.
- ☐ Deep-seated organs may require image guided FNAC e.g. guidance by ultrasound, CT etc.
- ☐ Imprint cytology involves making touch preparations from cut surfaces of fresh unfixed surgically excised mass lesions.
- ☐ Crush smear preparations of tissue particles are used in the diagnosis of brain tumours.
- ☐ Biopsy sediment cytology is examination of sediment obtained by centrifugation of fixatives in which surgical biopsy specimens are sent e.g. in bone tumours.

Appendix

Answers to Clinical Cases

PREAMBLE

With introduction of clinical cases as a method of learning pathology in this edition, a newer dimension has been added to enliven the field of “basic pathology” by directing the learner towards “applied pathology” as applied to clinical problems. These clinical cases (case 1 to 30) given at the end of most chapters are structured clinical exercises to stimulate the students of pathology to apply their knowledge and skills gained from the study of particular disease/s covered in that chapter in pathology (e.g. demographic profile, etiology, pathogenesis, clinical and morphologic features, complications etc) to clinical settings as encountered in real life.

The brief discussion on *clinical correlation* of each case given below follows an analytical and rational approach in order to resolve the clinical problem, giving due importance to each feature given in the clinical history, findings on examination, or any other data provided. This is concluded with a *probable clinical diagnosis*. An approach to *investigate* the case in a systematic manner follows next. In general, this scheme of investigations begins with some basic preliminary tests which are done in almost every case, listed as “*screening tests*”. This is followed by “*additional tests*” which help in confirming the diagnosis. However, the details of the disease given in the diagnosis are not repeated here but instead reference to the concerned page of the textbook has been given for further explanation and study.

✿ CLINICAL CASE 1 (Chapter 3, Page 77)

1. CLINICAL CORRELATION Major clinical feature of long-standing productive cough in this adult male smoker for 25 years is due to chronic bronchitis, which over a period of many years, has led to bronchiectasis and hence foul smelling expectoration for so many years. Interspersed haemoptysis can occur in bronchiectasis due to bleeding of friable inflamed mucosa although it requires further investigations to rule out lung cancer. Two earlier episodes of pneumonia are due to bacterial infections causing consolidation which are common in such patients. His current presenting feature of fever is also due to bacterial infection of the lung parenchyma. Shortness of breath and increased respiratory rate are due to impaired pulmonary function from damaged lung parenchyma in COPD. Rhonchi and crepitations reflect damaged airways containing secretions. Clubbing of fingers is due to chronic hypoxia for many years. Weight loss and anaemia are due to systemic features of chronic infection; mild icterus is owing to mild liver dysfunction. Pedal oedema is due to hypoproteinaemia which could be due to proteinuria since long-standing chronic infectious and destructive condition like bronchiectasis can cause secondary amyloidosis.

2. PROBABLE DIAGNOSIS Bronchiectasis with nephrotic syndrome, possibly due to secondary systemic amyloidosis

3. INVESTIGATIONS*Screening tests*

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear for type of anaemia.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.
- iv) Blood culture.
- v) Sputum (culture, cytologic examination, Gram's stain and tubercle bacilli).
- vi) X-ray chest.
- vii) Ultrasound examination of abdomen.

Additional tests

- i) Bronchoscopy along with cytologic and/or biopsy material.
- ii) Pulmonary function tests.
- iii) 24-hour urinary proteins.
- iv) Abdominal fat aspiration for amyloid.
- v) Renal biopsy for secondary amyloidosis.

Further details on page 61, 465.

✿ CLINICAL CASE 2 (Chapter 4, Page 115)

1. CLINICAL CORRELATION The woman underwent an abortion under poor hygienic conditions 3 days back and therefore, developed serious sepsis. Her high-grade fever is systemic manifestation of fulminant septicaemia. Her bleeding from gums is due to reduced platelet count from consumptive coagulopathy accompanying sepsis. Her unrecordable blood pressure and pulse along with rapid breathing are due to hypotension and metabolic abnormalities. She is unconscious due to metabolic derangement accompanying renal failure from hypoxia-ischaemia affecting higher centres. Thrombocytopenic bleeding is a pointer towards development of intravascular thrombosis in septic shock.

2. PROBABLE DIAGNOSIS Septic shock and disseminated intravascular coagulation (DIC)

3. INVESTIGATIONS

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear for type of anaemia.
- ii) Coagulation profile (PT, PTTK, TT, FDPs, D-dimer).
- iii) Blood grouping.
- iv) Serology for HBV, HCV, HIV.

- v) VDRL.
- vi) Arterial blood gas (ABG) analysis.
- vii) Blood grouping.
- viii) Urine examination (albumin, glucose, microscopy).
- ix) Biochemical estimation: Serum sodium, potassium and calcium, renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose.
- x) All cultures (blood, urine, vaginal discharge).
- xi) Radioimaging (X-ray chest, abdomen, ultrasound abdomen).

Further details on page 94.

CLINICAL CASE 3 (Chapter 5, Page 164)

1. CLINICAL CORRELATION This patient has acute exacerbation of a chronic disease which has caused significant weight loss in 6 months and progressive fatigue. Truck drivers who are on the move on highways are a well-recognised high-risk group for HIV-AIDS due to their casual multiple sexual activity. His acute symptoms of high-grade fever, productive cough and rapid breathing point towards a severe lung infection such as pneumonia or tuberculosis, both of which are more common in HIV-AIDS due to immunocompromised state. Headache, stiffness of neck and a positive Kernig's sign are features of meningitis, which could be dissemination of infection to the brain and meninges such as miliary spread of tuberculosis by haematogenous route. Papilloedema is due to increased CSF pressure from meningitis. Enlargement of lymph nodes and hepatosplenomegaly are due to involvement of reticuloendothelial organs in AIDS. Presence of warts at several sites point towards opportunistic infections in such patients.

2. PROBABLE DIAGNOSIS HIV infection with opportunistic infections, disseminated tuberculosis, with possibly tuberculous meningitis (TBM)

3. INVESTIGATIONS

Screening tests

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.
- iv) Sputum (culture, cytologic examination, Gram's stain and tubercle bacilli).
- v) Blood culture.
- vi) X-ray chest.
- vii) Ultrasound examination of abdomen.

Additional tests

- i) Serology for HIV, HBV, HCV.
- ii) Western blot.
- iii) STS/VDRL.
- iv) CD4 +T cell count and ratio of CD4:CD8+ cells.
- v) CSF examination (microscopy, chemical analysis).
- vi) Bronchoscopy along with cytologic and/or biopsy material.

- vii) Pulmonary function tests.
- viii) FNAC of enlarged lymph node.

Further details on pages 51, 137.

CLINICAL CASE 4 (Chapter 10, Page 303)

1. CLINICAL CORRELATION Presence of pallor, malaise and dyspnoea are systemic features of anaemia in this young woman who has history of blood loss by repeated abortions followed by menorrhagia. Anaemia due to blood loss and nutritional deficiency are most common causes of anaemia in women in reproductive years, especially in these from poor socioeconomic status.

2. PROBABLE DIAGNOSIS Nutritional anaemia due to blood loss, likely iron deficiency anaemia

3. INVESTIGATIONS

Screening tests

- i) CBC (haemoglobin, counts including reticulocyte count, indices), ESR, PCV, blood smear for type of anaemia.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose.
- iv) X-ray chest.
- v) Ultrasound examination of abdomen.

Additional tests

- i) Serum estimation of iron, TIBC, ferritin, B₁₂ and folate assay.
- ii) Bone marrow examination for type of anaemia.

Further details on page 272.

CLINICAL CASE 5 (Chapter 10, Page 304)

1. CLINICAL CORRELATION This child has severe anaemia with expansion of bones of cheek and forehead due to hyperplasia of the bone marrow. Growth retardation is due to deposition of iron in the pituitary gland. Bulging abdomen is due to moderate enlargement of the spleen and mildly enlarged liver. Such constellation of clinical features is due to inherited haemolytic anaemia. The mother too has persisting mild chronic anaemia since early years which could be due to thalassaemia trait.

2. PROBABLE DIAGNOSIS Congenital haemolytic anaemia, likely β -thalassaemia major

3. INVESTIGATIONS

Screening tests

- i) CBC (haemoglobin, counts including reticulocyte count, indices), ESR, PCV, blood smear for type of anaemia.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio).
- iv) Serology for HBV, HCV, HIV.

- v) X-ray chest.
- vi) Ultrasound examination of abdomen.
- vii) Family study for thalassaemia trait.

Additional tests

- i) Estimation of foetal haemoglobin.
- ii) Haemoglobin electrophoresis.
- iii) Osmotic fragility test
- iv) Serum estimation of iron, TIBC, ferritin.
- v) Bone marrow examination.

Further details on page 299.

✿ CLINICAL CASE 6 (Chapter 11, Page 320)

1. CLINICAL CORRELATION This 30 years old woman has bleeding tendencies in the form of purpuric spots recently, and epistaxis and heavy menstrual blood loss for the last more than 6 months. Such forms of bleeding are more common in bleeding due to thrombocytopenia rather than coagulation abnormality. Mild enlargement of the spleen points towards condition becoming chronic.

2. PROBABLE DIAGNOSIS Chronic immune thrombocytopenic purpura (ITP)

3. INVESTIGATIONS

Screening tests

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear for type of anaemia.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose.
- iv) X-ray chest.
- v) Ultrasound examination of abdomen.

Additional tests

- i) Bone marrow examination.
- ii) Antiplatelet antibody test.
- iii) Platelet survival studies.

Further details on page 311.

✿ CLINICAL CASE 7 (Chapter 12, Page 369)

1. CLINICAL CORRELATION The child has several manifestations pointing towards acute leukaemia—quite high TLC, low platelet count with thrombocytopenic bleeding from nose, moderate anaemia and mild organomegaly. Low-grade fever is a frequent presenting feature in acute leukaemia along with other features just described. Organomegaly is due to infiltration of the liver and spleen by leukaemic cells. Most common form of acute leukaemia in children is ALL.

2. PROBABLE DIAGNOSIS Acute lymphoblastic leukaemia

3. INVESTIGATIONS

Screening tests

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear for type of anaemia.

- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio).
- iv) X-ray chest.
- v) Ultrasound examination of abdomen.

Additional tests

- i) Bone marrow examination along with cytochemistry.
- ii) Immunophenotyping.
- iii) Cytogenetic studies.

Further details on page 353.

✿ CLINICAL CASE 8 (Chapter 12, Page 369)

1. CLINICAL CORRELATION This elderly patient has pain and tenderness of lower back which on X-ray shows lytic lesion in pelvis and sacrum. One of the cardinal features of multiple myeloma is presence of multiple osteolytic lesions from bone resorption due to infiltration by the malignant plasma cells in the marrow. It is seen more often in the central skeleton and occurs at advanced age. His systemic features of fatigue and anaemia also fit into profile of multiple myeloma rather than metastasis from prostatic carcinoma, another lesion in the central skeleton at this age group in which there are osteoblastic lesions in the bone.

2. PROBABLE DIAGNOSIS Multiple myeloma

3. INVESTIGATIONS

Screening tests

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear for type of anaemia, paraproteins and rouleaux formation.
- ii) Urine examination (albumin, glucose, microscopy and for Bence-Jones proteins).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile, calcium, phosphate.
- iv) Skeletal X-ray.
- v) Ultrasound examination of abdomen.

Additional tests

- i) Bone marrow examination.
- ii) Serum electrophoresis.
- iii) Urine electrophoresis.
- iv) CT-scan of the pelvis and abdomen.
- v) Bone scan.

Further details on page 361.

✿ CLINICAL CASE 9 (Chapter 13, Page 396)

1. CLINICAL CORRELATION This middle-aged executive having acute chest pain has several high risk factors for coronary artery disease—history of hypertension, family history of diabetes mellitus, hypercholesterolaemia, stressful type of job and his age. This is further supported by the history of intermittent chest pain in the past which improved with rest, which was apparently due to angina. It may also be noted that he has not been on medication for hypertension but has been

on dietary therapy, and thus he is not being monitored for hypertension. However, another risk factor, smoking, is absent.

2. PROBABLE DIAGNOSIS Coronary artery disease (acute myocardial infarction)

3. INVESTIGATIONS

- i) ECG
- ii) Biochemical estimation: Serum cardiac markers (CK-MB2: CK-MB1 ratio, LDH-1: LDH2 ratio, cardiac troponins T and I), renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), lipid profile, blood glucose, electrolytes.
- iii) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- iv) Urine examination (albumin, glucose, microscopy).
- v) X-ray chest.
- vi) Ultrasound examination of abdomen.

Further details on page 373, 409.

✿ CLINICAL CASE 10 (Chapter 14, Page 441)

1. CLINICAL CORRELATION This young boy has been having palpitation for one year, which could be due to a cardiac condition. Pansystolic murmur points towards mitral stenosis. For the same duration, he has been having fleeting arthralgia affecting large joints, which are tender and swollen. This is quite typical of jointaches in RHD. Like they say, "rheumatism licks the joints but bites the whole heart," holds true for this patient. Thus, this patient has developed mitral stenosis due to RHD along with involvement of big joints. His low-grade fever for one month along with chills is possibly due to superimposed bacterial infection on the diseased and damaged mitral valve in RHD, i.e. he has developed infective endocarditis on mitral stenosis due to RHD.

2. PROBABLE DIAGNOSIS Rheumatic heart disease and mitral stenosis with superimposed infective endocarditis

3. INVESTIGATIONS

- i) ECG
- ii) Doppler studies
- iii) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- iv) Urine examination (albumin, glucose, microscopy).
- v) C-reactive proteins.
- vi) ASO titres.
- vii) Blood culture.
- viii) Biochemical estimation: Serum cardiac markers (CK-MB2: CK-MB1 ratio, LDH-1: LDH2 ratio, cardiac troponins T and I), renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.
- ix) Serology for HBV, HCV, HIV.
- x) X-ray chest.
- xi) Ultrasound examination of abdomen.

Further details on page 418.

✿ CLINICAL CASE 11 (Chapter 15, Page 487)

1. CLINICAL CORRELATION This elderly unattended patient having fever accompanied with chills and rigors and having productive cough for 15 days fits into the diagnosis

of pneumonia. Infection of lung parenchyma causes crepts and rhonchi due to clogged secretions in the respiratory bronchioles. Fatigue and malaise are other systemic features of infection. Elderly patients due to debility and impaired immunity, especially when neglected, are more likely to progress from trivial upper respiratory infection to lower respiratory tract infection.

2. PROBABLE DIAGNOSIS Lobar pneumonia

3. INVESTIGATIONS

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile, electrolytes.
- iv) Blood culture.
- v) Sputum (culture, cytologic examination, Gram's stain and tubercle bacilli).
- vi) X-ray chest.
- vii) Ultrasound examination of abdomen.

Further details on page 449.

✿ CLINICAL CASE 12 (Chapter 15, Page 487)

1. CLINICAL CORRELATION This 54 years old patient has been having intermittent haemoptysis for 2 months along with loss of weight and appetite, all pointing towards malignancy of the lung. There is earlier history of regular chronic smoking for 3 decades, and thus he has been having chronic bronchitis. The pallor is due to anaemia of chronic disorder, clubbing of fingers is due to chronic hypoxia. Absence of breath sounds on one side of chest and lack of chest movement during breathing on the same side point towards consolidation, possibly from obstruction by a mass in the bronchus.

2. PROBABLE DIAGNOSIS Bronchogenic carcinoma

3. INVESTIGATIONS

Screening tests

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.
- iv) Sputum examination (culture, cytologic examination, Gram's stain and tubercle bacilli).
- v) X-ray chest.
- vi) Ultrasound examination of abdomen.

Additional tests

- i) Bronchoscopy along with cytologic and/or biopsy material.
- ii) FNAC of any enlarged cervical lymph node.
- iii) Pulmonary function tests.
- iv) CT scan of the chest.
- v) Bone scan.

Further details on page 477.

✿ CLINICAL CASE 13 (Chapter 16, Page 503)

1. CLINICAL CORRELATION This 20 years old young man has a polypoid nasal mass causing obstruction to the ostium of maxillary sinus and hence nasal stuffiness and anosmia. Obstruction causes stasis of secretions in the maxillary sinus leading to pain and infection, requiring antibiotics and painkillers. Prolonged chronic inflammation result in thickening of sinus mucosa projecting into the nose. He has also history of nasobronchial allergy as evident from complaint of frequent sneezing for 2 years.

2. PROBABLE DIAGNOSIS Antrochoanal polyp, allergic type

3. INVESTIGATIONS

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination, absolute eosinophil count.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose.
- iv) Sputum (culture, cytologic examination including for eosinophils, Gram's stain and tubercle bacilli).
- v) Serum IgE level.
- vi) X-ray chest.
- vii) Ultrasound examination of abdomen.

Further details on page 497.

✿ CLINICAL CASE 14 (Chapter 17, Page 520)

1. CLINICAL CORRELATION This 50-years old patient has a chronic non-healing ulcer with surrounding induration in the vestibule of his mouth for 2 years due to his chronic habit of keeping the bolus of tobacco in his mouth over many years. Habitual tobacco chewing for years is strongly implicated in causation of cancer of the oral cavity. The appearance of matted lymph nodes in the neck is indicative of nodal metastasis.

2. PROBABLE DIAGNOSIS Carcinoma oral cavity

3. INVESTIGATIONS

Screening tests

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.
- iv) Sputum examination (culture, cytologic examination, Gram's stain and tubercle bacilli).
- v) X-ray chest.
- vi) Ultrasound examination of abdomen.

Additional tests

- i) FNAC of enlarged cervical lymph node.
- ii) Histopathologic examination of biopsy of the lesion from oral cavity.
- iii) CT scan of the abdomen.
- iv) Bone scan.

Further details on page 507.

✿ CLINICAL CASE 15 (Chapter 18, Page 576)

1. CLINICAL CORRELATION This young adult patient has been having dull pain in the middle of upper abdomen with a peculiar pattern—pain getting relieved with food but getting worse on empty stomach at late night. This pattern fits into gastric peptic ulcer. Use of analgesics, particularly NSAIDS group, over an extended period of time are known to damage gastric mucosa. *H. pylori* is also implicated in its etiology. Stressful life and job contribute to it. Upper GI endoscopy has been done in the past indicate persistence of chronic complaints of the patient.

2. PROBABLE DIAGNOSIS Chronic peptic ulcer, gastric

3. INVESTIGATIONS

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.
- iv) Upper GI endoscopy and antral biopsy for *H. pylori*.
- v) X-ray chest.
- vi) Ultrasound examination of abdomen.
- vii) Stool for occult blood.
- viii) Urease breath test.

Further details on page 533.

✿ CLINICAL CASE 16 (Chapter 18, Page 576)

1. CLINICAL CORRELATION This young patient has complaint of acute and persisting abdominal pain without history of any trauma. Within next few hours, pain and tenderness have got localised in lower right iliac fossa where the appendix is located. Appearance of nausea and vomiting point towards colicky nature of pain while fever (102°F) points towards infective etiology.

2. PROBABLE DIAGNOSIS Acute appendicitis

3. INVESTIGATIONS

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Coagulation profile.
- iv) Blood grouping.
- v) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), amylase, blood glucose.
- vi) X-ray chest.
- vii) Plain X-ray abdomen.
- viii) Ultrasound examination of abdomen.

Further details on page 561.

✿ CLINICAL CASE 17 (Chapter 19, Page 634)

1. CLINICAL CORRELATION This elderly male patient's present symptoms are linked to the coronary bypass surgery in which multiple blood transfusions had been given and possibly

the patient contracted infection with viral hepatitis (HBV or HCV) which over the years has resulted in nodular enlargement of the liver indicative of post-hepatitis cirrhosis. His features of splenomegaly, haematemesis (due to bleeding from oesophageal varices), pedal oedema (from hypoproteinaemia), abdominal distension (due to ascites) and jaundice (from hepatocellular injury), all point towards portal hypertension due to cirrhosis. During the last 6 months, he has been losing weight and appetite, progressive weakness and malaise, all of which are indicative of development of malignancy in cirrhotic liver. Moreover, he has also been an ex-smoker for 20 years, which is a potent carcinogen for cancer of the liver.

2. PROBABLE DIAGNOSIS Post-necrotic cirrhosis with portal hypertension and superimposed hepatocellular carcinoma

3. INVESTIGATIONS

Screening tests

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination for type of anaemia.
- ii) Urine examination (albumin, glucose, microscopy, bile salts, bile pigments, urobilinogen).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.
- iv) Serum markers for viral hepatitis (HbSAg, HCV).
- v) HIV serology.
- vi) Coagulation profile.
- vii) X-ray chest.
- viii) Ultrasound examination of abdomen.

Additional tests

- i) Serum alpha foetoprotein (AFP).
- ii) US-guided FNAC of SOL liver.
- iii) CT scan of the abdomen.
- iv) Bone scan.

Further details on page 609, 618.

✿ CLINICAL CASE 18 (Chapter 19, Page 634)

1. CLINICAL CORRELATION This middle-aged obese woman has been having features of chronic disease for 6 months—intermittent dull pain upper abdomen, malabsorption, bloating, flatulence. These features fit into gallstone disease. Now for 2 days, she has developed acute symptoms—jaundice, nausea, vomiting, pain right hypochondrium radiating to interscapular region. These features are due to obstructive jaundice from impaction of gallstone in the common bile duct.

2. PROBABLE DIAGNOSIS Chronic cholecystitis with cholelithiasis and cholestatic jaundice

3. INVESTIGATIONS

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination for type of anaemia.
- ii) Urine examination (albumin, glucose, microscopy, bile salts, bile pigments, urobilinogen).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.

- iv) Serum markers for hepatitis (HbSAg, HCV).
- v) Coagulation profile.
- vi) X-ray chest.
- vii) Ultrasound examination of abdomen.

Further details on page 624.

✿ CLINICAL CASE 19 (Chapter 19, Page 635)

1. CLINICAL CORRELATION Deep jaundice in this elderly patient along with his other immediate clinical features for 2 weeks point towards development of cholestatic jaundice—passing high-coloured urine, clay-coloured stools, intense pruritus, mildly enlarged tender liver and pain in the right hypochondrium. Fever could also be due to obstruction in the biliary tract causing ascending cholangitis. His features of progressive loss of 10 kg weight in 2 months point towards a malignancy at this age. There is history of chronic smoking for 4 decades which is potent carcinogen for various cancers including pancreatic cancer. Obstructive jaundice due to cancer head of pancreas is a common presenting feature. His habit of occasional alcohol use, however, does not fit him into alcoholic liver disease, and alcohol is not implicated in cancer of pancreas.

2. PROBABLE DIAGNOSIS Carcinoma head of pancreas with obstructive jaundice

3. INVESTIGATIONS

Screening tests

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination for type of anaemia.
- ii) Urine examination (albumin, glucose, microscopy, bile salts, bile pigments, urobilinogen).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.
- iv) Serum markers for hepatitis (HbSAg, HCV).
- v) HIV serology.
- vi) Coagulation profile.
- vii) X-ray chest.
- viii) Ultrasound examination of abdomen.

Additional tests

- i) Serum amylase, lipase
- ii) Serum alpha foetoprotein (AFP).
- iii) US-guided FNAC of SOL epigastrium.
- iv) CT scan of the abdomen.
- v) Bone scan.

Further details on page 633.

✿ CLINICAL CASE 20 (Chapter 20, Page 690)

1. CLINICAL CORRELATION Various clinical features and findings on examination of this 5 years old child point towards nephritic syndrome—short history of one month, puffiness of face and pedal oedema (due to hypoproteinaemia and albuminuria), smoky urine (due to microscopic haematuria) and high blood pressure. His past history of neglected and partly healed multiple boils, a streptococcal infection, hint to post-infectious sequelae in the form of acute glomerulonephritis, which is common in children.

2. PROBABLE DIAGNOSIS Nephritic syndrome due to acute post-streptococcal glomerulonephritis

3. INVESTIGATIONS

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear for type of anaemia.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) 24-hour urinary proteins.
- iv) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.
- v) ASO titre.
- vi) Blood culture.
- vii) X-ray chest.
- viii) Ultrasound examination of abdomen.
- ix) Renal biopsy.

Further details on page 652.

✿ CLINICAL CASE 21 (Chapter 20, Page 690)

1. CLINICAL CORRELATION This 50 years old patient has gross haematuria which is otherwise painless, ruling out renal calculi as a possibility. His pain in the right flank and a bimanually palpable mass in the same location and history of significant weight loss in 6 months point towards this mass as malignant tumour in the right kidney. Classical triad of features in renal cell carcinoma are: gross painless haematuria, flank pain, and palpable mass.

2. PROBABLE DIAGNOSIS Renal cell carcinoma, right kidney

3. INVESTIGATIONS

Screening tests

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination for type of anaemia.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.
- iv) Blood grouping.
- v) Serum markers for hepatitis (HbSAg, HCV).
- vi) HIV serology.
- vii) Coagulation profile.
- viii) X-ray chest.
- ix) Ultrasound examination of abdomen.

Additional tests

- i) FNAC of right renal mass.
- ii) CT scan of the abdomen.
- iii) Bone scan.

Further details on page 681.

✿ CLINICAL CASE 22 (Chapter 21, Page 709)

1. CLINICAL CORRELATION This 25 years old young man has history of sudden enlargement of right testis without any history of antecedent trauma and replacement of testis with

a mass in a span of one month. The mass is not cystic, being negative by transillumination. Among testicular tumours, germ cell tumours comprise 95% cases and at this age are more common.

2. PROBABLE DIAGNOSIS Germ cell tumour, right testis

3. INVESTIGATIONS

Screening tests

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.
- iv) Blood grouping
- v) Serum markers for hepatitis (HbSAg, HCV).
- vi) HIV serology.
- vii) Coagulation profile.
- viii) X-ray chest.
- ix) Ultrasound examination of abdomen.

Additional tests:

- i) FNAC of right testicular mass.
- ii) CT scan of the abdomen.
- iii) Bone scan.
- iv) Serum AFP, CEA, hCG.

Further details on page 697.

✿ CLINICAL CASE 23 (Chapter 22, Page 744)

1. CLINICAL CORRELATION This 50 years old post-menopausal woman has ulcerated and friable cervix that bleeds on touch. These features are accompanied with foul smelling vaginal discharge and post-coital bleeding for 6 months. This combination of features is indicative of cervical carcinoma at this age. Her symptom of pain in the back and swelling in the right leg indicate the growth causing compression on neighbouring tissues.

2. PROBABLE DIAGNOSIS Carcinoma cervix

3. INVESTIGATIONS

Screening tests

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.
- iv) Blood grouping
- v) Serum markers for hepatitis (HbSAg, HCV).
- vi) HIV serology.
- vii) Coagulation profile.
- viii) X-ray chest.
- ix) Ultrasound examination of abdomen.

Additional tests

- i) Pap smear
- ii) Biopsy of cervical lesion from viable area.

- iii) CT scan of the abdomen.
- iv) Bone scan.

Further details on page 718.

CLINICAL CASE 24 (Chapter 23, Page 758)

1. CLINICAL CORRELATION This 65 years old woman has a hard irregular lump in the middle quadrant of the breast while the overlying areola shows ulceration, fissuring and oozing from the nipple without any history of trauma to the breast. These changes point to a case of breast cancer which has infiltrated through the overlying skin. Enlargement of a draining lymph node in the axilla is possibly owing to metastasis.

2. PROBABLE DIAGNOSIS Carcinoma breast with Paget's disease and axillary nodal metastasis

3. INVESTIGATIONS

Screening tests

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.
- iv) Blood grouping
- v) Serum markers for hepatitis (HbSAg, HCV).
- vi) HIV serology.
- vii) Coagulation profile.
- viii) X-ray chest.
- ix) Ultrasound examination of abdomen.

Additional tests

- i) Mammography (bilateral)
- ii) FNA of breast lump and axillary lymph node.
- iii) Core needle biopsy of the lesion.
- iv) CT scan of the abdomen and chest.
- v) Bone scan.

Further details on page 752.

CLINICAL CASE 25 (Chapter 24, Page 781)

1. CLINICAL CORRELATION This 60 years old man has been having a waxy nodular lesion on the forehead for about one year which has undergone changes slowly—ulceration and slow increase in size. The margins of ulcer are rolled out and pearly white. Such a non-pigmented ulcer on the face at this age is rodent ulcer. It is slow growing and generally does not involve regional lymph nodes.

2. PROBABLE DIAGNOSIS Basal cell carcinoma skin

3. INVESTIGATIONS

Screening tests

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.

- iv) Blood grouping.
- v) Serum markers for hepatitis (HbSAg, HCV).
- vi) HIV serology.
- vii) Coagulation profile.
- viii) X-ray chest.

Additional tests

- i) FNA of lesion on forehead or excision biopsy.
- ii) Bone scan.

Further details on page 775.

CLINICAL CASE 26 (Chapter 25, Page 820)

1. CLINICAL CORRELATION This young female has a gradually progressive diffuse enlargement of the thyroid for 6 months, which is not nodular or tender. Diffuse thyroid enlargement in a young woman is generally not due to tumours. Her following complaints point towards thyrotoxicosis—irregular and heavy menstrual cycles, weight loss, intermittent headache, nervousness, palpitation, excessive sweating, tremors in both hands, high blood pressure and rapid pulse rate. Lastly, prominence of both eyes completes the triad of Graves' disease (diffuse thyroid enlargement, thyrotoxicosis, ophthalmopathy).

2. PROBABLE DIAGNOSIS Graves' disease (diffuse toxic goitre)

3. INVESTIGATIONS

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.
- iv) Thyroid function tests.
- v) Serum autoantibodies.
- vi) FNA thyroid
- vii) Ultrasound examination of thyroid
- viii) X-ray chest.

Further details on page 796.

CLINICAL CASE 27 (Chapter 25, Page 820)

1. CLINICAL CORRELATION This 57 years old known diabetic (for 7 years) and hypertensive (for 10 years) patient has been on irregular treatment and intermittent monitoring for both these diseases. His present complaints of painful legs and darkening of right great toe indicates development of vascular complications in the form of claudication and gangrene respectively. Finding of pericardial rub points towards pleurisy and bilateral crepts are due to infection of the lungs, which most often in uncontrolled diabetics is of infectious etiology such as tuberculosis. Acute myocardial infarction suffered by him four years back has also been a consequence of poor control of diabetes and hypertension both of which are major risk factors for coronary artery disease.

2. PROBABLE DIAGNOSIS Systemic hypertension and uncontrolled and complicated diabetes mellitus type 2 (gangrene toe, pulmonary tuberculosis, pleurisy)

3. INVESTIGATIONS

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination for type of anaemia.
- ii) Urine examination (albumin, glucose, microscopy, ketones, bile salts, bile pigments, urobilinogen).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose, lipid profile.
- iv) HbA1C estimation.
- v) X-ray chest.
- vi) Doppler study of lower limb.
- vii) Ophthalmic examination.
- viii) Ultrasound examination of abdomen.

Further details on page 675, 808.

CLINICAL CASE 28 (Chapter 26, Page 850)

1. CLINICAL CORRELATION This 12 years old boy has pain and progressive swelling around knee for one month without any history of trauma. This swelling on examination is hard and on X-ray shows a metaphyseal lytic mass in the lower end of femur. Age range (most commonly 10-20 years) and lytic lesion in the metaphyseal region with extension point towards osteosarcoma.

2. PROBABLE DIAGNOSIS Osteosarcoma lower end of femur

3. INVESTIGATIONS**Screening tests**

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), blood glucose.
- iv) Blood grouping.
- v) Serum markers for hepatitis (HbSAg, HCV).
- vi) HIV serology.
- vii) Coagulation profile.
- viii) X-ray chest.

Additional tests

- i) MRI of bone mass.
- ii) FNA of the mass femur.
- iii) Core needle biopsy.
- iv) CT scan of abdomen.
- v) Bone scan.

Further details on page 832.

CLINICAL CASE 29 (Chapter 27, Page 862)

1. CLINICAL CORRELATION This 55 years old male patient has a progressively increasing soft to hard mass in the right upper arm which has attained the size of 6 × 4 cm in 2 months, points towards a malignant tumour. The skin overlying the mass

is stretched; the mass is in the soft tissues, has well-defined borders and is not attached to underlying bone, hints towards a soft tissue sarcoma.

2. PROBABLE DIAGNOSIS Soft tissue sarcoma

3. INVESTIGATIONS**Screening tests**

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), lipid profile, blood glucose.
- iv) Blood grouping.
- v) Serum markers for hepatitis (HbSAg, HCV).
- vi) HIV serology.
- vii) Coagulation profile.
- viii) X-ray chest.

Additional tests

- i) MRI right upper arm.
- ii) FNA of the soft tissue mass.
- iii) Core needle biopsy.
- iv) CT scan of abdomen.
- v) Bone scan.

Further details on page 856.

CLINICAL CASE 30 (Chapter 28, Page 887)

1. CLINICAL CORRELATION This 62 years old man had sudden development of paralysis on right side of the body. He is a known patient of hypertension for 12 years and diabetes mellitus for 10 years, past smoker, and has also been having isolated episodes of stable angina. These features point towards his compromised cardiovascular status due to poor control of hypertension and diabetes. Attack of severe headache preceding the present episode is due to sudden elevation in his blood pressure which has caused intracerebral haemorrhage and cerebral infarct.

2. PROBABLE DIAGNOSIS Stroke (cerebrovascular accident or CVA)

3. INVESTIGATIONS

- i) CBC (haemoglobin, counts, indices), ESR, PCV, blood smear examination.
- ii) Urine examination (albumin, glucose, microscopy).
- iii) Biochemical estimation: Renal function tests (urea, creatinine, BUN), liver function tests (bilirubin, ALT, AST, alkaline phosphatase, total proteins and AG ratio), electrolytes, blood glucose, lipid profile.
- iv) ECG
- v) Coagulation profile
- vi) CT scan head.
- vii) CSF examination (microscopy, chemical analysis).
- viii) Ultrasound examination of abdomen.
- ix) X-ray chest.

Further details on page 871.

Appendix

Normal Values

WEIGHTS AND MEASUREMENTS OF NORMAL ORGANS

In order to understand the significance of alterations in weight and measurement of an organ in disease, it is important to be familiar with the normal values. In the foregoing chapters, normal figures are given alongside the normal structure of each organ/system that precedes the discussion of pathologic states

affecting it. Here, a comprehensive list of generally accepted normal weights and measurements of most of the normal organs in fully-developed, medium-sized individual and a normal healthy newborn are compiled in **Table A-III.1**.

Single value and value within brackets are indicative of the average figure for that organ. Measurements have been given as width × breadth (thickness) × length. An alphabetic order has been followed.

Table A-III.1 Weights and measurements of normal organs.

| <i>Organ</i> | <i>In Adults</i> | <i>At Birth (wherever applicable)</i> |
|---|---------------------|---------------------------------------|
| Adrenal gland | | |
| Weight | 4–5 gm | 8–11 gm |
| Brain | | |
| Weight (in males) | 1400 gm | 320–420 gm |
| Weight (in females) | 1250 gm | — |
| Measurements (sagittal × vertical) | 16.5 × 12.5 cm | — |
| Volume of cerebrospinal fluid | 120–150 ml | — |
| Heart | | |
| Weight (in males) | 300–350 gm | 17–30 gm |
| Weight (in females) | 250–300 gm | — |
| Thickness of right ventricular wall | 0.3–0.5 cm | — |
| Thickness of left ventricular wall | 1.3–1.5 cm | — |
| Circumference of mitral valve | 10 cm | — |
| Circumference of aortic valve | 7.5 cm | — |
| Circumference of pulmonary valve | 8.5 cm | — |
| Circumference of tricuspid valve | 12 cm | — |
| Volume of pericardial fluid | 10–30 ml | — |
| Intestines | | |
| Length of duodenum | 30 cm | — |
| Total length of small intestine | 550–650 cm | — |
| Length of large intestine | 150–170 cm | — |
| Kidneys | | |
| Weight each (in males) | 150 gm | 20–30 gm |
| Weight each (in females) | 135 gm | — |
| Measurements | 3.5 × 5.5 × 11.5 cm | — |
| Liver | | |
| Weight (in males) | 1400–1600 (1500) gm | 100–160 gm |
| Weight (in females) | 1200–1400 (1300) gm | — |
| Measurements | 27 × 8 × 20 cm | — |
| Lungs | | |
| Weight (right lung) | 375–500 (450) gm | 35–55 gm |
| Weight (left lung) | 325–450 (400) gm | — |
| Volume of pleural fluid | < 15 ml | — |
| Oesophagus | | |
| Length (cricoid cartilage to cardia) | 25 cm | — |
| Distance from incisors to gastro-oesophageal junction | 40 cm | — |
| Ovaries | | |
| Weight (each) | 4–8 (6) gm | — |
| Measurements | 1 × 2.5 × 4.5 cm | — |
| Pancreas | | |
| Total weight | 60–100 (80) gm | 3–6 gm |
| Weight of endocrine pancreas | 1–1.5 gm | — |
| Measurements | 3.8 × 4.5 × 18 cm | — |
| Parotid glands | | |
| Weight (each) | 30 gm | — |
| Pituitary gland (Hypophysis) | | |
| Weight | 500 mg | — |

Contd...

Table A-III.1 Weights and measurements of normal organs. (Contd...)

| Organ | In Adults | At Birth (wherever applicable) |
|-------------------------------|-------------------|--------------------------------|
| Placenta | | |
| Weight at term | 400–600 gm | — |
| Prostate | | |
| Weight | 20 gm | — |
| Spleen | | |
| Weight | 125–175 (150) gm | 6–14 gm |
| Measurements | 3.5 × 8.5 × 13 cm | |
| Stomach | | |
| Length | 25–30 cm | — |
| Testis and epididymis | | |
| Weight each (in adults) | 20–27 gm | — |
| Thymus | | |
| Weight | 5–10 gm | 10–35 gm |
| Thyroid | | |
| Weight | 15–40 gm | — |
| Uterus | | |
| Weight (in nonpregnant woman) | 35–40 gm | — |
| Weight (in parous woman) | 75–125 gm | — |

LABORATORY VALUES OF CLINICAL SIGNIFICANCE

The concept of 'normal values' and 'normal ranges' has been replaced by 'reference values' and 'reference limits' in which the variables for establishing the values for the reference

population in a particular test are well defined. Reference ranges are valuable guidelines for the clinician. However, the following cautions need to be exercised in their interpretation:

◆ *Firstly*, they should not be regarded as absolute indicators of health and ill-health since values for healthy individuals often overlap with values for persons afflicted with disease.

◆ *Secondly*, laboratory values may vary with the method and mode of standardisation used; reference ranges given below are based on the generally accepted values by the standard methods in laboratory medicine.

◆ *Thirdly*, International Federation of Clinical Chemistry (IFCC) and International Committee for Standardisation in Haematology (ICSH) have recommended adoption of Systeme International d'Unites or SI units (i.e. IU) by the scientific community throughout world for standardisation of data. Although most clinical laboratories and all medical and scientific journals conform to the SI system, conventional units are still used in many laboratories in many developing countries of the world.

In this section, laboratory values are given in both conventional and international units. Conversion from one system to the other can be done as follows:

$$\text{mg/dl} = \frac{\text{mmol/L} \times \text{atomic weight}}{10}$$

$$\text{mmol/L} = \frac{\text{mg/dl} \times 10}{\text{atomic weight}}$$

In SI system, whole-unit multiple of three as power of ten is used (i.e. 10^3 , 10^6 , 10^9 , 10^{12} , 10^{15} , 10^{18}). The prefixes and conversion factors used for metric units of length (metre), weight (kilogram) and volume (litre) are given in **Table A-III.2**.

The laboratory values given here are divided into three sections: clinical chemistry of blood (**Table A-III.3**), other body fluids (**Table A-III.4**), and haematologic values (**Table A-III.5**). In general, an alphabetic order has been followed.

Table A-III.2 Prefixes and conversion factors in SI system.

| Prefix | Prefix Symbol | Factor | Units of Length | Units of Weight | Units of Volume |
|--------|---------------|------------|------------------------------|-----------------------------|------------------------------|
| kilo- | k | 10^3 | kilometre (km) | kilogram (kg) | kilolitre (kl) |
| | | 1 | metre (m) | gram (g) | litre (l) |
| deci- | d | 10^{-1} | decimetre (dm) | decigram (dg) | decilitre (dl) |
| centi- | c | 10^{-2} | centimetre (cm) | centigram (cg) | centilitre (cl) |
| milli- | m | 10^{-3} | millimetre (mm) | milligram (mg) | millilitre (ml) |
| micro- | μ | 10^{-6} | micrometre (μm) | microgram (μg) | microlitre (μl) |
| nano- | n | 10^{-9} | nanometre (nm) | nanogram (ng) | nanolitre (nl) |
| pico- | p | 10^{-12} | picometre (pm) | picogram (pg) | picolitre (pl) |
| femto- | f | 10^{-15} | femtometre (fm) | femtogram (fg) | femtolitre (fl) |
| atto- | a | 10^{-18} | attometre (am) | attogram (ag) | attolitre (al) |

Table A-III.3 Clinical chemistry of blood. (Contd...)

| Component | Specimen | Reference Value | | |
|---------------------------------|------------------------------|--|-----------------------|-----------------|
| | | Conventional | SI Units | |
| Glucose (fasting) | Plasma | normal | 70–100 mg/dl | < 5.6 mmol/L |
| | | impaired fasting glucose (IFG) | 101–125 mg/dl | 5.6–6.9 mmol/L |
| | | diabetes mellitus | ≥126 mg/dl | ≥7.0 mmol/L |
| Glucose (2-hr post-prandial) | Plasma | normal | <140 mg/dl | <7.8 mmol/L |
| | | impaired glucose tolerance (IGT) | 140–200 mg/dl | 7.8–11.1 mmol/L |
| | | diabetes mellitus | >200 mg/dl | >11.1 mmol/L |
| Haemoglobin A _{1c} | Whole blood | 4–6% | 0.04–0.06 Hb fraction | |
| Immunoglobulins | Serum | IgA | 70–350 mg/dl | 0.70–3.50 g/L |
| | | IgD | 0–14 mg/dl | 0–140 mg/L |
| | | IgE | <0.025 mg/dl | 24–430 µg/L |
| | | IgG | 700–1700 mg/dl | 7.0–17.0 g/L |
| | | IgM | 50–300 mg/dl | 0.50–3.0 g/L |
| Lactate | Plasma (arterial) | 4.5–14.4 mg/dl | 0.5–1.6 mmol/L | |
| Lactate dehydrogenase (LDH) | Serum | 115–221 U/L | 2.0–3.8 µkat/L | |
| Lactate/pyruvate ratio | | 10/1 | | |
| Lipase | Serum | 3–43 U/L | 0.51–0.73 µkat/L | |
| Lipids | <i>See under cholesterol</i> | | | |
| Lipoproteins | Serum | 0–30 mg/dl | 0–300 mg/L | |
| 5- Nucleotidase | Serum | 0–11 U/L | 0.02–0.19 µkat/L | |
| Oxygen (% saturation) | arterial blood | 94–100% | | |
| | venous blood | 60–85% | | |
| pH | Blood | 7.35–7.45 | 7.35–7.45 | |
| Phosphatases | acid phosphatase | 0–5.5 U/L | 0.90 µkat/L | |
| | alkaline phosphatase | 33–96 U/L | 0.56–1.63 µkat/L | |
| Phosphorus, inorganic | Serum | 2.5–4.3 mg/dl | 0.81–1.4 mmol/L | |
| Potassium | Serum | 3.5–5.0 mEq/L | 3.5–5.0 mmol/L | |
| Prostate specific antigen (PSA) | Serum | 0–4.0 ng/ml | 0–4.0 µg/L | |
| Proteins | Serum | total | 6.7–8.6 g/dl | 67–86 g/L |
| | | albumin | 3.5–5.5 g/dl (50–60%) | 35–55 g/L |
| | | globulins | 2.0–3.5 g/dl (40–50%) | 20–35 g/L |
| | | α ₁ globulin | 0.2–0.4 g/dl (4–7%) | 2–4 g/L |
| | | α ₂ globulin | 0.5–0.9 g/dl (7–10%) | 5–9 g/L |
| | | β globulin | 0.6–1.1 g/dl (9–15%) | 6–11 g/L |
| | | γ globulin | 0.7–1.7 g/dl (13–23%) | 7–17 g/L |
| A/G ratio | | 1.5–3 : 1 | | |
| Pyruvate | Plasma (arterial) | 0.35–1.14 mg/dl | 40–130 µmol/L | |
| Renal blood flow | | 1200 ml/min | | |
| Rheumatoid factor | Serum | < 30 IU/ml | < 30 kIU/L | |
| Sodium | Serum | 136–146 mEq/L | 136–146 mmol/L | |
| Thyroid function tests | Serum | radioactive iodine uptake (RAIU) 24-hr | 5–30% | |
| | | thyroxine (T ₄) total | 5.4–11.7 µg/dl | 70–151 nmol/L |
| | | triiodothyronine (T ₃) total | 77–135 ng/dl | 1.2–2.1 nmol/L |
| | | thyroid stimulating hormone (TSH) | 0.4–5.0 µU/ml | 0.4–5.0 mU/L |
| Troponins, cardiac (cTn) | Serum | troponin I (cTnI) | 0–0.08 ng/ml | 0–0.8 µg/L |
| | | troponin T (cTnT) | 0–0.01 ng/ml | 0–0.1 µg/L |

Table A-III.3 Clinical chemistry of blood. (Contd...)

| Component | Specimen | Reference Value | |
|---------------------|----------|-----------------|-----------------------|
| | | Conventional | SI Units |
| Urea | Blood | 20–40 mg/dl | 3.3–6.6 mmol/L |
| Urea nitrogen (BUN) | Blood | 7–20 mg/dl | 2.5–7.1 mmol/L |
| Uric acid | Serum | | |
| males | | 3.1–7.0 mg/dl | 0.18–0.41 μ mol/L |
| females | | 2.5–5.6 mg/dl | 0.15–0.33 μ mol/L |

Table A-III.4 Other body fluids.

| Component | Specimen | Reference Value | |
|--|-------------------------|--|--------------------------|
| | | Conventional | SI Units |
| Body volume, water | | | |
| total | | 50–70% (60%) | |
| intracellular | | 33% | |
| extracellular | | 27% | |
| interstitial fluid including lymph fluid | | 12% | |
| intravascular fluid or blood plasma | | 5% | |
| fluid in mesenchymal tissues | | 9% | |
| transcellular fluid | | 1% | |
| Catecholamines | 24-hr urinary excretion | | |
| epinephrine | | < 10 ng/day | |
| free catecholamines | | <100 mg/day | |
| metanephrine | | <1.3 mg/day | |
| vanillyl mandelic acid (VMA) | | <8 mg/day | |
| Cerebrospinal fluid (CSF) | CSF | | |
| CSF volume | | 120–150 ml | |
| CSF pressure | | 60–150 mm water | |
| leucocytes | | 0–5 lymphocytes/ μ l | |
| pH | | 7.31–7.34 | |
| glucose | | 40–70 mg/dl | |
| proteins | | 20–50 mg/dl | |
| FIGLU | 24-hr urine | <3 mg/day | <17.2 μ mol/day |
| Gastric analysis | Gastric juice | | |
| 24-hr volume | | 2–3 L | |
| pH | | 1.6–1.8 | 1.6–1.8 |
| basal acid output (BAO) | | 1–5 mEq/hr | 1–5 mmol/hr |
| maximal acid output (MAO) | | 5–40 mEq/hr | 5–40 mmol/hr |
| after injection of stimulant | | | |
| BAO/MAO ratio | | <0.6 | |
| Glomerular filtration rate (GFR) | Urine | 180 L/day (about 125 ml/min) | |
| 5-HIAA | 24-hr urinary excretion | 2–9 mg/day | 10–47 μ mol/day |
| 17-Ketosteroids | 24-hr urinary excretion | | |
| males | | 7–25 mg/day | |
| females | | 4–15 mg/day | |
| Microalbumin | 24-hr urinary excretion | 0–30 mg/24 hr | 0–0.03 g/day |
| Seminal fluid | Semen | | |
| liquefaction | | Within 20 min | |
| sperm morphology | | >70% normal, mature spermatozoa | |
| sperm motility | | >60% | |
| pH | | >7.0 (average 7.7) | |
| sperm count | | 60–150 million/ml | 60–150 $\times 10^6$ /ml |
| volume | | 1.5–5.0 ml | |
| Stool examination | Stool | | |
| coproporphyrin | | 400–1000 mg/day | |
| faecal fat excretion | | <6.0 g/day | |
| occult blood | | Negative (<2 ml blood /day) | |
| urobilinogen | | 40–280 mg/day | |
| D-xylose excretion | Stool | 5–8 g within 5 hrs after oral dose of 25 g | |

Contd...

Table A-III.4 Other body fluids. (Contd...)

| Component | Specimen | Reference Value | |
|---|-------------------------|--|---|
| | | Conventional | SI Units |
| Schilling's test (Intrinsic factor test) | 24-hr urinary excretion | >10% of ingested dose of 'hot' vitamin B ₁₂ (Details on page 284) | |
| Urine examination | 24-hr volume | 600–1800 ml (variable) | |
| pH | Urine | 5.0–9.0 | |
| specific gravity, quantitative | Urine (random) | 1.002–1.028 (average 1.018) | |
| protein excretion | 24-hr urine | <150 mg/day | |
| protein, qualitative | Urine (random) | Negative | |
| glucose excretion, quantitative | 24-hr urine | 50–300 mg/day | |
| glucose, qualitative | Urine (random) | Negative | |
| porphobilinogen | Urine (random) | Negative | |
| urobilinogen | 24-hr urine | 1.0–3.5 mg/day | |
| microalbuminuria (24 hour) | | 0–30 mg/24 hr (0–30 µg/mg creatinine) | 0–0.03 g/day (0–0.03 g/g creatinine) |
| Urobilinogen | Urine (random) | Present in 1:20 dilution | |

Table A-III.5 Normal haematologic values.

| Component | Specimen | Reference Value | |
|---|-----------|--|-----------------|
| | | Conventional | SI Units |
| Erythrocytes and Haemoglobin | | | |
| Erythrocyte count | Blood | | |
| males | | 4.5–6.5 × 10 ¹² /L (mean 5.5 × 10 ¹² /L) | |
| females | | 3.8–5.8 × 10 ¹² /L (mean 4.8 × 10 ¹² /L) | |
| Erythrocyte diameter | | 6.7–7.7 µm (mean 7.2 µm) | |
| Erythrocyte thickness | | | |
| peripheral | | 2.4 µm | |
| central | | 1.0 µm | |
| Erythrocyte indices (Absolute values) | Blood | (also see page 268) | |
| mean corpuscular haemoglobin (MCH) | | 27–32 pg | |
| mean corpuscular volume (MCV) | | 77–93 fl | |
| mean corpuscular haemoglobin concentration (MCHC) | | 30–35 g/dl | |
| Erythrocyte life-span | Blood | 120±30 days | |
| Erythrocyte sedimentation rate (ESR) | Blood | | |
| Westergren 1st hr, males | | 0–15 mm 1 st hour | |
| females | | 0–20 mm 1 st hour | |
| Wintrobe, 1st hr, males | | 0–9 mm 1 st hour | |
| females | | 0–20 mm 1 st hour | |
| Ferritin | Serum | | |
| males | | 30–250 ng/ml | 30–250 µg/L |
| females | | 10–150 ng/ml | 10–150 µg/L |
| Folate | | | |
| body stores | | 2–3 mg | |
| daily requirement | | 100–200 µg | |
| red cell level | Red cells | 150–450 ng/ml | 340–1020 nmol/L |
| serum level | Serum | 6–18 ng/ml | 12–40 nmol |
| Free erythrocyte protoporphyrin (FEP) | Red cells | 20 µg/dl | |
| Haematocrit (PCV) | Blood | | |
| males | | 40–54% | 0.47 ± 0.07 L/L |
| females | | 37–47% | 0.42 ± 0.05 L/L |
| Haptoglobin | Serum | 60–270 mg/dl | 0.6–2.7 g/L |

Contd...

Table A-III.5 Normal haematologic values. (Contd...)

| Component | Specimen | Reference Value | |
|--|------------------------|--|-----------------|
| | | Conventional | SI Units |
| Haemoglobin (Hb) | | | |
| adult haemoglobin (HbA) | Whole blood | 95–98% | |
| males | | 13.0–18.0 g/dl | 130–180 g/L |
| females | | 11.5–16.5 g/dl | 115–165 g/L |
| plasma Hb (quantitative) | | 0.5–5 mg/dl | 5–50 mg/L |
| haemoglobin A ₂ (HbA ₂) | | 1.5–3.5% | |
| haemoglobin, foetal (HbF) in adults | | <0–2% | |
| HbF, children under 6 months | | <5% | |
| Iron, total | Serum | 40–140 µg/dl | 7–25 µmol/L |
| total iron binding capacity (TIBC) | Serum | 250–406 µg/dl | 45–73 µmol/L |
| iron saturation | Serum | 20–45% (mean 33%) | 0.20–0.45 |
| Iron intake | | 10–15 mg/day | |
| Iron loss | | | |
| males | | 0.5–1.0 mg/day | |
| females | | 1–2 mg/day | |
| Iron, total body content | | | |
| males | | 50 mg/kg body weight | |
| females | | 35 mg/kg body weight | |
| Iron, storage form (ferritin and haemosiderin) | | 30% of body iron | |
| Osmotic fragility | Blood | | |
| slight haemolysis | | at 0.45 to 0.39 g/dl NaCl | |
| complete haemolysis | | at 0.33 to 0.36 g/dl NaCl | |
| mean corpuscular fragility | | 0.4–0.45 g/dl NaCl | |
| Reticulocytes | Blood | | |
| adults | | 0.5–2.5% | |
| infants | | 2–6% | |
| Transferrin | Serum | 200–400 mg/dl | 2–4 g/L |
| Vitamin B ₁₂ | | | |
| body stores | | 10–12 mg | |
| daily requirement | | 2–4 µg | |
| serum level | Serum | 280–1000 pg/ml | 280–1000 pmol/L |
| Leucocytes | | | |
| Differential leucocyte count (DLC) | Blood film/CBC counter | | |
| P (polymorphs or neutrophils) | | 40–75% (2,000–7,500/µl) | |
| L (lymphocytes) | | 20–50% (1,500–4,000/µl) | |
| M (monocytes) | | 2–10% (200–800/µl) | |
| E (eosinophils) | | 1–6% (40–400/µl) | |
| B (basophils) | | < 1% (10–100/µl) | |
| Muramidase | Serum | 5–20 µg/ml | |
| Total leucocyte count (TLC) | Blood | | |
| adults | | 4,000–11,000/µl | |
| infants (full term, at birth) | | 10,000–25,000/µl | |
| infants (1 year) | 6,000–16,000/µl | | |
| Myelogram | | See Table 10.2 on page 264 | |
| Platelets and Coagulation | | | |
| Bleeding time (BT) | | | |
| Ivy's method | Prick blood | 2–7 min | |
| template method | | 2.5–9.5 min | |
| Clot retraction time | Clotted blood | | |
| qualitative | | Visible in 60 min (complete in <24-hr) | |
| quantitative | | 48–64% (55%) | |
| Clotting time (CT) | Whole blood | | |
| Lee and White method | | 4–9 min at 37°C | |
| Euglobin lysis time | | 72 hr | |
| Fibrinogen | Plasma | 200–400 mg/dl | 2–4 g/L |

Contd...

Table A-III.5 Normal haematologic values. (Contd...)

| Component | Specimen | Reference Value | |
|--|----------|---------------------------|----------|
| | | Conventional | SI Units |
| Fibrin split (or degradation) products (FSP or FDP) | Plasma | <10 µg/ml | <10 mg/L |
| Partial thromboplastin time with kaolin (PTTK) or activated partial thromboplastin time (APTT) | Plasma | 30–40 sec | |
| Platelet count | Blood | 150,000–400,000/µl | |
| Prothrombin time (PT) (Quick's one-stage method) | Plasma | 10–14 sec | |
| Thrombin time (TT) | Plasma | <20 sec (control ± 2 sec) | |

Further Reading

In compilation of the material in this textbook, books and original works of several authors and websites listed below have been consulted which are gratefully acknowledged. In order to stimulate an inquisitive and indulgent reader, general references used as the resource material for the book have been listed first, followed by chapter-wise list of additional references consulted. An author index in alphabetic order has been followed.

Viral hepatitis, (*see details under* Hepatitis, viral), 590-9

Viral oncogenesis, 216-22
 DNA, 217-20
 RNA, 220-1

Virchow cells, 149

Virchow's node, 194

Virchow's sign, 541

Virchow-Robin space, 864

Virchow, Rudolf, 6f

Virilism, adrenal, 788-9

Virtual microscopy, 7

Viruses and human cancer, 221-2

Viruses, in infections, 175t
 in tumours, 216-22

Vital reaction, 26

Vital staining, 265

Vitalism, theory of, 3

Vitamins, disorders of, 241-9
 A, 241-3
 B1, 247-2
 B2, 248
 B3, 248
 B6, 248
 B12, 248, 280-5
 B-complex, 247-8
 B12 metabolism, 280-1
 biotin, 248-9
 C, 246-7
 choline, 249
 D, 243-5
 E, 245
 fat-soluble, 241-6
 flavonoids, 249
 folate, 248, 281-5
 folate metabolism, 281
 K, 245-6
 niacin, 248
 water-soluble, 246-8

Vitellointestinal duct, 544

Vitiligo, 22

Vocal nodules, 501

Volvulus, 546

von Gierke's disease, 257

von Hippel-Lindau syndrome, 681, 819
 von Kossa stain, 34
 von Recklinghausen's disease, 199, 885-6
 von Willebrand's disease, 314
 Vulva, 710-2
 tumours of, 711-2

W

Waldenstrom's
 macroglobulinaemia, 364-5
 Wallerian degeneration, 884
 Walther cell rests, 728
 Warthin's tumour, 517-8
 Warts, viral, 218, 762-3
 Wassermann reaction, 151, 318
 Water-soluble vitamins, 246-8
 Water, total body, 78
 deficiency of (dehydration), 87
 excess of (overhydration), 87
 Watershed (border zone) infarcts, brain, 872
 Watson, Crick, 6
 Wax-D, 140
 Wear and tear pigment, 25-6
 Webs, oesophageal, 522
 Wegener's granulomatosis, 383-4, 475-6, 498, 647t
 limited form, 384
 Weights and measurements, normal organs, 915-6
 Wermer's syndrome, 819
 Wernicke-Korsakoff psychosis, 247-8

Wet-fixed *versus* air-dried smear, 902t
 Wheal, 117
 Whipple's disease, 559
 White blood cells, diseases of, 321-69
 White lesions, 507, 710
 WHO classification of leukaemia-lymphomas, 337t, 348t, 349t
 Whooping cough, 169-70, 333
 Wilms' tumour, 683-5
 Wilson's disease, 612-3
 Wilmut, Ian, 7
 Wintrobe, MM, 6
 Wolffian cyst, 713
 Working formulation for clinical usage, 345
 Wound, 158-61
 complications of, 159-60
 contraction of, 160
 healing of, 158-61
 strength, 160
 Woven bone, normal structure of, 821
 callus, 161-2
 Wry neck, 503
Wuchereria bancrofti, 180, 693-4

X

X-chromosome, 252f, 327, 896
 X-linked disorders, 255t
 X-ray crystallography, 67
 Xanthelasma, 21
 Xanthine stones, 674
 Xanthofibroma, 846

Xanthogranuloma, 856
 Xanthogranulomatous pyelonephritis, 669
 Xanthomas, 21, 780
 Xenograft, 49
 Xeroderma pigmentosum, 198, 209, 773-4
 Xerophthalmia, 242
 Xerostomia, 515

Y

Y-chromatin, 255, 896-7
 Yellow atrophy, acute, 598
 Yellow fever, 175
 Yolk sac tumour,
 ovary, 737-8
 testis, 699

Z

Zahn, infarct of, 114
 lines of, 104f
Zarda, 232
 Zeiss glands, 489
 Zellballen pattern, 790
 Zenker's degeneration, 18
 Zenker's fluid, 350
 Ziehl-Neelsen staining, 139, 147, 903
 Zollinger-Ellison syndrome, 528, 818-9
 Zonal necrosis, liver, 583
 Zones, hepatic lobules, 578f
 Zoster virus infection, 177, 764

LIST OF CLINICAL CASES

| CASE NUMBER | CHAPTER & PAGE NUMBER | DIAGNOSIS & DISCUSSION (PAGE NUMBER) |
|-------------|-----------------------|---|
| 1 | Ch. 3, page 77 | Bronchiectasis with nephrotic syndrome, possibly due to secondary systemic amyloidosis (page 906) |
| 2 | Ch. 4, page 115 | Septic shock and disseminated intravascular coagulation (DIC) (page 906) |
| 3 | Ch. 5, page 164 | HIV infection with opportunistic infections, disseminated tuberculosis, with possibly tuberculous meningitis (TBM) (page 907) |
| 4 | Ch. 10, page 303 | Nutritional anaemia due to blood loss, likely iron deficiency anaemia (page 907) |
| 5 | Ch. 10, page 304 | Congenital haemolytic anaemia, likely β -thalassaemia major (page 907) |
| 6 | Ch. 11, page 320 | Chronic immune thrombocytopenic purpura (ITP) (page 908) |
| 7 | Ch. 12, page 369 | Acute lymphoblastic leukaemia (page 908) |
| 8 | Ch. 12, page 369 | Multiple myeloma (page 908) |
| 9 | Ch. 13, page 396 | Coronary artery disease (acute myocardial infarction) (page 908) |
| 10 | Ch. 14, page 441 | Rheumatic heart disease and mitral stenosis with superimposed infective endocarditis (page 909) |
| 11 | Ch. 15, page 487 | Lobar pneumonia (page 909) |
| 12 | Ch. 15, page 487 | Bronchogenic carcinoma (page 909) |
| 13 | Ch. 16, page 503 | Antrochoanal polyp, allergic type (page 910) |
| 14 | Ch. 17, page 520 | Carcinoma oral cavity (page 910) |
| 15 | Ch. 18, page 576 | Chronic peptic ulcer, gastric (page 910) |
| 16 | Ch. 18, page 576 | Acute appendicitis (page 910) |
| 17 | Ch. 19, page 634 | Post-necrotic cirrhosis with portal hypertension and superimposed hepatocellular carcinoma (page 910) |
| 18 | Ch. 19, page 634 | Chronic cholecystitis with cholelithiasis and cholestatic jaundice (page 911) |
| 19 | Ch. 19, page 635 | Carcinoma head of pancreas with obstructive jaundice (page 911) |
| 20 | Ch. 20, page 690 | Nephritic syndrome due to acute post-streptococcal glomerulonephritis (page 911) |
| 21 | Ch. 20, page 690 | Renal cell carcinoma, right kidney (page 912) |
| 22 | Ch. 21, page 709 | Germ cell tumour, right testis (page 912) |
| 23 | Ch. 22, page 744 | Carcinoma cervix (page 912) |
| 24 | Ch. 23, page 758 | Carcinoma breast with Paget's disease and axillary nodal metastasis (page 913) |
| 25 | Ch. 24, page 781 | Basal cell carcinoma skin (page 913) |
| 26 | Ch. 25, page 819 | Graves' disease (diffuse toxic goitre) (page 913) |
| 27 | Ch. 25, page 820 | Systemic hypertension and uncontrolled and complicated diabetes mellitus type 2 (gangrene toe, pulmonary tuberculosis, pleurisy) (page 913) |
| 28 | Ch. 26, page 850 | Osteosarcoma lower end of femur (page 914) |
| 29 | Ch. 27, page 862 | Soft tissue sarcoma (page 914) |
| 30 | Ch. 28, page 887 | Stroke (cerebrovascular accident or CVA) (page 914) |
