Second Edition : 1994
Third Edition : 1998
Fourth Edition : 2000
Fifth Edition : 2005
Sixth Edition : 2010
Reprint : 2013

Seventh Edition: 2015

Assistant Editors: Praveen Mohan, Tanya Mohan, Sugandha Mohan

ISBN: 978-93-5152-369-7

Printed at

To deeds alone you have a right and
never at all to its fruits;
Let not the fruits of deeds be your motive;
Neither let there be in you
any detachment to performing your duty.

The Bhagvadgita (Chapter II, verse 47)

Dedicated to

*My loving soulmate, Praveen, for being there for me and with me always,
Tanya-Vivek, for giving happiness of being together forever,
Sugandha, for being the daughter who is my best friend,*

&

*To all my students and colleagues, present and past:
For their enduring inspiration.*

Foreword

This is the third time that I was asked to write a foreword to Dr Mohan's Textbook, and again I am at a loss for words to adequately express my enthusiasm for this book which has such a long history of excellence. Over all those years spanning the previous six editions, it has served as an introduction to clinical medicine to generations of medical students, and I am sure that it will continue in that function way into the twenty first century. A book of this caliber does not need introductions, forewords and endorsements for its continuous success. Its value has been proven over and over again by those for whom it was written and those who have used it in its previous editions—the medical students and their professors.

For the new edition, Dr Mohan has thoroughly revised his previous text, expanding it with novel data selected judiciously from both laboratory and clinical research papers. Yet the basic structure of the book remains unchanged, with an unconditional dedication to the systematic coverage of the basics, strong clinical underpinning, and a good sense for didactics. It reflects the author's lifelong experience in the classroom and his passion for teaching of pathology to medical students. The text is illustrated with informative artists' drawings and photographs. It also contains highlighted summary boxes and valuable tables. At the end of each chapter there are clinical cases, designed to stimulate further studies and discussions. The condensed Quick Review Book, appended to the textbook as a lagniappe, will remain attractive to medical students preparing for their examinations.

In a short foreword of this kind, it is not possible to mention all the strong points of this textbook. It should suffice to say that Dr Mohan's Textbook has retained all the features which have made previous editions so popular with medical students and their teachers alike. It was masterfully updated and with the new didactic elements it will be even more attractive to its readers. It will remain an essential must-have for all medical undergraduate students, serving them as a pathfinder and bridge during their transition from basic medical sciences to clinical medicine.

Ivan Damjanov, MD, PhD
Professor

Department of Pathology
The University of Kansas School of Medicine
Kansas City, Kansas, USA

As I sit down to put my thoughts into words for the 7th revised edition of my *Textbook of Pathology*, I look back with satisfaction how this book has grown phenomenally since its modest beginning in 1992. During these years, successive editions of the textbook have brought me closer to enumerable well-wishers, won me life-long friends, rewarded me with respect and faith of my colleagues, got me blessings of senior professionals, and earned me affection of innumerable students and fans. It has been really highly gratifying journey so far. At the same time, such an abiding trust by users of previous editions of my textbook certainly puts an onerous responsibility on me to come up to their expectations and make it better with every new edition. It is this motivation and zeal which I pursued while preparing the thoroughly transformed and updated 7th revised edition which I am pleased to present to users.

Diagnostic pathology has been growing exponentially with advances in molecular methods, cytogenetics and immunology, besides the ready availability of immunohistochemistry. In fact, in the current era, immunophenotyping and cytogenetics have been recommended as defining criteria for classification, diagnosis and prognostication of growing number of cancers. In such a scenario, it is quite natural that undergraduate students of pathology should be made aware of what is happening in the realm of diagnostic science while at the same time not forgetting to lose hold of the fundamental aspects of pathology of diseases. Thus, for beginners in pathology, for whom this textbook is primarily meant, a balanced approach for learning of pathology is recommended i.e. the students must learn basic morphologic pathology including recent knowledge of etiology and pathogenesis of diseases, and simultaneously they should know the contribution of modern diagnostic techniques mentioned above towards achieving the goal of an objective 'final diagnosis' that is prognostically relevant as well. This philosophy for teaching and learning of pathology has been followed in the present edition but without disturbing the basic format of the book.

Some of the *Key Features* of the Seventh Edition are as follows:

Revised and Updated Text Most of the topics in chapters have undergone revision and updating of various aspects of diseases including their newer causes and recent mechanisms by insertion of latest information between the lines. Emphasis has also been placed on contemporary diagnostic modalities in a simple and lucid manner. In doing so, the basic accepted style of the book—simple, easy-to-understand and reproduce the subject matter, and emphasis on clarity and accuracy, has not been disturbed. Considering their utility, a dozen new tables have been added in different chapters in the revised edition while many others have been updated.

Reorganisation of the Book The redistribution of the textbook into three sections (General Pathology, Haematology and Lymphoreticular Tissues, and Systemic Pathology) done in the previous edition has been widely accepted and appreciated for its ease for locating material and has, therefore, been retained. In order to make space for addition of new information, topics of normal cell structure and function and laboratory techniques have been relocated, after editing them, to relevant chapters to which they belong.

Newer and Revised Images Morphologic pathology has always been regarded as a highly visual branch of medicine, and therefore, there is always need and scope of doing more and making this aspect better in the new edition. In the revised edition, many newer illustrations have been added while some old ones have been replaced with better quality images or improved after eliminating their shortcomings. Inboxes have been incorporated in some photomicrographs for a close-up microscopic view. In general, the effort has been to give soft and pleasing colours for soothing visual look to the new edition.

Gist Boxes In the revised edition, at the end of every topic a short summary of the subject covered has been given. These 'Gist Boxes' (226 in all) include salient must-know features of the covered topic in bulleted points for a rapid revision in ultrashort time. These Gist Boxes have been given a distinctive eye-catching colour throughout the book to be visible on a glance and for looking up quickly by turning the pages of the book for a last minute revision before facing an evaluation in examination.

Clinical Focus on Learning A novel modality of learning and self-assessment has been added in the revised edition by including 30 structured clinical cases. At the end of most of the chapters, one or more clinical cases with history and findings of examination have been given based on a common or an important disease pertaining to the system of that chapter. Questions framed at the end of these cases have been rationally answered and discussed in an analytical manner in Appendix II.

Revised Pathology Quick Review and MCQs The 7th edition of textbook is accompanied with the new revised baby-book popular with many students and interns. This small book has been found profoundly useful by the students just before practical examination to face viva voce when they need to revise huge course content in a short time, or by those preparing to take postgraduate entrance examinations. The revised edition has over 50 more new MCQs while some old ones have either been edited or replaced.

A Word on Foreword Professor Ivan Damjanov, MD, PhD, Kansas University, USA, has been very generous and gracious in writing Foreword for the last three successive editions of my textbook which has brought the textbook closer to users in other

parts of the world, which is appreciated and gratefully acknowledged. He is gifted with qualities of perfection, clarity of mind and meticulous approach, besides having an excellent knack for choosing measured words in his language. I wholeheartedly express my gratitude to this adorable teacher and an eminent author and editor.

In essence, the revised edition is a comprehensive text of pathology meant primarily for students of pathology; however, the practicing clinicians and students of other branches of medicine, dentistry, pharmacy, alternate system of medicine, and paramedical courses may also find it useful.

ACKNOWLEDGEMENTS

The magnitude of work pertaining to revision of the textbook after 5 years is massive and would not have been possible without active cooperation and support from friends and well-wishers in general, and my departmental colleagues in particular. The task of fresh photomicrography for the present edition was ably assisted by my colleagues, Dr Shilpa, Senior Resident, Department of Pathology; and Ms Agam Verma, Senior Lab Technician, which is greatly appreciated. Here, I wish to recall and put on record the sincere and selfless services rendered by my former students and colleagues in preparation of images in earlier editions of the book and thank them once again. As always, I remain indebted to those from whom I had the opportunity to learn basics of pathology—Professor K Joshi, MD, PhD, formerly at PGIMER, Chandigarh, Late Professor TS Jaswal, MD, and Professor Uma Singh, MD, formerly at PGIMS, Rohtak, Haryana, India.

Constant strategic encouragement and support extended by the Department of Medical Education and Research, Chandigarh Administration, during the completion of this academic work is gratefully acknowledged.

I have strived to be as accurate and perfect as possible, and in doing so, I may have been quite harsh and demanding with Production team at the M/s Jaypee Brothers Medical Publishers (P) Ltd. But I must appreciate their patience, cooperation and commitment in general, and Mr Manoj Pahuja, Senior Graphic Designer and Mrs Y Kapoor, Senior Desktop Operator, in particular, for acceding to all my requests for amendments smilingly and ungrudgingly till the very last minute, and to Mr Sunil Dogra, Production Executive, for overseeing the entire project vigilantly and efficiently.

Lastly, the passionate involvement of Shri Jitendar P Vij (Group Chairman) and enthusiasm of Mr Ankit Vij (Group President), M/s Jaypee Brothers Medical Publishers (P) Ltd, in the revised edition of the textbook has raised the bar for a high standard for which I am deeply thankful to both of them. While the content and product quality of the revised edition of the textbook are of an uncompromising quality, the book continues to be of reasonable volume and has been kept affordable.

Finally, I owe gratitude to the users of previous editions who have been generous in giving feedback and suggestions. Every suggestion helps me to introspect and attempt to make the textbook better. I request all the users of present edition to continue giving their valuable suggestions and point out errors, if any, to help me to improve it further.

Harsh Mohan, MD, FAMS, FICPath, FUICC
Professor & Head
Department of Pathology

Section I: GENERAL PATHOLOGY

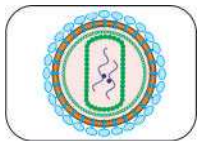

Chapter 1: Introduction to Pathology 1

- ◆ **Study of Pathology, 1:** Health and Disease, 1; Common Terms in Pathology, 1
- ◆ **Evolution of Pathology, 2:** Prehistoric Times to Medieval Period, 2; Human Anatomy and Era of Gross Pathology, 3; Era of Technology Development and Cellular Pathology, 4; Modern Pathology, 6; Telepathology and Virtual Microscopy, 7
- ◆ **Subdivisions of Pathology, 7:** Morphological Branches, 7; Non-Morphological Branches, 8

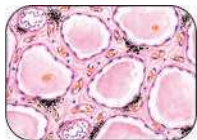

Chapter 2: Cell Injury, Cellular Adaptations and Cellular Ageing 9

- ◆ **Cell Injury, 9:** Etiology of Cell Injury, 9; Pathogenesis of Cell Injury, 10; Morphology of Reversible Cell Injury, 17; Intracellular Accumulations, 19; Pigments, 22; Morphology of Irreversible Cell Injury (Cell Death), 26; Changes after Cell Death, 32
- ◆ **Adaptive Disorders, 37:** Atrophy, 37; Hypertrophy, 38; Hyperplasia, 39; Metaplasia, 39; Dysplasia, 41
- ◆ **Ageing, 42:** Theories of Ageing, 42; Organ Changes in Ageing, 43

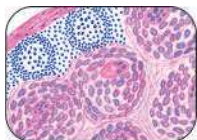

Chapter 3: Immunopathology Including Amyloidosis 44

- ◆ **The Immune System, 44:** Organs and Cells of Immune System, 44; Cytokines, 48; HLA System and Major Histocompatibility Complex, 48; Transplant Rejection, 49
- ◆ **Diseases of Immunity, 50:** Acquired Immunodeficiency Syndrome (AIDS), 51; Hypersensitivity Reactions (Immunologic Tissue Injury), 57; Autoimmune Diseases, 61
- ◆ **Amyloidosis, 66:** Physical and Chemical Nature of Amyloid, 67; Pathogenesis of Amyloidosis, 69; Classification of Amyloidosis, 70; Staining Characteristics of Amyloid, 72; Diagnosis of Amyloidosis, 73; Morphologic Features of Amyloidosis of Organs, 73; Prognosis of Amyloidosis, 75

Chapter 4: Derangements of Homeostasis and Haemodynamics 78

- ◆ **Homeostasis, 78:** Normal Water and Electrolyte Balance (Gibbs-Donnan Equilibrium), 79; Acid-Base Balance, 79; Pressure Gradients and Fluid Exchanges, 79
- ◆ **Disturbances of Body Water, 80:** Oedema, 80; Dehydration, 87; Overhydration, 87
- ◆ **Disturbances of Electrolytes and pH of Blood, 88:** Acid Base Imbalance, 89
- ◆ **Haemodynamic Derangements, 89:** Disturbances in the Volume of Circulating Blood, 90; Circulatory Disturbances of Obstructive Nature, 99

Chapter 5: Inflammation and Healing 116

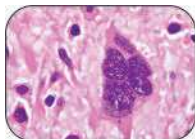

- ◆ **Acute Inflammation, 116:** Acute Inflammatory Response, 116; Mediators of Inflammation, 122; Regulation of Inflammation, 127; The Inflammatory Cells, 128; Acute Inflammation—Factors, Morphology, Effects, Fate, 131
- ◆ **Chronic Inflammation, 134:** Granulomatous Inflammation, 135; Examples of Granulomatous Inflammation, 137
- ◆ **Healing, 155:** Regeneration and Repair, 155; Healing of Skin Wounds, 158; Healing in Specialised Tissues, 161; Stem Cell Concept of Healing—Regenerative Medicine, 163

Chapter 6: Infectious and Parasitic Diseases 165

- ◆ **Diseases Caused by Bacteria, Spirochaetes and Mycobacteria, 167:** Plague, 167; Anthrax, 168; Whooping Cough (Pertussis), 169; Donovanosis, 170; Lymphogranuloma Venereum, 170; Cat-Scratch Disease, 170; Staphylococcal Infections, 170; Streptococcal Infections, 171; Clostridial Diseases, 172
- ◆ **Diseases Caused by Fungi, 173:** Mycetoma, 173; Candidiasis, 173; Cutaneous Superficial Mycosis, 174
- ◆ **Diseases Caused by Viruses, 174:** Viral Haemorrhagic Fevers, 175; Influenza Virus Infections, 176; Varicella Zoster Virus Infection, 177; Herpes Simplex Virus Infection, 177; Rabies, 178

- ◆ **Diseases Caused by Parasites, 178:** Amoebiasis, 178; Malaria, 179; Filariasis, 180; Cysticercosis, 181
- ◆ **Torch Complex, 182:**

Chapter 7: Neoplasia

184

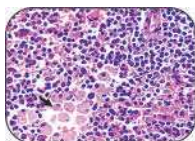

- ◆ **Nomenclature and Classification, 184**
- ◆ **Characteristics of Tumours, 186**
 - I. Rate of Growth, 186; II. Cancer Phenotype and Stem Cells, 188; III. Clinical and Gross Features, 188;
 - IV. Microscopic Features, 188; V. Spread of Tumours, 192; Grading and Staging of Cancer, 197
- ◆ **Epidemiology and Molecular Pathogenesis of Cancer, 197:** Epidemiologic Factors, 198; Molecular Basis of Cancer, 201
- ◆ **Carcinogens and Carcinogenesis, 209:** A. Chemical Carcinogenesis, 210; B. Physical Carcinogenesis, 214; C. Biologic Carcinogenesis, 216
- ◆ **Clinical Aspects of Neoplasia, 222:** Host Response against Tumour (Tumour Immunology), 222; Effect of Tumour on Host, 224; Pathologic Diagnosis of Cancer, 226

Chapter 8: Environmental and Nutritional Diseases

231

- ◆ **Environmental Diseases, 231:** Environmental Pollution, 231; Chemical and Drug Injury, 233; Injury by Physical Agents, 237
- ◆ **Nutritional Diseases, 238:** Obesity, 238; Starvation, 240; Protein-Energy Malnutrition, 240; Metals and Trace Elements, 240; Disorders of Vitamins, 241; Diet and Cancer, 249

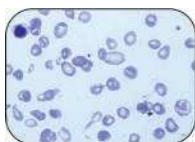

Chapter 9: Genetic and Paediatric Diseases

251

- ◆ **Genetic Diseases, 251:** Developmental Defects, 251; Cytogenetic (Karyotypic) Abnormalities, 252; Single-Gene Defects (Mendelian Disorders), 254; Multifactorial Inheritance, 256; Storage Diseases (Inborn Errors of Metabolism), 256
- ◆ **Other Paediatric Diseases, 258:** Tumours of Infancy and Childhood, 259

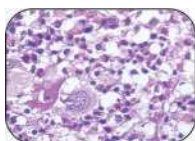

Section II: HAEMATOLOGY AND LYMPHORETICULAR TISSUES

Chapter 10: Introduction to Haematopoietic System and Disorders of Erythroid Series

261

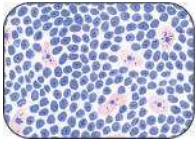

- ◆ **Bone Marrow and Haematopoiesis, 261:** Haematopoietic Organs, 261; Haematopoietic Stem Cells, 262; Bone Marrow Examination, 262
- ◆ **Erythropoiesis, 264:** Erythropoietin, 264; Erythroid Series, 265; The Red Cell, 265; Nutritional Requirements for Erythropoiesis, 266
- ◆ **Anaemia—General Considerations, 268:** General Clinical Features, 268; General Scheme of Investigations of Anaemia, 269; Classification of Anaemias, 271
- ◆ **Hypochromic Anaemias, 272:** Iron Deficiency Anaemia, 272; Sideroblastic Anaemia, 277; Anaemia of Chronic Disorders, 278
- ◆ **Megaloblastic Anaemias—Vitamin B₁₂ and Folate Deficiency, 280:** Megaloblastic Anaemia, 280; Pernicious Anaemia, 285
- ◆ **Haemolytic Anaemias and Anaemia due to Blood Loss, 286:** General Aspects, 287; I. Acquired Haemolytic Anaemias, 288; II. Hereditary Haemolytic Anaemias, 291; Anaemia of Blood Loss, 301
- ◆ **Aplastic Anaemia and Other Primary Bone Marrow Disorders, 301:** Aplastic Anaemia, 301; Myelophthistic Anaemia, 303; Pure Red Cell Aplasia, 303

Chapter 11: Disorders of Platelets, Bleeding Disorders and Basic Transfusion Medicine

305

- ◆ **Disorders of Platelets, 305:** Investigations of Haemostatic Function, 306
- ◆ **Bleeding Disorders (Haemorrhagic Diathesis), 309:** Haemorrhagic Diatheses due to Vascular Disorders, 309; Haemorrhagic Diatheses due to Platelet Disorders, 310; Coagulation Disorders, 313; Other Bleeding and Coagulation Disorders, 315
- ◆ **Blood Groups and Blood Transfusion, 317:** Blood Transfusion, 318; Haemolytic Disease of Newborn, 319

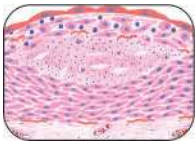

Chapter 12: Disorders of Leucocytes and Lymphoreticular Tissues 321

xiii

- ◆ **Lymph Nodes: Normal and Reactive, 321:** Reactive Lymphadenitis, 322
- ◆ **White Blood Cells: Normal and Reactive, 324:** Granulopoiesis, 324; Lymphopoiesis, 326; Mature Leucocytes in Health and Reactive Proliferation in Disease, 326; Infectious Mononucleosis, 329; Leukaemoid Reactions, 331
- ◆ **Lymphohaematopoietic Malignancies (Leukaemias-Lymphomas): General, 333:** Etiology of Lymphohaematopoietic Malignancies, 334; Pathogenesis, 334
- ◆ **Myeloid Neoplasms, 335:** Myeloproliferative Diseases, 335; Acute Myeloid Leukaemia, 340; Myelodysplastic Syndromes, 343
- ◆ **Lymphoid Neoplasms: General, 344:** Common to ALL Lymphoid Malignancies, 347
- ◆ **Hodgkin's Disease, 348**
- ◆ **Non-Hodgkin's Lymphomas-Leukaemias, 352:** Precursor (Immature) B- and T-Cell Leukaemia/Lymphoma, 353; Peripheral (Mature) B-Cell Malignancies, 355; Peripheral (Mature) T-Cell Malignancies, 359; Staging of NHL, 360; Lymph Node Metastatic Tumours, 360
- ◆ **Plasma Cell Disorders, 360**
- ◆ **Histiocytic Neoplasms: Langerhans Cell Histiocytosis, 365**
- ◆ **Spleen, 366:** Splenic Enlargement and Effects on Function, 367
- ◆ **Thymus, 368:** Structural and Functional Changes in Thymus, 369

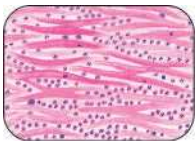

Contents

Section III: SYSTEMIC PATHOLOGY

Chapter 13: The Blood Vessels and Lymphatics 370

- ◆ **Normal Structure, 370**
- ◆ **Arteriosclerosis, 371:** Senile Arteriosclerosis, 371; Hypertensive Arteriolosclerosis, 371; Mönckeberg's Arteriosclerosis (Medial Calcific Sclerosis), 372; Atherosclerosis, 373
- ◆ **Vasculitis, 381:** I. Infectious Arteritis, 381; II. Non-Infectious Arteritis, 382
- ◆ **Aneurysms, 386**
- ◆ **Common Diseases of Veins, 389**
- ◆ **Diseases of Lymphatics, 390**
- ◆ **Tumours and Tumour-like Lesions, 391:** A. Benign Tumours and Hamartomas, 391; B. Intermediate Grade Tumours, 394; C. Malignant Tumours, 394

Chapter 14: The Heart 397

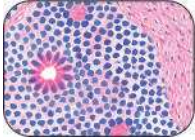

- ◆ **Normal Structure and Classification, 397**
- ◆ **Heart Failure, 399:** Etiology, 399; Types of Heart Failure, 399; Compensatory Mechanisms: Cardiac Hypertrophy and Dilatation, 400
- ◆ **Congenital Heart Disease, 402:** I. Malpositions of the Heart, 403; II. Shunts (Cyanotic Congenital Heart Disease), 403; III. Obstructions (Obstructive Congenital Heart Disease), 406
- ◆ **Ischaemic Heart Disease, 407:** Etiopathogenesis, 407; Effects of Myocardial Ischaemia, 408
- ◆ **Hypertensive Heart Disease, 417**
- ◆ **Cor Pulmonale, 418**
- ◆ **Rheumatic Fever and Rheumatic Heart Disease, 418**
- ◆ **Non-Rheumatic Endocarditis, 424:** Atypical Verrucous (Libman-Sacks) Endocarditis, 424; Non-Bacterial Thrombotic (Cachectic, Marantic) Endocarditis, 425; Infective (Bacterial) Endocarditis, 425
- ◆ **Valvular Diseases and Deformities, 429**
- ◆ **Myocardial Diseases, 432:** Myocarditis, 432; Cardiomyopathy, 434
- ◆ **Pericardial Diseases, 437:** Pericardial Fluid Accumulations, 437; Pericarditis, 437
- ◆ **Tumours of the Heart, 439**
- ◆ **Pathology of Cardiovascular Interventions, 440**

Chapter 15: The Respiratory System 442

- ◆ **Normal Structure of Lungs, 442**
- ◆ **Paediatric Lung Disease, 443**
- ◆ **Pulmonary Vascular Disease, 446**
- ◆ **Pulmonary Infections, 448:** Pneumonias, 448; Lung Abscess, 457; Pulmonary Tuberculosis, 457
- ◆ **Chronic Obstructive Pulmonary Disease, 458:** Chronic Bronchitis, 458; Emphysema, 459; Bronchial Asthma, 463; Bronchiectasis, 465; Small Airways Disease, 466

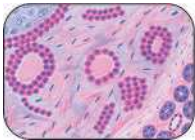

- ◆ **Chronic Restrictive Pulmonary Disease, 467:** Pneumoconioses, 467; ILDs Associated with Immunologic Lung Diseases, 474; ILDs Associated with Connective Tissue Diseases, 475; Idiopathic Pulmonary Fibrosis, 476; ILDs Associated with Smoking, 476
- ◆ **Tumours of Lungs, 477:** Bronchogenic Carcinoma, 477; Bronchial Carcinoid and Other Neuroendocrine Tumours, 483; Hamartoma, 484; Metastatic Lung Tumours, 484
- ◆ **Diseases of Pleura, 485:** Inflammations, 485; Non-Inflammatory Pleural Effusions, 485; Pneumothorax, 485; Tumours of Pleura, 486; Secondary Pleural Tumours, 487

Chapter 16: The Eye, ENT and Neck

488

- ◆ **Eye, 488:** Congenital Lesions, 488; Inflammatory Conditions, 489; Vascular Lesions, 489; Miscellaneous Conditions, 491; Tumours and Tumour-like Lesions, 492
- ◆ **Ear, 495:** Inflammatory and Miscellaneous Lesions, 495; Tumours and Tumour-Like Lesions, 495
- ◆ **Nose and Paranasal Sinuses, 496:** Inflammatory Conditions, 496; Tumours, 498
- ◆ **Pharynx, 499:** Inflammatory Conditions, 499; Tumours, 499
- ◆ **Larynx, 500:** Inflammatory Conditions, 500; Tumours, 500
- ◆ **Neck, 501:** Cysts of Neck, 502; Tumours, 502

Chapter 17: The Oral Cavity and Salivary Glands

504

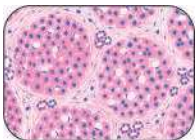

- ◆ **Oral Soft Tissues, 504:** Developmental Anomalies, 504; Mucocutaneous Lesions, 504; Inflammatory and Pigmentary Diseases, 504; Tumours and Tumour-like Lesions, 505
- ◆ **Teeth and Periodontal Tissues, 509:** Inflammatory Diseases, 510; Epithelial Cysts of the Jaw, 511; Odontogenic Tumours, 513
- ◆ **Salivary Glands, 515:** Inflammatory and Salivary Flow Diseases, 515; Tumours of Salivary Glands, 516

Chapter 18: The Gastrointestinal Tract

521

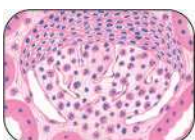

- ◆ **Oesophagus, 521:** Congenital Anomalies, 521; Muscular Dysfunctions, 521; Haematemesis of Oesophageal Origin, 522; Inflammatory Lesions, 523; Tumours of Oesophagus, 524
- ◆ **Stomach, 526:** Gastric Analysis, 527; Congenital and Miscellaneous Acquired Conditions, 529; Inflammatory Conditions, 529; Haematemesis and Melaena of Gastric Origin, 537; Tumours and Tumour-like Lesions, 537
- ◆ **Small Intestine, 544:** Congenital Anomalies and Intestinal Obstruction, 544; Ischaemic Bowel Disease (Ischaemic Enterocolitis), 546; Inflammatory Bowel Disease (Crohn's Disease and Ulcerative Colitis), 548; Infective and Other Enterocolitis, 552; Malabsorption Syndrome, 556; Small Intestinal Tumours, 559
- ◆ **Appendix, 561:** Appendicitis, 561; Tumours of Appendix, 562

Section I GENERAL PATHOLOGY

1

Introduction to Pathology

STUDY OF PATHOLOGY

The word '*Pathology*' is derived from two Greek words—*pathos* (meaning suffering) and *logos* (meaning study). Pathology is, thus, scientific study of changes in the structure and function of the body in disease. In other words, pathology consists of the abnormalities in normal anatomy (including histology) and normal physiology owing to disease. Another commonly used term with reference to study of diseases is '*pathophysiology*' (*patho*=suffering, *physiology*=study of normal function). Pathophysiology, thus, includes study of disordered function (i.e. physiological changes) and breakdown of homeostasis in diseases (i.e. biochemical changes). Pathologists contribute in patient management by providing final diagnosis of disease. Therefore, knowledge and understanding of pathology is essential for all would-be doctors, as well as general medical practitioners and specialists because unless they have knowledge and understanding of the language in the form of pathology laboratory reports, they would not be able to institute appropriate treatment or suggest preventive measures to the patient.

For the student of any system of medicine, the discipline of pathology forms a vital bridge between initial learning phase of preclinical sciences and the final phase of clinical subjects. The role and significance of learning of pathology in clinical medicine is quite well summed up by *Sir William Osler* (1849–1919), acclaimed physician and teacher in medicine considered as 'Father of Modern Medicine' by his famous quote "your practice of medicine will be as good as is your understanding of pathology" (Fig. 1.1).

HEALTH AND DISEASE

Before there were humans on earth, there was disease, albeit in early animals. Since pathology is the study of disease, then what is *disease*? In simple language, disease is opposite of health i.e. what is not healthy is disease. *Health* may be defined as a condition when the individual is in complete accord with the surroundings, while *disease* is loss of ease (or comfort) to the body (i.e. dis+ease). However, it must be borne in mind that in health there is a wide range of 'normality' e.g. in height, weight, blood and tissue chemical composition etc. It also needs to be appreciated that at cellular level, the cells display wide range of activities within the broad area of health similar to what is seen in diseased cells. Thus, a disease or an illness means a condition marked by pronounced deviation from the normal

Figure 1.1 Sir William Osler (1849–1919). Canadian physician and one of the four founding Professors of Johns Hopkins Hospital, Baltimore, US, is regarded as 'Father of Modern Medicine', Sir Osler had keen interest in pathology, was an acclaimed teacher and is also remembered for his famous quotations.

healthy state. The term *syndrome* (meaning running together) is used for a combination of several clinical features caused by altered physiologic processes.

COMMON TERMS IN PATHOLOGY

It is important for a beginner in pathology to be familiar with the language used in pathology (Fig.1.2):

- ◆ *Patient* is the person affected by disease.
- ◆ *Lesions* are the characteristic changes in tissues and cells produced by disease in an individual or experimental animal.
- ◆ *Pathologic changes* or *morphology* consist of examination of diseased tissues. These can be recognised with the naked eye (*gross or macroscopic changes*) or studied by *microscopic examination* of tissues.

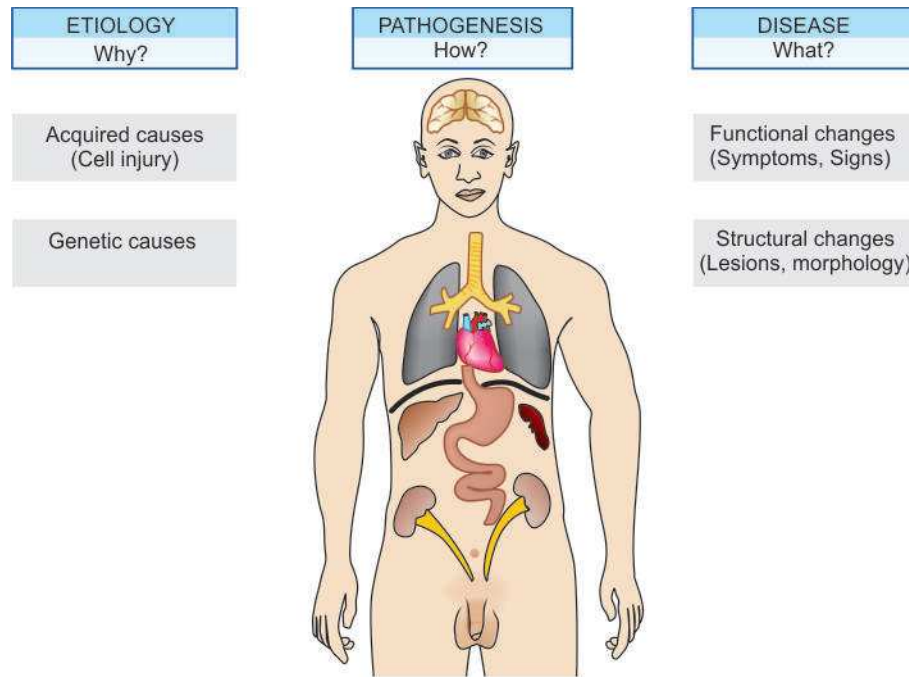

Figure 1.2 Diagrammatic depiction of disease and various terms used in pathology.

- ◆ Causal factors responsible for the lesions are included in *etiology* of disease (i.e. 'why' of disease).
- ◆ Mechanism by which the lesions are produced is termed *pathogenesis* of disease (i.e. 'how' of disease).
- ◆ Functional implications of the lesion felt by the patient are *symptoms* and those discovered by the clinician are the *physical signs*.
- ◆ Clinical significance of the morphologic and functional changes together with results of other investigations help to arrive at an answer to what is wrong (*diagnosis*), what is going to happen (*prognosis*), what can be done about it (*treatment*), and finally what should be done to avoid complications and spread (*prevention*) (i.e. 'what' of disease).

EVOLUTION OF PATHOLOGY

Pathology as the scientific study of disease processes has its deep roots in medical history. Since the beginning of mankind, there has been desire as well as need to know more about the causes, mechanisms and nature of diseases. The answers to these questions have evolved over the centuries—from supernatural beliefs to the present state of our knowledge of modern pathology. However, pathology is not separable from other multiple disciplines of medicine and owes its development to interaction and interdependence on advances in diverse neighbouring branches of science, in addition to the strides made in medical technology. As we shall see in the pages that follow, pathology has evolved over the years as a distinct discipline from anatomy, medicine and surgery, in that sequence.

The following brief review of fascinating history of pathology and its many magnificent personalities with their outstanding contribution in the form of a disease or a process known by their names, is meant to stimulate and generate interest in the inquisitive beginner in pathology as to how this colourful specialty has emerged.

PREHISTORIC TIMES TO MEDIEVAL PERIOD

Present-day knowledge of primitive culture which was prevalent in the world in prehistoric times reveals that religion, magic and medical treatment were quite linked to each other in those times. The earliest concept of disease understood by the patient and the healer was the religious belief that disease was the outcome of 'curse from God' or the belief in magic that the affliction had supernatural origin from 'evil eye of spirits.' To ward them off, priests through prayers and sacrifices, and magicians by magic power used to act as faith-healers and invoke supernatural powers and please the gods. Remnants of ancient superstitions still exist in some parts of the world. The link between medicine and religion became so firmly established throughout the world that different societies had their gods and goddesses of healing; for example: mythological Greeks had *Aesculapius* and *Apollo* as the principal gods of healing, *Dhanvantri* as the deity of medicine in India, and orthodox Indians' belief in *Mata Sheetal Devi* as the pox goddess.

The insignia of healing, the Caduceus, having snake and staff, is believed to represent the god Hermes or Mercury, which according to Greek mythology has power of healing since snake has regenerative powers expressed by its periodic sloughing of its skin. God of Greek medicine, *Aesculapius*, performed his functions with a staff having a single serpent wound around it. Later (around AD1800), however, the Caduceus got replaced with twin-serpents wound around a staff topped by a round knob and flanked by two wings and now represents the symbol of medicine instead of cross (**Fig. 1.3**).

The period of ancient religious and magical beliefs was followed by the philosophical and rational approach to disease by the methods of observations. This happened at the time when great Greek philosophers—*Socrates*, *Plato* and *Aristotle*, introduced philosophical concepts to all natural phenomena.

But the real practice of medicine began with *Hippocrates* (460–370 BC), the great Greek clinical genius of all times and regarded as ‘the father of medicine’ (Fig. 1.4). Hippocrates dissociated medicine from religion and magic. Instead, he firmly believed in study of patient’s symptoms and described methods of diagnosis. He recorded his observations on cases in the form of collections of writings called Hippocratic Corpus which remained the mainstay of learning of medicine for nearly two thousand years. However, the prevailing concept at that time on mechanism of disease based on disequilibrium of four basic humors (water, air, fire, and earth) was propagated by Hippocrates too but this concept was later abandoned.

Hippocrates followed rational and ethical attitudes in practice and teaching of medicine and is revered by the medical profession by taking ‘*Hippocratic oath*’ at the time of entry into practice of medicine.

After Hippocrates, Greek medicine reached Rome (now Italy) which controlled Greek world after 146 BC and, therefore, it dominated the field of development of medicine in ancient Europe then. In fact, since old times, many tongue-twisting terminologies in medicine have their origin from Latin language which was the official language of countries included in ancient Roman empire (Spanish, Portuguese, Italian, French and Greek languages have their origin from Latin).

In Rome, Hippocratic teaching was propagated by Roman physicians, notably by *Cornelius Celsus* (53 BC–7 AD) and *Claudius Galen* (130–200 AD). Celsus first described four cardinal signs of inflammation—*rubor* (redness), *tumor* (swelling), *calor* (heat), and *dolor* (pain). Galen postulated humoral theory, later called Galenic theory. This theory suggested that the illness resulted from imbalance between *four humors* (or body fluids): blood, lymph, black bile (believed at that time to be from the spleen), and biliary secretion from the liver.

The hypothesis of disequilibrium of four elements constituting the body (*Dhatus*) similar to Hippocratic doctrine finds mention in ancient Indian medicine books compiled about 200 AD—*Charaka Samhita*, a finest document by *Charaka* on medicine listing 500 remedies, and *Sushruta Samhita*, similar

Figure 1.4 Hippocrates (460–370 BC). The great Greek clinical genius and regarded as ‘the Father of Medicine’. He introduced ethical aspects to medicine.

book of surgical sciences by *Sushruta*, and includes about 700 plant-derived medicines.

The end of Medieval period was marked by backward steps in medicine. There were widespread and devastating epidemics which reversed the process of rational thinking again to supernatural concepts and divine punishment for ‘sins.’ The dominant belief during this period was that life was due to influence of vital substance under the control of soul (*theory of vitalism*). Thus, dissection of human body was strictly forbidden at that time as that would mean hurting the ‘soul.’

HUMAN ANATOMY AND ERA OF GROSS PATHOLOGY

The backwardness of Medieval period was followed by the Renaissance period i.e. revival of learning. The Renaissance began from Italy in late 15th century and spread to whole of Europe. During this period, there was quest for advances in art and science. Since there was freedom of thought, there was emphasis on philosophical and rational attitudes again.

The beginning of the development of human anatomy took place during this period with the art works and drawings of human muscles and embryos by famous Italian painter *Leonardo da Vinci* (1452–1519). Dissection of human body was started by *Vesalius* (1514–1564) on freshly executed criminals. His pupils, *Gabriel Fallopius* (1523–1562) who described human oviducts (Fallopian tubes) and *Fabricius* who discovered lymphoid tissue around the intestine of birds (bursa of Fabricius) further popularised the practice of human anatomic dissection for which special postmortem amphitheatres came in to existence in various parts of ancient Europe.

Figure 1.3 The Caduceus, representing symbol of medicine, is the traditional symbol of god Hermes or Mercury. It features twin serpents winding around a winged staff.

Antony van Leeuwenhoek (1632–1723), a cloth merchant by profession in Holland, during his spare time invented the first ever microscope by grinding the lenses himself through which he recognised male spermatozoa as tiny preformed men (or “homunculi”) and other single-celled organisms which he called animalcules. He also introduced histological staining in 1714 using saffron to examine muscle fibres.

Marcello Malpighi (1624–1694) used microscope extensively and observed the presence of capillaries and described the malpighian layer of the skin, and lymphoid tissue in the spleen (malpighian corpuscles). Malpighi is known as ‘the father of histology.’

The credit for beginning of the study of morbid anatomy (pathologic anatomy), however, goes to Italian anatomist-pathologist, *Giovanni B. Morgagni* (1682–1771). Morgagni was an excellent teacher in anatomy, a prolific writer and a practicing clinician. By his work, Morgagni demolished the ancient humoral theory of disease and published his life-time experiences based on 700 postmortems and their corresponding clinical findings. He, thus, laid the foundations of clinicopathologic methodology in the study of disease and introduced the concept of clinicopathologic correlation (CPC), establishing a coherent sequence of cause, lesions, symptoms, and outcome of disease (**Fig. 1.5**).

Sir Percivall Pott (1714–1788), famous surgeon in England, described arthritic tuberculosis of the spine (Pott’s disease) and identified the first ever occupational cancer (cancer of scrotal skin) in the chimney sweeps in 1775 and discovered chimney soot as the first carcinogenic agent. The study of anatomy in England during the latter part of 18th Century was dominated by the two Hunter brothers. These were *John Hunter* (1728–1793), a student of Sir Percivall Pott, who rose to become the greatest surgeon-anatomist of all times (**Fig. 1.6**) and his elder brother *William Hunter* (1718–1788) who was a reputed anatomist-obstetrician. These brothers together started the first ever museum by collection of surgical specimens from their flourishing practice, arranged them into separate organ systems, made comparison of specimens from animals and plants with humans, and included many clinical pathology specimens as well, and thus developed the first museum of comparative anatomy and pathology in the world which became the Hunterian Museum, now housed in Royal College of Surgeons of London. Among many pupils of John Hunter was *Edward Jenner* (1749–1823) whose work on inoculation in smallpox is well known. Another prominent English pathologist was *Matthew Baillie* (1760–1823), nephew of Hunter brothers, who published first-ever systematic textbook of morbid anatomy in 1793. The era of gross pathology had three more illustrious and brilliant physician-pathologists in England who were colleagues at Guy’s Hospital in London:

- ◆ *Richard Bright* (1789–1858) who described non-suppurative nephritis, later termed glomerulonephritis or Bright’s disease;
- ◆ *Thomas Addison* (1793–1860) who gave an account of chronic adrenocortical insufficiency termed Addison’s disease; and
- ◆ *Thomas Hodgkin* (1798–1866), who observed the complex of chronic enlargement of lymph nodes, often with enlargement of the liver and spleen, later called Hodgkin’s disease.

Towards the end of 18th century, *Xavier Bichat* (1771–1802) in France described that organs were composed of tissue and divided the study of morbid anatomy into General Pathology and Systemic Pathology. *R.T.H. Laennec* (1781–1826), another

French physician, dominated the early part of 19th century by his numerous discoveries. He described several lung diseases (tubercles, caseous lesions, miliary lesions, pleural effusion, and bronchiectasis), chronic sclerotic liver disease (later called Laennec’s cirrhosis) and invented stethoscope.

Morbid anatomy attained its zenith with appearance of *Carl F. von Rokitansky* (1804–1878), self-taught German pathologist who performed nearly 30,000 autopsies himself. He described acute yellow atrophy of the liver, wrote an outstanding monograph on diseases of arteries and congenital heart defects. Unlike most other surgeons of that time, Rokitansky did not do clinical practice of surgery but instead introduced the concept that pathologists should confine themselves to making diagnosis which became the accepted role of pathologist later.

ERA OF TECHNOLOGY DEVELOPMENT AND CELLULAR PATHOLOGY

Up to middle of the 19th century, correlation of clinical manifestations of disease with gross pathological findings at autopsy became the major method of study of disease. Sophistication in surgery led to advancement in pathology. The anatomist-surgeons of earlier centuries got replaced largely with surgeon-pathologists in the 19th century.

Pathology started developing as a diagnostic discipline in later half of the 19th century with the evolution of cellular pathology which was closely linked to technology advancements in machinery manufacture for cutting thin sections of tissue, improvement in microscope, and development of chemical industry and dyes for staining.

The discovery of existence of disease-causing microorganisms was made by French chemist *Louis Pasteur* (1822–1895), thus demolishing the prevailing theory of spontaneous generation of disease and firmly established germ theory of disease. Subsequently, *G.H.A. Hansen* (1841–1912) in Germany identified Hansen’s bacillus in 1873 as the first microbe causative for leprosy (Hansen’s disease). While the study of infectious diseases was being made, the concept of immune tolerance and allergy emerged which formed the basis of immunisation initiated by Edward Jenner. *Metchnikoff* (1845–1916), a Russian zoologist, introduced the existence of phenomenon of phagocytosis by human defense cells against invading microbes.

Developments in chemical industry helped in switch over from earlier dyes of plant and animal origin to synthetic dyes; aniline violet being the first such synthetic dye prepared by *Perkin* in 1856. This led to emergence of a viable dye industry for histological and bacteriological purposes. The impetus for the flourishing and successful dye industry came from the works of numerous pioneers as under:

- ◆ *Paul Ehrlich* (1854–1915), German physician, conferred Nobel prize in 1908 for his work in immunology, described Ehrlich’s test for urobilinogen using Ehrlich’s aldehyde reagent, staining techniques of cells and bacteria, and laid the foundations of clinical pathology (**Fig. 1.7**).
- ◆ *Christian Gram* (1853–1938), Danish physician, developed bacteriological staining by crystal violet.
- ◆ *D.L. Romanowsky* (1861–1921), Russian physician, developed stain for peripheral blood film using eosin and methylene blue derivatives.
- ◆ *Robert Koch* (1843–1910), German bacteriologist, besides Koch’s postulate and Koch’s phenomena, developed techniques

Figure 1.5 Giovanni B. Morgagni (1682–1771), an Italian physician-anatomist who introduced clinicopathologic methodology in the study of disease by correlation of clinical findings with findings at postmortem examination.

Figure 1.6 John Hunter (1728–1793). Scottish surgeon, regarded as the greatest surgeon-anatomist of all times who established first ever unique collection of pathological specimens that later resulted in the Hunterian Museum of the Royal College of Surgeons, London.

Figure 1.7 Paul Ehrlich (1854–1915). German physician, conferred Nobel prize for his work in immunology, described Ehrlich's test for urobilinogen, staining techniques of cells and bacteria, and laid the foundations of haematology and clinical pathology.

of fixation and staining for identification of bacteria, discovered tubercle bacilli in 1882 and cholera vibrio organism in 1883.

◆ *May-Grünwald* in 1902 and *Giemsa* in 1914 developed blood stains and applied them for classification of blood cells and bone marrow cells.

◆ *Sir William Leishman* (1865–1926) described Leishman's stain for blood films in 1914 and observed Leishman-Donovan bodies (LD bodies) in leishmaniasis.

◆ *Robert Feulgen* (1884–1955) described Feulgen reaction for DNA staining and laid the foundations of cytochemistry and histochemistry.

Simultaneous technological advances in machinery manufacture led to development and upgrading of microtomes for obtaining thin sections of organs and tissues for staining by dyes for enhancing detailed study of sections.

Though the presence of cells in thin sections of non-living object cork had been first demonstrated much earlier by *Robert Hooke* in 1667, it was revived as a unit of living matter in the 19th century by *FT. Schwann* (1810–1882), the first neurohistologist, and *Claude Bernarde* (1813–1878), pioneer in pathophysiology.

Until the end of the 19th century, the study of morbid anatomy had remained largely autopsy-based and thus had remained a retrospective science. *Rudolf Virchow* (1821–1905) in Germany is credited with the beginning of microscopic examination of diseased tissue at cellular level and thus began histopathology as a method of investigation. Virchow hypothesised cellular theory having following two components:

- ◆ All cells come from other cells.
- ◆ Disease is an alteration of normal structure and function of these cells.

Virchow was revered as Pope in pathology in Europe and is aptly known as the 'father of cellular pathology' (Fig. 1.8). Thus, sound foundation of diagnostic pathology based on

microscopy had been laid which was followed and promoted by numerous brilliant successive workers. This gave birth to biopsy pathology and thus emerged the discipline of surgical pathology. Virchow also described etiology of embolism (Virchow's triad—slowing of blood-stream, changes in the vessel wall, changes in the blood itself), metastatic spread of tumours (Virchow's lymph node), and components and diseases of blood (fibrinogen, leukocytosis, leukaemia).

The concept of frozen section examination while the patient was still on the operation table was introduced by Virchow's student, *Julius Cohnheim* (1839–1884). In fact, during the initial period of development of surgical pathology around the turn of the 19th century, frozen section was considered more acceptable by the surgeons.

The concept of surgeon and physician doubling up in the role of pathologist which started in the 19th century continued as late as the middle of the 20th century in most clinical departments. Assigning biopsy pathology work to some faculty member in the clinical department was common practice; that is why some of the notable pathologists of the first half of 20th century had background of clinical training e.g. *James Ewing* (1866–1943), *A.P. Stout* (1885–1967) and *Lauren Ackerman* (1905–1993) in US, *Pierre Masson* (1880–1958) in France, and *R.A. Willis* in Australia.

A few other landmarks in further evolution of modern pathology in this era are as follows:

◆ *Karl Landsteiner* (1863–1943) described the existence of major human blood groups in 1900 and is considered "father of blood transfusion"; he was awarded Nobel prize in 1930 (Fig. 1.9).

◆ *Ruska* and *Lorries* in 1933 developed electron microscope which aided the pathologist to view ultrastructure of cell and its organelles.

FATHER OF CELLULAR PATHOLOGY

Figure 1.8 Rudolf Virchow (1821–1905). German pathologist who proposed cellular theory of disease and initiated biopsy pathology for diagnosis of diseases.

FATHER OF BLOOD TRANSFUSION

Figure 1.9 Karl Landsteiner (1863–1943). An Austrian pathologist who first discovered the existence of major human blood groups in 1900 and was recipient of Nobel prize in 1930.

FATHER OF EXFOLIATIVE CYTOLOGY

Figure 1.10 George N Papanicolaou (1883–1962). An American pathologist, who developed Pap test for diagnosis of cancer of uterine cervix.

◆ The development of exfoliative cytology for early detection of cervical cancer began with *George N. Papanicolaou* (1883–1962), a Greek-born, American pathologist, in 1930s and is known as ‘father of exfoliative cytology’ (**Fig. 1.10**).

Another pioneering contribution in pathology in the 20th century was by an eminent teacher-author, *William Boyd* (1885–1979), psychiatrist-turned pathologist, whose textbooks—‘Pathology for Surgeons’ (first edition 1925) and ‘Textbook of Pathology’ (first edition 1932), dominated and inspired the students of pathology all over the world due to his flowery language and lucid style for a few generations. *M.M. Wintrobe* (1901–1986), a pupil of Boyd who discovered haematocrit technique, regarded him as a very stimulating teacher.

MODERN PATHOLOGY

The strides made in the latter half of 20th century until recent times in 21st century have made it possible to study diseases at genetic and molecular level, and provide an evidence-based and objective diagnosis that may enable the physician to institute targeted therapy. The major impact of advances in molecular biology are in the field of diagnosis and treatment of genetic disorders, immunology and in cancer. Some of the revolutionary discoveries during this time are as under (**Fig. 1.11**):

- ◆ Description of the structure of DNA of the cell by Watson and Crick in 1953.
- ◆ Identification of chromosomes and their correct number in humans (46) by Tijo and Levan in 1956.

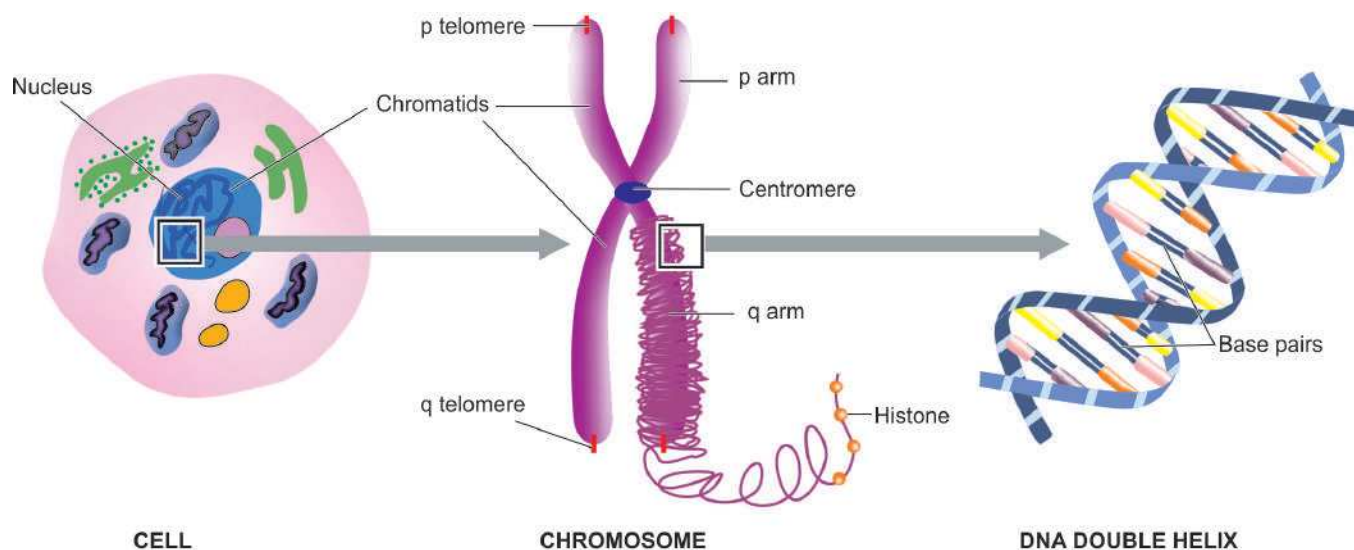

Figure 1.11 Molecular structure of human chromosome.

- ◆ Identification of *Philadelphia chromosome* t(9;22) in chronic myeloid leukaemia by Nowell and Hagerford in 1960 as the first chromosomal abnormality in any cancer.
- ◆ *In Situ hybridization* (ISH) introduced in 1969 in which a labelled probe is employed to detect and localise specific RNA or DNA sequences '*in situ*' (i.e. in the original place). Its later modification employs use of fluorescence microscopy (FISH) to detect specific localisation of the defect on chromosomes.
- ◆ *Recombinant DNA technique* developed in 1972 using restriction enzymes to cut and paste bits of DNA.
- ◆ Introduction of *polymerase chain reaction* (PCR) i.e. "xeroxing" of DNA fragments by Kary Mullis in 1983 has revolutionised the diagnostic molecular genetics. PCR analysis is more rapid than ISH, can be automated by thermal cyclers and requires much lower amount of starting DNA.
- ◆ Invention of *flexibility and dynamism of DNA* by Barbara McClintock for which she was awarded Nobel prize in 1983.
- ◆ *Mammalian cloning* started in 1997 by *Ian Wilmut* and his colleagues at Roslin Institute in Edinburgh, by successfully using a technique of somatic cell nuclear transfer to create the clone of a sheep named Dolly. Reproductive cloning for human beings, however, is very risky besides being absolutely unethical.
- ◆ The era of *stem cell research* started in 2000s by harvesting these primitive cells isolated from embryos and maintaining their growth in the laboratory. There are 2 types of sources of stem cells in humans: embryonic stem cells and adult stem cells, the former being more numerous. Stem cells are seen by many researchers as having virtually unlimited applications in the treatment of many human diseases such as Alzheimer's disease, diabetes, cancer, strokes, etc. At some point of time, stem cell therapy may be able to replace whole organ transplant and instead stem cells 'harvested' from the embryo may be used.
- ◆ *Human Genome Project (HGP)* consisting of a consortium of countries was completed in April 2003 coinciding with 50 years of description of DNA double helix by Watson and Crick in April 1953. The sequencing of human genome reveals that human genome contains approximately 3 billion base pairs of amino acids, which are located in the 23 pairs of chromosomes within the nucleus of each human cell. Each chromosome contains an estimated 30,000 genes in the human genome which carry the instructions for making proteins. The HGP has given us the ability to read nature's complete genetic blueprint used in making of each human being (i.e. gene mapping). Clinical trials by gene therapy on treatment of some single gene defects have resulted in some success, especially in haematological and immunological diseases. Future developments in genetic engineering may result in designing new and highly effective individualised treatment options for genetic diseases as well as suggest prevention against diseases.

TELEPATHOLOGY AND VIRTUAL MICROSCOPY

Telepathology is defined as the practice of diagnostic pathology by a remote pathologist utilising images of tissue specimens transmitted over a telecommunication network. The main *components* of a telepathology system are as under:

- ◆ Conventional light microscope.

- ◆ Method of image capture, commonly a camera mounted on light microscope.
- ◆ Telecommunications link between sending and receiving side.
- ◆ Workstation at receiving end with a high quality monitor.

Depending upon need and budget, telepathology system is of two *types*:

Static (store-and-forward, passive telepathology) In this, selected images are captured, stored and then transmitted over the internet via e-mail attachment, file transfer protocol, web page or CD-ROM. It is quite inexpensive and is more common but suffers from disadvantage of having sender's bias in selection of transmitted images.

Dynamic (Robotic interactive telepathology) Here, the images are transmitted in real-time from a remote microscope. Robotic movement of stage of microscope is controlled remotely and the desired images and fields are accessioned from a remote/local server. Thus, it almost duplicates to perfection the examination of actual slides under the microscope, hence is referred to as *Virtual Microscopy*. However, image quality and speed of internet can be major hurdles.

The era of "*digital pathology*" in 21st Century has reached its zenith with availability of technology for preparation of *virtual pathology slides (VPS)* by high speed scanners and then storing the scanned data in large memory output computers. VPS stored in the memory of the computer can then be examined and reported at any place on computer, without having to use microscope. However, the moot question remains whether current pathologists used to conventional microscopy will get the same perception on monitor. At present, this technology holds potential for pathology education, storage for records, clinical meetings and quality control.

SUBDIVISIONS OF PATHOLOGY

Human pathology is conventionally studied under two broad divisions: *General Pathology* dealing with general principles of disease, and *Systemic Pathology* that includes study of diseases pertaining to the specific organs and body systems. In general, the study of pathology includes morphological and non-morphological disciplines as follows:

MORPHOLOGICAL BRANCHES

These branches essentially involve application of microscope as an essential tool for the study and include histopathology, cytopathology and haematology.

A. HISTOPATHOLOGY Histopathology, used synonymously with anatomic pathology, pathologic anatomy, morbid anatomy, or tissue pathology, is the classic method of study and still the most useful one which has stood the test of time. The study includes structural changes observed by naked eye examination referred to as gross or macroscopic changes, and the changes detected by microscopy, which may be further supported by numerous special staining methods such as histochemistry and immunohistochemistry to arrive at the most accurate diagnosis. Modern time anatomic pathology includes sub-specialities such as cardiac pathology, pulmonary pathology, neuropathology, renal pathology, gynaecologic pathology, breast pathology, dermatopathology,

gastrointestinal pathology, oral pathology, and so on. Anatomic pathology includes the following subdivisions:

1. Surgical pathology It deals with the study of tissues removed from the living body by biopsy or surgical resection. Surgical pathology forms the bulk of tissue material for the pathologist and includes study of tissue by conventional *paraffin embedding* technique; *intraoperative frozen section* may be employed for rapid diagnosis.

2. Experimental pathology This is defined as production of disease in the experimental animal and study of morphological changes in organs after sacrificing the animal. However, all the findings of experimental work in animals may not be applicable to human beings due to species differences.

3. Forensic pathology and autopsy work This includes the study of organs and tissues removed at postmortem for medicolegal work and for determining the underlying sequence and cause of death. By this, the pathologist attempts to reconstruct the course of events how they may have happened in the patient during life which culminated in his death. Postmortem anatomical diagnosis is helpful to the clinician to enhance his knowledge about the disease and his judgement while forensic autopsy is helpful for medicolegal purposes. The significance of a careful postmortem examination is appropriately summed up in the old saying 'the dead teach the living'.

B. CYTOPATHOLOGY Though a branch of anatomic pathology, cytopathology has developed as a distinct subspeciality in recent times. It includes study of cells shed off from the lesions (exfoliative cytology) and fine-needle aspiration cytology (FNAC) of superficial and deep-seated lesions for diagnosis (Appendix I).

C. HAEMATOLOGY Haematology deals with the diseases of blood. It includes laboratory haematology and clinical haematology; the latter covers the management of patient as well.

NON-MORPHOLOGICAL BRANCHES

These diagnostic branches of pathology include clinical pathology, clinical biochemistry, microbiology, immunology, genetics and molecular pathology. In these diagnostic branches, qualitative, semi-quantitative or quantitative determinations are carried out in the laboratory. Microscope may also be required for at least some of these lab tests.

A. CLINICAL PATHOLOGY Analysis of various fluids including blood, urine, semen, CSF and other body fluids is included in this branch of pathology. Such analysis may be qualitative, semi-quantitative or quantitative.

B. CLINICAL BIOCHEMISTRY Quantitative determination of various biochemical constituents in serum and plasma, and in other body fluids is included in clinical biochemistry.

Obviously, there is likely to be overlapping between clinical pathology and clinical biochemistry.

C. MICROBIOLOGY This is study of disease-causing microbes implicated in human diseases. Depending upon the type of microorganisms studied, it has further developed into such as bacteriology, parasitology, mycology, virology etc.

D. IMMUNOLOGY Detection of abnormalities in the immune system of the body comprises immunology and immunopathology.

E. MEDICAL GENETICS This is the branch of human genetics that deals with the relationship between heredity and disease. There have been important developments in the field of medical genetics e.g. in blood groups, inborn errors of metabolism, chromosomal aberrations in congenital malformations and neoplasms etc.

F. MOLECULAR PATHOLOGY The detection and diagnosis of abnormalities at the level of DNA of the cell is included in molecular pathology such as in situ hybridisation, PCR etc. These methods are now not only used for research purposes but are also being used as a part of diagnostic pathology reports.

The above divisions of pathology into several subspecialities are quite artificial since overlapping of disciplines is likely, ultimate aim of pathologist being to establish the final diagnosis and learn the causes and mechanisms of disease. Towards this aim, the beginner as well as the teacher in pathology remain life-long students of pathology, eager to learn more in their quest to become better with every passing day.

GIST BOX 1.1

Introduction to Pathology

- ▣ Pathology is the study of structural and functional changes in disease.
- ▣ Pathologic changes present with clinical features (symptoms, signs) in the patient.
- ▣ In pathology, we study causes (etiology), mechanisms (pathogenesis) and arrive at final diagnosis by various laboratory methods; gross and microscopic examination of tissues is the major method.
- ▣ The Caduceus representing ancient Greek gods is symbol of medicine.
- ▣ 'Father of medicine' is Hippocrates; 'Father of modern medicine' is Sir William Osler.
- ▣ 'Father of pathology' is Rudolf Virchow; 'Father of CPCs' is Giovanni B. Morgagni; 'Father of museum' is John Hunter; 'Father of clinical pathology' is Paul Ehrlich; 'Father of blood transfusion' is Karl Landsteiner; 'Father of cytology' is George N. Papanicolaou.
- ▣ Morphologic branches of diagnostic pathology are histopathology, cytopathology and haematology.
- ▣ Important ancillary diagnostic techniques in pathology are immunohistochemistry, cytogenetics and molecular methods such as ISH and PCR.

Cells are the basic units of tissues, which form organs and systems in the human body. Traditionally, body cells are divided into two main types: epithelial and mesenchymal cells. In health, the cells remain in accord with each other. In 1859, Virchow first published cellular theory of disease, bringing in the concept that diseases occur due to abnormalities at the level of cells. Since then, study of abnormalities in structure and function of cells in disease has remained the focus of attention in understanding of diseases. Thus, most forms of diseases begin with cell injury followed by consequent loss of cellular function.

CELL INJURY

Cell injury is defined as the effect of a variety of stresses due to etiologic agents a cell encounters resulting in changes in its internal and external environment. In general, cells of the body have inbuilt mechanism to deal with changes in environment to an extent. The cellular response to stress may vary and depends upon following two variables:

- i) Host factors i.e. the type of cell and tissue involved.
- ii) Factors pertaining to injurious agent i.e. extent and type of cell injury.

Various forms of cellular responses to cell injury may be as follows (Fig. 2.1):

1. When there is increased functional demand, the cell may adapt to the changes which are expressed morphologically, which then revert back to normal after the stress is removed (*cellular adaptations*, see Fig. 2.36).
2. When the stress is mild to moderate, the injured cell may recover (*reversible cell injury*), while persistent and severe form of cell injury may cause cell death (*irreversible cell injury*).
3. The residual effects of reversible cell injury may persist in the cell as evidence of cell injury at subcellular level

(*subcellular changes*), or metabolites may accumulate within the cell (*intracellular accumulations*).

In order to learn the fundamentals of disease processes at cellular level, it is essential to have an understanding of the causes (etiology) and mechanisms (pathogenesis) of cell injury and cellular adaptations which are discussed below.

ETIOLOGY OF CELL INJURY

The cells may be broadly injured by two major ways:

- A. Genetic causes
- B. Acquired causes

The genetic causes of various diseases are discussed in Chapter 9. The acquired causes of disease comprise vast majority of common diseases afflicting mankind. Based on underlying agent, the acquired causes of cell injury can be further categorised as under:

1. Hypoxia and ischaemia
2. Physical agents
3. Chemical agents and drugs
4. Microbial agents
5. Immunologic agents
6. Nutritional derangements
7. Ageing
8. Psychogenic diseases
9. Iatrogenic factors
10. Idiopathic diseases.

In a given situation, more than one of the above etiologic factors may be involved. These factors are briefly outlined below.

HYPOXIA AND ISCHAEMIA Cells of different tissues essentially require oxygen to generate energy and perform metabolic functions. Deficiency of oxygen or hypoxia results in failure to carry out these activities by the cells. Hypoxia is the

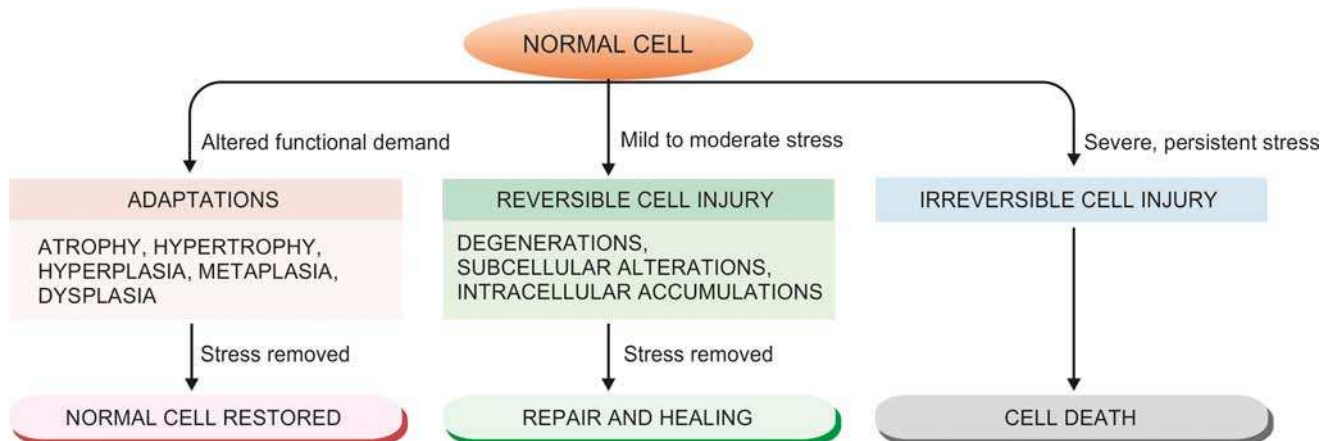

Figure 2.1 Cellular responses to cell injury.

most common cause of cell injury. Hypoxia may result from the following 2 ways:

- ◆ The most common mechanism of hypoxic cell injury is by reduced supply of blood to cells due to interruption i.e. ischaemia.
- ◆ Hypoxia may also result from impaired blood supply from causes other than interruption e.g. disorders of oxygen-carrying RBCs (e.g. anaemia, carbon monoxide poisoning), heart diseases, lung diseases and increased demand of tissues.

PHYSICAL AGENTS Physical agents in causation of disease are as under:

- i) mechanical trauma (e.g. road accidents);
- ii) thermal trauma (e.g. by heat and cold);
- iii) electricity;
- iv) radiation (e.g. ultraviolet and ionising); and
- v) rapid changes in atmospheric pressure.

CHEMICALS AND DRUGS An ever-increasing list of chemical agents and drugs may cause cell injury. Important examples include the following:

- i) chemical poisons such as cyanide, arsenic, mercury;
- ii) strong acids and alkalis;
- iii) environmental pollutants;
- iv) insecticides and pesticides;
- v) oxygen at high concentrations;
- vi) hypertonic glucose and salt;
- vii) social agents such as alcohol and narcotic drugs; and
- viii) therapeutic administration of drugs.

MICROBIAL AGENTS Injuries by microbes include infections caused by bacteria, rickettsiae, viruses, fungi, protozoa, metazoa, and other parasites.

Diseases caused by biologic agents are discussed in Chapter 6.

IMMUNOLOGIC AGENTS Immunity is a 'double-edged sword'—it protects the host against various injurious agents but it may also turn lethal and cause cell injury e.g.

- i) hypersensitivity reactions;
- ii) anaphylactic reactions; and
- iii) autoimmune diseases.

Immunologic tissue injury is discussed in Chapter 3.

NUTRITIONAL DERANGEMENTS A deficiency or an excess of nutrients may result in nutritional imbalances.

◆ Nutritional deficiency diseases may be due to overall deficiency of nutrients (e.g. starvation), of protein calorie (e.g. marasmus, kwashiorkor), of minerals (e.g. anaemia), or of trace elements.

◆ Nutritional excess is a problem of affluent societies resulting in obesity, atherosclerosis, heart disease and hypertension.

Nutritional diseases are discussed in Chapter 8.

AGEING Cellular ageing or senescence leads to impaired ability of the cells to undergo replication and repair, and ultimately lead to cell death culminating in death of the individual. This aspect is dealt at the end of this chapter.

PSYCHOGENIC DISEASES There are no specific biochemical or morphologic changes in common acquired mental diseases due to mental stress, strain, anxiety, overwork and frustration e.g. depression, schizophrenia. However, problems of drug addiction, alcoholism, and smoking result in various organic diseases such as liver damage, chronic bronchitis, lung cancer, peptic ulcer, hypertension, ischaemic heart disease etc.

IATROGENIC CAUSES Although as per Hippocratic oath, every physician is bound not to do or administer anything that causes harm to the patient, there are some diseases as well as deaths attributed to iatrogenic causes (owing to physician). Examples include occurrence of disease or death due to error in judgement by the physician and untoward effects of administered therapy (drugs, radiation).

IDIOPATHIC DISEASES Idiopathic means "of unknown cause". Finally, although so much is known about the etiology of diseases, there still remain many diseases for which exact cause is undetermined. For example, most common form of hypertension (90%) is idiopathic (or essential) hypertension. Similarly, exact etiology of many cancers is still incompletely known.

GIST BOX 2.1

Etiology of Cell Injury

- Cell injury is the effect of a variety of stresses due to etiologic agents a cell encounters resulting in changes in its internal and external environment.
- The cellular response to stress depends upon the type of cell and tissue involved, and the extent and type of cell injury.
- Initially, cells adapt to the changes due to injurious agent and may revert back to normal.
- Mild to moderate stress for shorter duration causes reversible cell injury; severe and persistent stress causes cell death.
- Among various etiologic factors, hypoxia-ischaemia is most important; others are chemical and physical agents, microbes, immunity, ageing etc.

PATHOGENESIS OF CELL INJURY

Injury to the normal cell by one or more of the above listed etiologic agents may result in a state of reversible or irreversible cell injury. The underlying alterations in biochemical systems of cells for reversible and irreversible cell injury by various agents are complex and varied. However, in general, irrespective of the type, following common scheme applies to most forms of cell injury by various agents:

1. Factors pertaining to etiologic agent and host As mentioned above, factors pertaining to host cells and etiologic agent determine the outcome of cell injury:

i) Type, duration and severity of injurious agent: The extent of cellular injury depends upon type, duration and severity of the stimulus e.g. small dose of chemical toxin or short duration of ischaemia cause reversible cell injury while large dose of the same chemical agent or persistent ischaemia cause cell death.

ii) Type, status and adaptability of target cell: The type of cell as regards its susceptibility to injury, its nutritional and metabolic status, and adaptation of the cell to hostile environment determine the extent of cell injury e.g. skeletal muscle can withstand hypoxic injury for long-time while cardiac muscle suffers irreversible cell injury after persistent ischaemia due to total coronary occlusion ≥ 20 minutes.

2. Common underlying mechanisms Irrespective of other factors, following essential intracellular biochemical phenomena underlie all forms of cell injury:

- i) Mitochondrial damage causing ATP depletion.

ii) Cell membrane damage disturbing the metabolic and trans-membrane exchanges.

iii) Release of toxic free radicals.

3. Usual morphologic changes Biochemical and molecular changes underlying cell injury from various agents become apparent first, and are associated with appearance of ultrastructural changes in the injured cell. However, eventually, gross and light microscopic changes in morphology of organ and cells appear. The morphologic changes of reversible cell injury (e.g. hydropic swelling) appear earlier while later morphologic alterations of cell death are seen (e.g. in myocardial infarction).

4. Functional implications and disease outcome Eventually, cell injury affects cellular function adversely which has bearing on the body. Consequently, clinical features in the form of symptoms and signs would appear. Further course or prognosis will depend upon the response to treatment versus the biologic behaviour of disease.

The interruption of blood supply (i.e. ischaemia) and impaired oxygen supply to the tissues (i.e. hypoxia) are most common form of cell injury in human beings. Pathogenesis of hypoxic and ischaemic cell injury is, therefore, described in detail below followed by brief discussion on pathogenesis of chemical and physical (principally ionising radiation) agents.

PATHOGENESIS OF ISCHAEMIC AND HYPOXIC INJURY

Ischaemia and hypoxia are the most common forms of cell injury. Although underlying intracellular mechanisms and

ultrastructural changes seen in reversible and irreversible cell injury by hypoxia-ischaemia (depending upon extent of hypoxia and type of cells involved) are a continuation of the process, these mechanisms are discussed separately below and illustrated diagrammatically in **Figs. 2.2 and 2.3**:

REVERSIBLE CELL INJURY If the ischaemia or hypoxia is of short duration, the effects may be reversible on rapid restoration of circulation e.g. in coronary artery occlusion, myocardial contractility, metabolism and ultrastructure are reversed if the circulation is quickly restored. The sequential biochemical and ultrastructural changes in reversible cell injury are as under (**Fig. 2.3,A**):

1. Decreased generation of cellular ATP: Damage by ischaemia from interruption versus hypoxia from other causes

All living cells require continuous supply of oxygen to produce ATP which is essentially required for a variety of cellular functions (e.g. membrane transport, protein synthesis, lipid synthesis and phospholipid metabolism). ATP in human cell is derived from 2 sources:

- ◆ *Firstly*, by aerobic respiration or oxidative phosphorylation (which requires oxygen) in the mitochondria.
- ◆ *Secondly*, cells may subsequently switch over to anaerobic glycolytic oxidation to maintain constant supply of ATP (in which ATP is generated from glucose/glycogen in the absence of oxygen).

Ischaemia due to interruption in blood supply as well as hypoxia from other causes limit the supply of oxygen to the cells, thus causing decreased ATP generation from ADP:

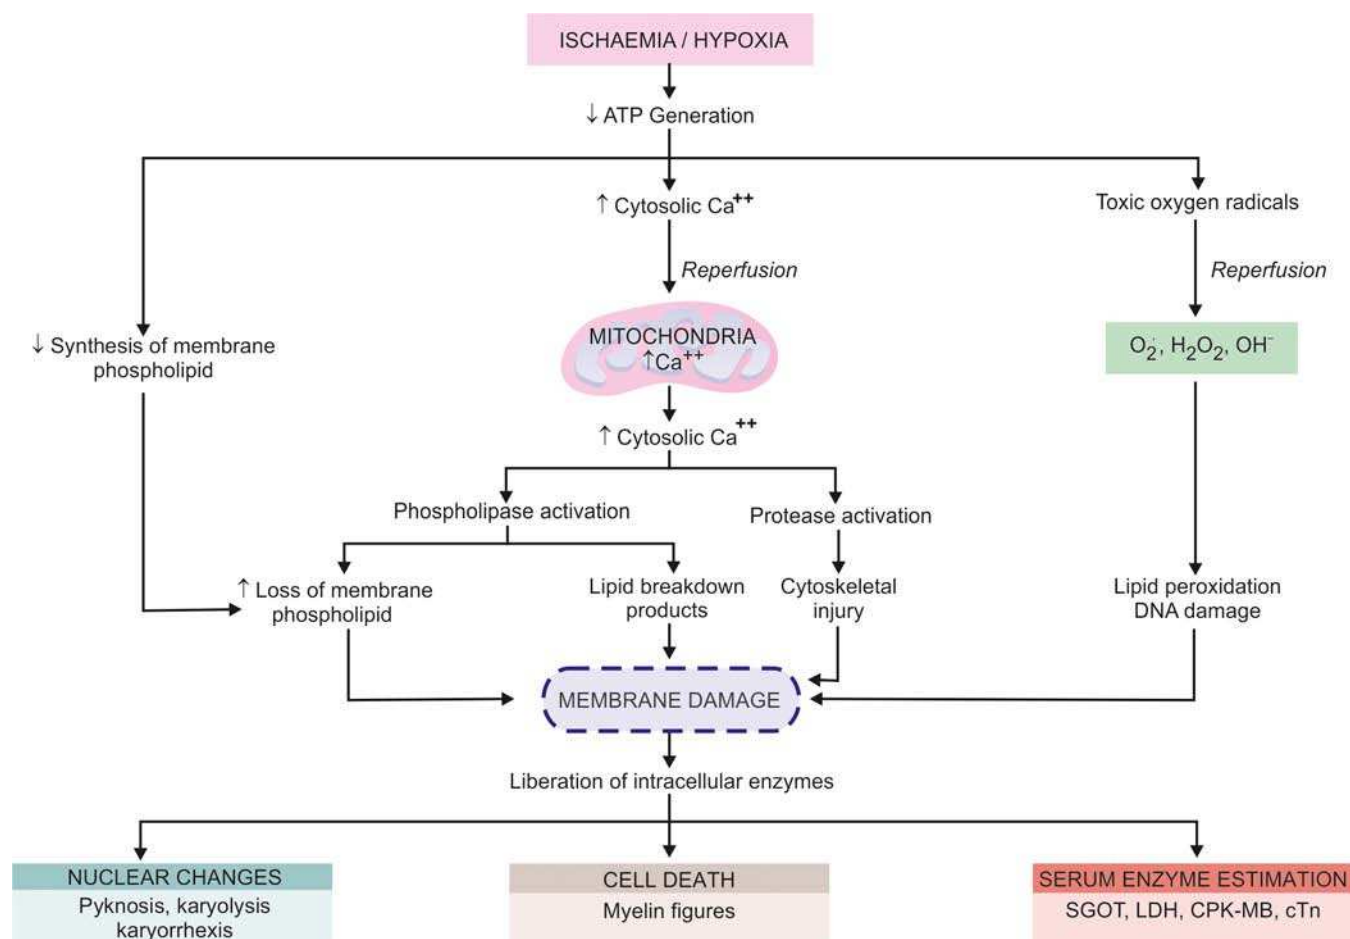

Figure 2.2 Sequence of events in the pathogenesis of reversible and irreversible cell injury caused by hypoxia/ischaemia.

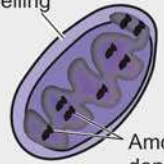

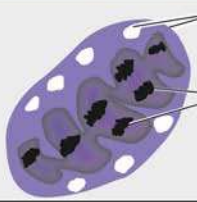

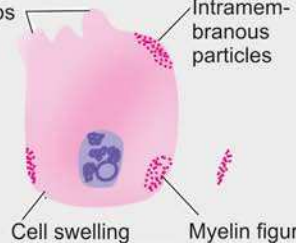

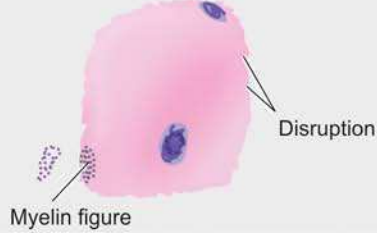

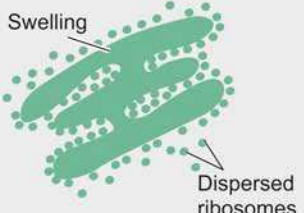

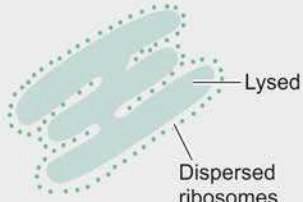

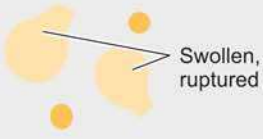

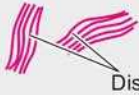

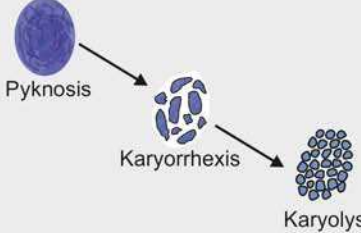

| ORGANELLES IN NORMAL CELL | A, REVERSIBLE CELL INJURY | B, IRREVERSIBLE CELL INJURY |
|---|---|---|
| 1. MITOCHONDRIA  | Swelling Amorphous densities  | Swollen with vacuoles Large densities  |
| 2. MEMBRANES  | Blebs Intramembranous particles Cell swelling Myelin figure  | Disruption Myelin figure  |
| 3. RER AND RIBOSOMES  | Swelling Dispersed ribosomes  | Lysed Dispersed ribosomes  |
| 4. LYSOSOMES  | Autophagy  | Swollen, ruptured  |
| 5. CYTOSKELETON  | Aggregated  | Disrupted  |
| 6. NUCLEUS  | Clumped chromatin  | Pyknosis Karyorrhexis Karyolysis  |

Figure 2.3 Ultrastructural changes during cell injury due to hypoxia-ischæmia.

◆ In *ischæmia* from interruption of blood supply, aerobic respiration as well as glucose availability are both compromised resulting in more severe and faster effects of cell injury. Ischaemic cell injury also causes accumulation of metabolic waste products in the cells.

◆ On the other hand, in *hypoxia from other causes* (RBC disorders, heart disease, lung disease), anaerobic glycolytic ATP generation continues, and thus cell injury is less severe.

However, highly specialised cells such as myocardium, proximal tubular cells of the kidney, and neurons of the CNS are dependent solely on aerobic respiration for ATP generation and thus these tissues suffer from ill-effects of ischaemia more severely and rapidly.

2. Intracellular lactic acidosis: Nuclear clumping Due to low oxygen supply to the cell, aerobic respiration by mitochondria fails first. This is followed by switch to anaerobic

glycolytic pathway for the requirement of energy (i.e. ATP). This results in rapid depletion of glycogen and accumulation of lactic acid lowering the intracellular pH. Early fall in intracellular pH (i.e. intracellular lactic acidosis) results in clumping of nuclear chromatin.

3. Damage to plasma membrane pumps: Hydropic swelling and other membrane changes Lack of ATP interferes in generation of phospholipids from the cellular fatty acids which are required for continuous repair of membranes. This results in damage to membrane pumps operating for regulation of sodium-potassium and calcium as under:

i) *Failure of sodium-potassium pump* Normally, the energy (ATP)-dependent sodium pump (also called $\text{Na}^+\text{-K}^+$ ATPase) operating at the plasma membrane allows active transport of sodium out of the cell and diffusion of potassium into the cell. Lowered ATP in the cell lowers the activity of sodium pump and consequently interferes with this membrane-regulated process. This results in intracellular accumulation of sodium and diffusion of potassium out of the cell. The accumulation of sodium in the cell leads to increase in intracellular water to maintain iso-osmotic conditions (i.e. hydropic swelling occurs, discussed later in the chapter).

ii) *Failure of calcium pump* Membrane damage causes disturbance in the calcium ion exchange across the cell membrane. Excess of calcium moves into the cell (i.e. calcium influx), particularly in the mitochondria, causing its swelling and deposition of phospholipid-rich amorphous densities.

4. Reduced protein synthesis: Dispersed ribosomes As a result of continued hypoxia, membranes of endoplasmic reticulum and Golgi apparatus swell up. Ribosomes are detached from granular (rough) endoplasmic reticulum and polysomes are degraded to monosomes, thus dispersing ribosomes in the cytoplasm and inactivating their function. Similar reduced protein synthesis occurs in Golgi apparatus.

Ultrastructural evidence of reversible cell membrane damage is seen in the form of loss of microvilli, intramembranous particles and focal projections of the cytoplasm (blebs). *Myelin figures* may be seen lying in the cytoplasm or present outside the cell; these are derived from membranes (plasma or organellar) enclosing water and dissociated lipoproteins between the lamellae of injured membranes.

Up to this point, withdrawal of acute stress that resulted in reversible cell injury can restore the cell to normal state.

IRREVERSIBLE CELL INJURY Persistence of ischaemia or hypoxia results in irreversible damage to the structure and function of the cell (cell death). The stage at which this *point of no return or irreversibility* is reached from reversible cell injury is unclear but the sequence of events is a continuation of reversibly injured cell. Two essential phenomena always distinguish irreversible from reversible cell injury (**Fig. 2.2**):

- ◆ Inability of the cell to reverse *mitochondrial dysfunction* on reperfusion or reoxygenation.
- ◆ *Disturbance in cell membrane function* in general, and in plasma membrane in particular.

In addition, there is further reduction in ATP, continued depletion of proteins, reduced intracellular pH, and leakage of lysosomal enzymes into the plasma. These biochemical changes have effects on the ultrastructural components of the cell (**Fig. 2.3, B**):

1. Calcium influx: Mitochondrial damage As a result of continued hypoxia, a large cytosolic influx of calcium ions occurs, especially after reperfusion of irreversibly injured cell. Excess intracellular calcium collects in the mitochondria disabling its function. Morphological changes are in the form of vacuoles in the mitochondria and deposits of amorphous calcium salts in the mitochondrial matrix.

2. Activated phospholipases: Membrane damage Damage to membrane function in general, and plasma membrane in particular, is the most important event in irreversible cell injury. Increased cytosolic influx of calcium in the cell activates endogenous *phospholipases*. These, in turn, degrade membrane phospholipids progressively which are the main constituent of the lipid bilayer membrane. Besides, there is also decreased replacement-synthesis of membrane phospholipids due to reduced ATP. Other lytic enzyme which is activated is *ATPase* which causes further depletion of ATP.

3. Intracellular proteases: Cytoskeletal damage The normal cytoskeleton of the cell (microfilaments, microtubules and intermediate filaments) which anchors the cell membrane is damaged due to degradation by activated intracellular proteases or by physical effect of cell swelling producing irreversible cell membrane injury.

4. Activated endonucleases: Nuclear damage DNA or nucleoproteins are damaged by the activated lysosomal enzymes such as proteases and endonucleases. Irreversible damage to the nucleus can be in three forms:

- i) *Pyknosis*: Condensation and clumping of nucleus which becomes dark basophilic.
- ii) *Karyorrhexis*: Nuclear fragmentation in to small bits dispersed in the cytoplasm.
- iii) *Karyolysis*: Dissolution of the nucleus.

Damaged DNA activates proapoptotic proteins leading the cell to death.

5. Lysosomal hydrolytic enzymes: Lysosomal damage, cell death and phagocytosis The lysosomal membranes are damaged and result in escape of lysosomal hydrolytic enzymes. These enzymes are activated due to lack of oxygen in the cell and acidic pH. These hydrolytic enzymes: (e.g. hydrolase, RNAase, DNAase, protease, glycosidase, phosphatase, lipase, amylase, cathepsin etc) on activation bring about enzymatic digestion of cellular components and hence cell death. The dead cell is eventually replaced by masses of phospholipids called *myelin figures* which are either phagocytosed by macrophages or there may be formation of calcium soaps.

Liberated enzymes just mentioned leak across the abnormally permeable cell membrane into the serum, the estimation of which may be used as clinical parameters of cell death. For example, in myocardial infarction, estimation of elevated serum glutamic oxaloacetic transaminase (SGOT), lactic dehydrogenase (LDH), isoenzyme of creatine kinase (CK-MB), and cardiac troponins (cTn) are useful guides for death of heart muscle. Some of the common enzyme markers for different forms of cell death are given in **Table 2.1**.

While cell damage from oxygen deprivation by above mechanisms develops slowly, taking several minutes to hours, the cell injury may be accentuated after restoration of blood supply and subsequent events termed *ischaemic-reperfusion injury and liberation of toxic free radicals (or reactive oxygen species)*, discussed below.

Table 2.1 Common enzyme markers of cell death.

| ENZYME | DISEASE |
|--|--|
| 1. <i>Aspartate aminotransferase (AST, SGOT)</i> | Diffuse liver cell necrosis e.g. viral hepatitis, alcoholic liver disease Acute myocardial infarction |
| 2. <i>Alanine aminotransferase (ALT, SGPT)</i> | More specific for diffuse liver cell damage than AST e.g. viral hepatitis |
| 3. <i>Creatine kinase-MB (CK-MB)</i> | Acute myocardial infarction, myocarditis Skeletal muscle injury |
| 4. <i>Lipase</i> | More specific for acute pancreatitis |
| 5. <i>Amylase</i> | Acute pancreatitis Sialadenitis |
| 6. <i>Lactic dehydrogenase (LDH)</i> | Acute myocardial infarction Myocarditis Skeletal muscle injury |
| 7. <i>Cardiac troponin (CTn)</i> | Specific for acute myocardial infarction |

Ischaemia-Reperfusion Injury and Free Radical-Mediated Cell Injury

Depending upon the duration of ischaemia/hypoxia, restoration of blood flow may result in the following 3 different consequences:

1. From ischaemia to reversible injury *When the period of ischaemia is of short duration, reperfusion with resupply of oxygen restores the structural and functional state of the injured cell i.e. reversible cell injury.*

2. From ischaemia to irreversible injury *Another extreme is when much longer period of ischaemia has resulted in irreversible cell injury during ischaemia itself i.e. when so much time has elapsed that neither blood flow restoration is helpful nor reperfusion injury can develop. Cell death in such cases is not attributed to formation of activated oxygen species. But instead, on reperfusion there is further marked intracellular excess of sodium and calcium ions due to persistent cell membrane damage.*

3. From ischaemia to reperfusion injury *When ischaemia is for somewhat longer duration, then restoration of blood supply to injured but viable cells (i.e. reperfusion), rather than restoring structure and function of the cell, paradoxically deteriorates the already injured cell and leads it to cell death. This is termed ischaemia-reperfusion injury. The examples*

of such forms of cell injury are irreversible cell injury in myocardial and cerebral ischaemia.

Ischaemia-reperfusion injury occurs due to excessive accumulation of free radicals or reactive oxygen species. The mechanism of reperfusion injury by free radicals is complex but following three aspects are involved:

1. Calcium overload.
2. Excessive generation of free radicals (superoxide, H_2O_2 , hydroxyl radical, pernitrite).
3. Subsequent inflammatory reaction.

These are discussed below:

1. CALCIUM OVERLOAD Upon restoration of blood supply, the ischaemic cell is further bathed by the blood fluid that has more calcium ions at a time when the ATP stores of the cell are low. This results in further calcium overload on the already injured cells, triggering lipid peroxidation of the membrane causing further membrane damage.

2. EXCESSIVE GENERATION OF FREE RADICALS Although oxygen is the lifeline of all cells and tissues, its molecular forms as reactive oxygen radicals or reactive oxygen species can be most devastating for the cells. Free radical-mediated cell injury has been extensively studied and a brief account is given below.

Oxygen free radical generation Normally, reduction-oxidation (redox) reaction in the metabolism of the cell involves generation of ATP by oxidative process in which biradical oxygen (O_2) combines with hydrogen atom (H), and in the process, water (H_2O) is formed. This normal reaction of O_2 to H_2O involves 'four electron donation' in four steps involving transfer of one electron at each step. Free radicals are intermediate chemical species having a single unpaired electron in its outer orbit. These are generated within mitochondrial inner membrane where cytochrome oxidase catalyses the O_2 to H_2O reaction. Three intermediate molecules of partially reduced species of oxygen are generated depending upon the number of electrons transferred (Fig. 2.4):

- i) Superoxide oxygen (O_2^-): one electron
- ii) Hydrogen peroxide (H_2O_2): two electrons
- iii) Hydroxyl radical (OH^-): three electrons

These are generated from enzymatic and non-enzymatic reaction as under:

i) *Superoxide (O_2^-):* Superoxide anion O_2^- may be generated by direct auto-oxidation of O_2 during mitochondrial electron transport reaction. Alternatively, O_2^- is produced enzymatically by xanthine oxidase and cytochrome P_{450} in the mitochondria or cytosol.

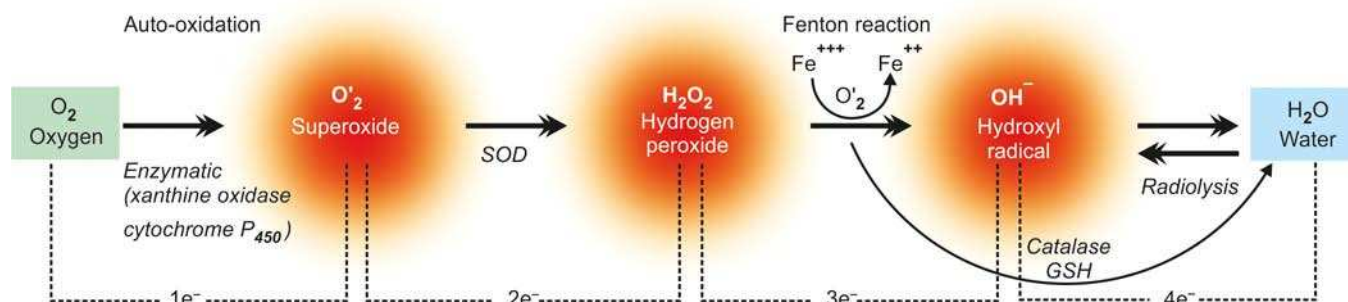

Figure 2.4 Mechanisms of generation of free radicals by four electron step reduction of oxygen. (SOD = superoxide dismutase; GSH = glutathione peroxidase).

ii) *Hydrogen peroxide (H_2O_2)*: O_2^- so formed as above is catabolised to produce H_2O_2 by superoxide dismutase (SOD). H_2O_2 is reduced to water enzymatically by catalase (in the peroxisomes) and glutathione peroxidase, GSH (both in the cytosol and mitochondria).

iii) *Hydroxyl radical (OH^\cdot)*: OH^\cdot radical is formed by 2 ways in biologic processes—by radiolysis of water and by reaction of H_2O_2 with ferrous (Fe^{2+}) ions; the latter process is termed as Fenton reaction. Fenton reaction involves reduction of normal intracellular ferric (Fe^{3+}) to ferrous (Fe^{2+}) form, a reaction facilitated by O_2^- .

Other free radicals In addition to superoxide, H_2O_2 and hydroxyl radicals generated during conversion of O_2 to H_2O reaction, a few other free radicals active in the body are as follows:

i) *Nitric oxide (NO) and peroxynitrite (ONOO)*: NO is a chemical mediator formed by various body cells (endothelial cells, neurons, macrophages etc), and is also a free radical. NO can combine with superoxide and forms ONOO which is a highly reactive free radical.

ii) *Halide reagent* (chlorine or chloride) released in the leucocytes reacts with superoxide and forms *hypochlorous acid (HOCl)* which is a cytotoxic free radical.

iii) *Exogenous sources* of free radicals include some environmental agents such as tobacco and industrial pollutants.

Cytotoxicity of free radicals Free radicals are formed in physiologic as well as pathologic processes. Basically, oxygen radicals are unstable and are destroyed spontaneously. The rate of spontaneous destruction is determined by catalytic action of certain enzymes such as superoxide dismutase (SOD), catalase and glutathione peroxidase (GSH). The net effect of free radical injury in physiologic and disease states, therefore, depends upon the rate of their formation and rate of their elimination.

However, if not degraded, then free radicals are highly destructive to the cell since they have electron-free residue and thus bind to all molecules of the cell; this is termed *oxidative stress*. Out of various free radicals, hydroxyl radical is the most reactive species. Free radicals may produce membrane damage by the following mechanisms (Fig. 2.5):

i) *Lipid peroxidation* Polyunsaturated fatty acids (PUFA) of membrane are attacked repeatedly and severely by oxygen-derived free radicals to yield highly destructive PUFA radicals—lipid hydroperoxy radicals and lipid hypoperoxides. This reaction is termed lipid peroxidation. The lipid peroxides are decomposed by transition metals such as iron. Lipid peroxidation is propagated to other sites causing widespread membrane damage and destruction of organelles.

ii) *Oxidation of proteins* Oxygen-derived free radicals cause cell injury by oxidation of protein macromolecules of the cells, cross-linkages of labile amino acids as well as by fragmentation of polypeptides directly. The end-result is degradation of cytosolic neutral proteases and cell destruction.

iii) *DNA damage* Free radicals cause breaks in the single strands of the nuclear and mitochondrial DNA. This results in cell injury; it may also cause malignant transformation of cells.

iv) *Cytoskeletal damage* Reactive oxygen species are also known to interact with cytoskeletal elements and interfere in mitochondrial aerobic phosphorylation and thus cause ATP depletion.

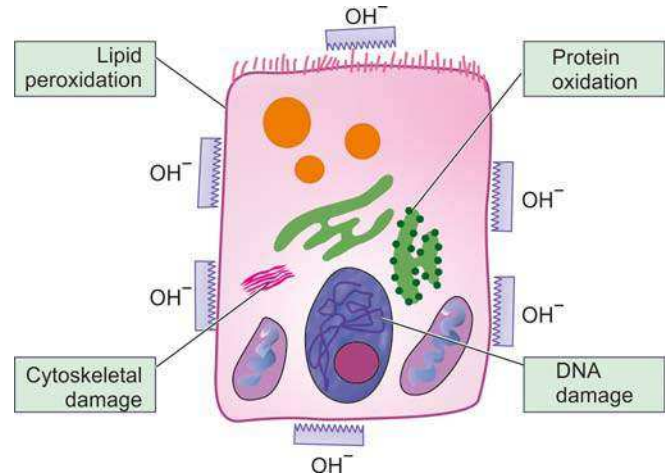

Figure 2.5 Mechanism of cell death by hydroxyl radical, the most reactive oxygen species.

Conditions with free radical injury Currently, oxygen-derived free radicals have been known to play an important role in many forms of cell injury:

- i) Ischaemic reperfusion injury
- ii) Ionising radiation by causing radiolysis of water
- iii) Chemical toxicity
- iv) Chemical carcinogenesis
- v) Hyperoxia (toxicity due to oxygen therapy)
- vi) Cellular ageing
- vii) Killing of microbial agents
- viii) Inflammatory damage
- ix) Destruction of tumour cells
- x) Atherosclerosis.

Antioxidants Antioxidants are endogenous or exogenous substances which inactivate the free radicals. These substances include the following:

- i) Vitamins E, A and C (ascorbic acid)
- ii) Sulfhydryl-containing compounds e.g. cysteine and glutathione.
- iii) Serum proteins e.g. ceruloplasmin and transferrin.

3. SUBSEQUENT INFLAMMATORY REACTION Ischaemia-reperfusion event is followed by inflammatory reaction. Incoming activated neutrophils utilise oxygen quickly (*oxygen burst*) and release large excess of oxygen free radicals. Ischaemia is also associated with accumulation of precursors of ATP, namely ADP and pyruvate, which further build-up generation of free radicals.

Stress Proteins in Cell Injury

When cells are exposed to stress of any type, a protective response by the cell is by release of proteins that move molecules within the cell cytoplasm; these are called stress protein. There are 2 types of stress-related proteins: *heat shock proteins (HSP)* and *ubiquitin* (so named due to its universal presence in the cells of the body).

HSPs These are a variety of intracellular carrier proteins present in most cells of the body, especially in renal tubular epithelial cells. They normally perform the role of *molecular chaperones* (house-keeping) i.e. they direct and guide metabolic molecules to the sites of metabolic activity e.g. protein folding,

disaggregation of protein-protein complexes and transport of proteins into various intracellular organelles (*protein kinesis*). However, in response to stresses of various types (e.g. toxins, drugs, poisons, ischaemia), their level goes up, both inside the cell and also they leak out into the plasma, and hence the name stress proteins.

In experimental studies HSPs have been shown to limit tissue necrosis in ischaemic reperfusion injury in myocardial infarcts. In addition, they have also been shown to have a central role in protein aggregation in amyloidosis.

Ubiquitin This is another related stress protein which has ubiquitous presence in human body cells. Like HSPs, ubiquitin too directs intracellular molecules for either degradation or for synthesis. Ubiquitin has been found to be involved in a variety of human degenerative diseases, especially in the nervous system in ageing e.g. activation of genes for protein synthesis in neurodegenerative diseases such as in Alzheimer's disease, Creutzfeldt-Jakob disease, Parkinson's disease.

PATHOGENESIS OF CHEMICAL INJURY

Chemicals induce cell injury by one of the two mechanisms: by direct cytotoxicity, or by conversion of chemical into reactive metabolites.

DIRECT CYTOTOXIC EFFECTS Some chemicals combine with components of the cell and produce direct cytotoxicity without requiring metabolic activation. The cytotoxic damage is usually greatest to cells which are involved in the metabolism of such chemicals e.g. in mercuric chloride poisoning, the greatest damage occurs to cells of the alimentary tract where it is absorbed and the kidney where it is excreted. Cyanide kills the cell by poisoning mitochondrial cytochrome oxidase thus blocking oxidative phosphorylation.

Other examples of directly cytotoxic chemicals include chemotherapeutic agents used in treatment of cancer, toxic heavy metals such as mercury, lead and iron.

CONVERSION TO REACTIVE TOXIC METABOLITES This mechanism involves metabolic activation to yield ultimate toxin that interacts with the target cells. The target cells in this group of chemicals may not be the same cell that metabolised the toxin. Example of cell injury by conversion of reactive metabolites is toxic liver necrosis caused by carbon tetrachloride (CCl_4), acetaminophen (commonly used analgesic and antipyretic) and bromobenzene. Cell injury by CCl_4 is classic example of an industrial toxin (earlier used in dry-cleaning industry) that produces cell injury by conversion to a highly toxic free radical, CCl_3 , in the body's drug-metabolising P450 enzyme system in the liver cells. Thus, it produces profound liver cell injury by free radical generation. Other mechanism of cell injury includes direct toxic effect on cell membrane and nucleus.

PATHOGENESIS OF PHYSICAL INJURY

Injuries caused by mechanical force are of medicolegal significance. But they may lead to a state of shock. Injuries by changes in atmospheric pressure (e.g. decompression sickness) are detailed in Chapter 4. Radiation injury to human by accidental or therapeutic exposure is of importance in treatment of persons with malignant tumours as well as may have carcinogenic influences (Chapter 7).

Killing of cells by *ionising radiation* is the result of direct formation of hydroxyl radicals from radiolysis of water

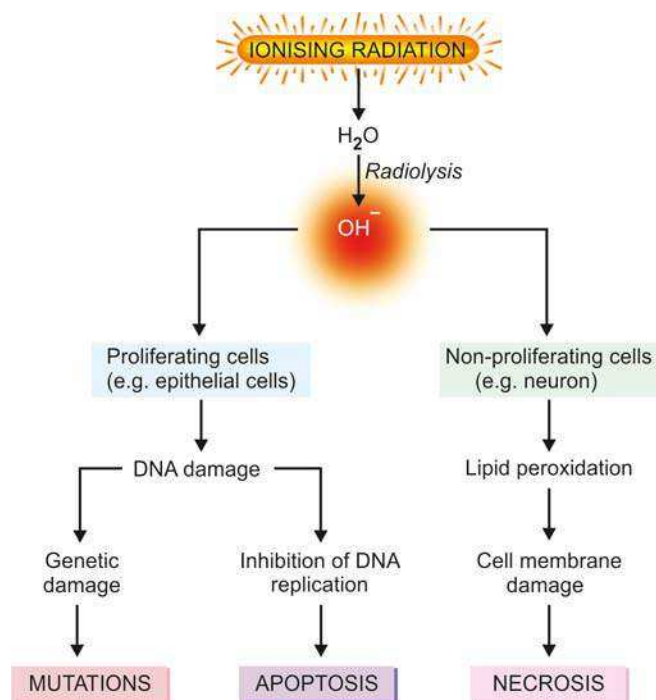

Figure 2.6 Mechanisms of cell injury by ionising radiation.

(Fig. 2.6). These hydroxyl radicals damage the cell membrane as well as may interact with DNA of the target cell. In proliferating cells, there is inhibition of DNA replication and eventual cell death by apoptosis (e.g. epithelial cells). In non-proliferating cells, there is no effect of inhibition of DNA synthesis and in these cells there is cell membrane damage followed by cell death by necrosis (e.g. neurons).

GIST BOX 2.2

Pathogenesis of Cell Injury

- ▣ Irrespective of the type of cell injury, common underlying mechanism involves mitochondrial damage and cell membrane damage.
- ▣ Hypoxic-ischaemic cell injury is the prototype. It may be reversible or irreversible.
- ▣ Reversible cell injury occurs due to decreased cellular ATP causing initially impaired aerobic respiration, followed by anaerobic glycolytic oxidation. Other changes are intracellular lactic acidosis, damage to membrane pumps (Na^+ - K^+ , and Ca^{++}), and dispersal of ribosomes.
- ▣ Irreversible cell injury is due to continuation of earlier changes and includes further calcium influx in the mitochondria, and further damage to membranes, cytoskeleton and nucleus.
- ▣ Lysosomal damage causes release of hydrolytic enzymes which can be estimated in the blood as indicators of cell death e.g. SGOT, SGPT, LDH, CK-MB, cardiac troponins etc.
- ▣ Ischaemia-reperfusion injury is due to release of reactive oxygen species or free radicals. These include OH^- as the most potent radical; others are O_2^- and H_2O_2 .
- ▣ Free radical injury occurs when their generation exceeds their elimination and is implicated in mechanism of cell injury from various etiologies.
- ▣ Stress proteins (heat shock proteins and ubiquitin) are released as a form of protective response to environmental stresses.

MORPHOLOGY OF REVERSIBLE CELL INJURY

After having discussed the molecular and biochemical mechanisms of various forms of cell injury, we now turn to morphologic changes of reversible and irreversible cell injury. Morphologic terms used in cell injury of varying intensity and from different mechanisms are given in **Table 2.2** and are discussed below.

In older literature, the term degeneration was commonly used to denote morphology of reversible cell injury. However, since this term does not provide any information on the nature of underlying changes, currently the term *retrogressive changes* or simply reversible cell injury are applied to non-lethal cell injury.

Common examples of morphologic forms of reversible cell injury are as under:

1. Hydropic change
2. Hyaline change
3. Mucoïd change
4. Fatty change (discussed under intracellular accumulations)

HYDROPIc CHANGE

Hydropic change means accumulation of water within the cytoplasm of the cell. Other synonyms used are *cloudy swelling* (for gross appearance of the affected organ) and *vacuolar degeneration* (due to cytoplasmic vacuolation). Hydropic swelling is an entirely reversible change upon removal of the injurious agent.

ETIOLOGY This is the commonest and earliest form of cell injury from almost all causes. The common causes include acute and subacute cell injury from various etiologic agents such as bacterial toxins, chemicals, poisons, burns, high fever, intravenous administration of hypertonic glucose or saline etc.

PATHOGENESIS Cloudy swelling results from impaired regulation of sodium and potassium at the level of cell membrane. This results in intracellular accumulation of sodium and escape of potassium. This, in turn, is accompanied with rapid flow of water into the cell to maintain iso-osmotic

Table 2.2 Classification of morphologic forms of cell injury.

| MECHANISM OF CELL INJURY | NOMENCLATURE |
|-------------------------------------|--|
| 1. <i>Reversible cell injury</i> | Retrogressive changes (older term: degenerations) |
| 2. <i>Irreversible cell injury</i> | Cell death—necrosis |
| 3. <i>Programmed cell death</i> | Apoptosis |
| 4. <i>Deranged cell metabolism</i> | Intracellular accumulation of lipid, protein, carbohydrate |
| 5. <i>After-effects of necrosis</i> | Gangrene, pathologic calcification |

conditions and hence cellular swelling occurs. In addition, influx of calcium too occurs.

MORPHOLOGIC FEATURES *Grossly*, the affected organ such as kidney, liver, pancreas, or heart muscle is enlarged due to swelling. The cut surface bulges outwards and is slightly opaque.

Microscopically, the features of hydropic swelling of kidney are as under (**Fig. 2.7**):

- i) The tubular epithelial cells are swollen and their cytoplasm contains small clear vacuoles and hence the term vacuolar degeneration. These vacuoles represent distended cisternae of the endoplasmic reticulum.
- ii) Small cytoplasmic blebs may be seen.
- iii) The nucleus may appear pale.
- iv) The microvasculature of the interstitium is compressed due to swollen tubular cells.

HYALINE CHANGE

The word 'hyaline' or 'hyalin' means glassy (*hyalos* = glass). Hyalinisation is a common descriptive histologic term for glassy, homogeneous, eosinophilic appearance of proteinaceous material in haematoxylin and eosin-stained sections and does not refer to any specific substance. Though fibrin and amyloid have hyaline appearance, they have distinctive features and staining reactions and can be distinguished from non-specific hyaline material. Hyaline change is seen in heterogeneous pathologic conditions and may be intracellular or extracellular.

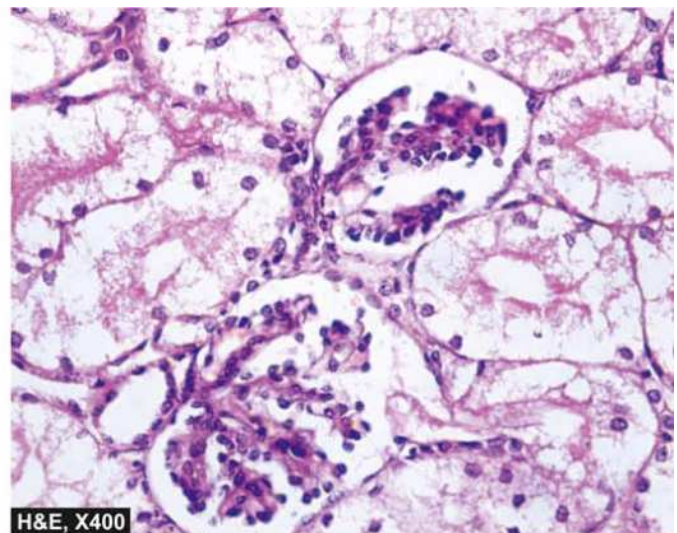

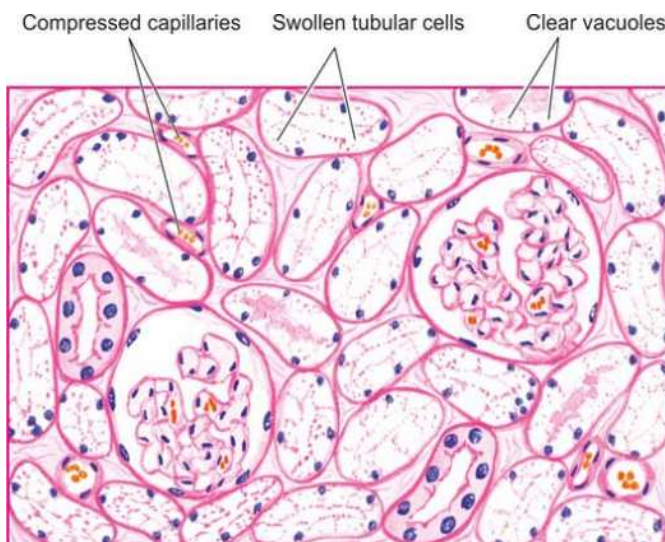

Figure 2.7 Hydropic change kidney. The tubular epithelial cells are distended with cytoplasmic vacuoles while the interstitial vasculature is compressed. The nuclei of affected tubules are pale.

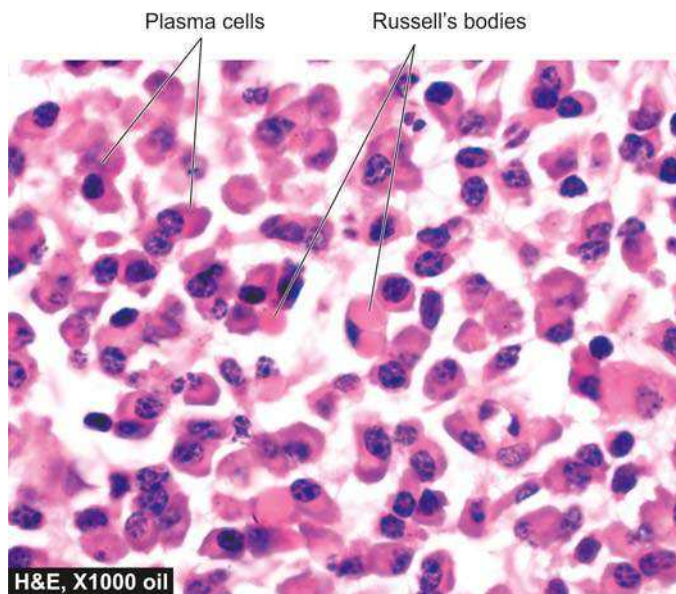

Figure 2.8 Intracellular hyaline as Russell's bodies in the plasma cells. The cytoplasm shows pink homogeneous globular material due to accumulated immunoglobulins.

INTRACELLULAR HYALINE Intracellular hyaline is mainly seen in epithelial cells. A few examples are as follows:

1. *Hyaline droplets* in the proximal tubular epithelial cells due to excessive reabsorption of plasma proteins in proteinuria.
2. *Hyaline degeneration* of rectus abdominalis muscle called Zenker's degeneration, occurring in typhoid fever. The muscle loses its fibrillar staining and becomes glassy and hyaline.
3. *Mallory's hyaline* represents aggregates of intermediate filaments in the hepatocytes in alcoholic liver cell injury.
4. Nuclear or cytoplasmic *hyaline inclusions* seen in some viral infections.
5. *Russell's bodies* representing excessive immunoglobulins in the rough endoplasmic reticulum of the plasma cells (**Fig. 2.8**).

EXTRACELLULAR HYALINE Extracellular hyaline commonly termed hyalinisation is seen in connective tissues. A few examples of extracellular hyaline change are as under:

1. Hyaline degeneration in *leiomyomas* of the uterus (**Fig. 2.9**).
2. Hyalinised *old scar* of fibrocollagenous tissues.
3. *Hyaline arteriosclerosis* in renal vessels in hypertension and diabetes mellitus.
4. Hyalinised glomeruli in *chronic glomerulonephritis*.
5. *Corpora amylacea* seen as rounded masses of concentric hyaline laminae in the enlarged prostate in the elderly, in the brain and in the spinal cord in old age, and in old infarcts of the lung.

MUCOID CHANGE

Mucoid means mucus-like. Mucus is the secretory product of mucous glands and is a combination of proteins complexed with mucopolysaccharides. *Mucin*, a glycoprotein, is its chief constituent. Mucin is normally produced by epithelial cells of mucous membranes and mucous glands, as well as by some connective tissues such as ground substance in the umbilical cord. By convention, connective tissue mucin is termed myxoid. Both epithelial and connective tissue mucin are

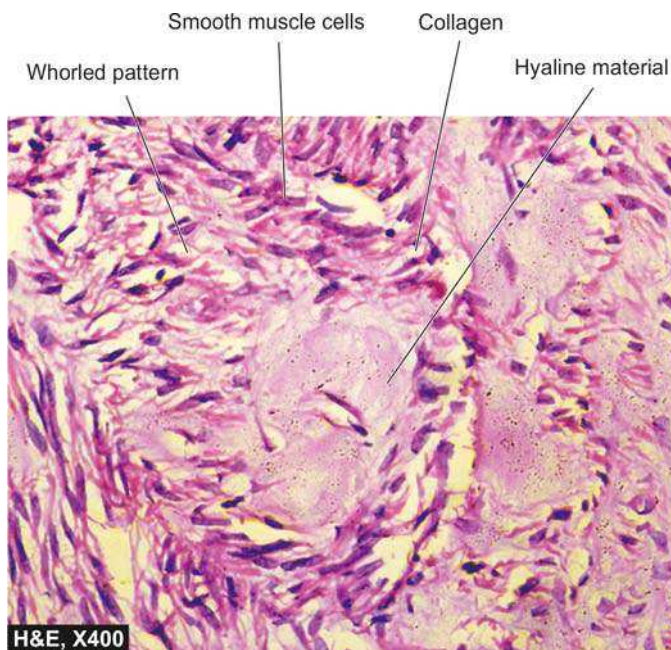

Figure 2.9 Extracellular hyaline deposit in leiomyoma uterus. The centres of whorls of smooth muscle and connective tissue show pink homogeneous hyaline material (connective tissue hyaline).

stained by alcian blue. However, epithelial mucin stains positively with periodic acid-Schiff (PAS), while connective tissue mucin is PAS negative but is, instead, stained positively with colloidal iron.

EPITHELIAL MUCIN Following are some examples of functional excess of epithelial mucin:

1. Catarrhal inflammation of mucous membrane (e.g. of respiratory tract, alimentary tract, uterus).
2. Obstruction of duct leading to mucocele in the oral cavity and gallbladder.
3. Cystic fibrosis of the pancreas.
4. Mucin-secreting tumours (e.g. of ovary, stomach, large bowel etc) (**Fig. 2.10**).

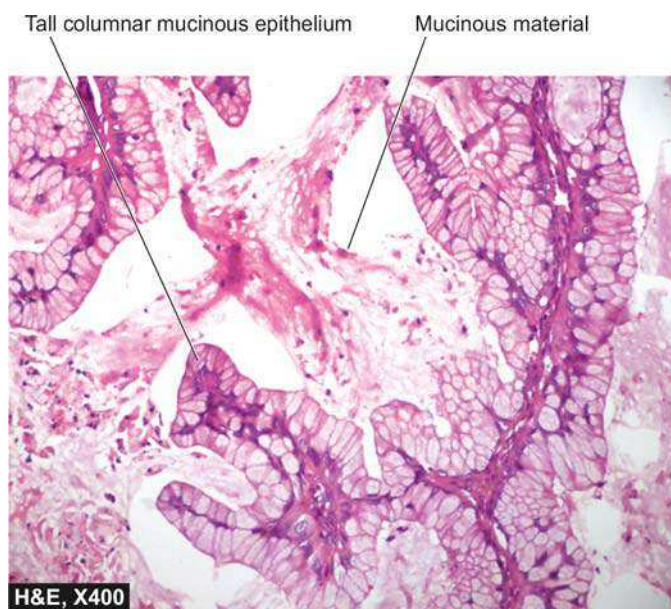

Figure 2.10 Epithelial mucin. Mucinous cystadenoma of the ovary showing intracytoplasmic mucinous material in the epithelial cells lining the cyst.

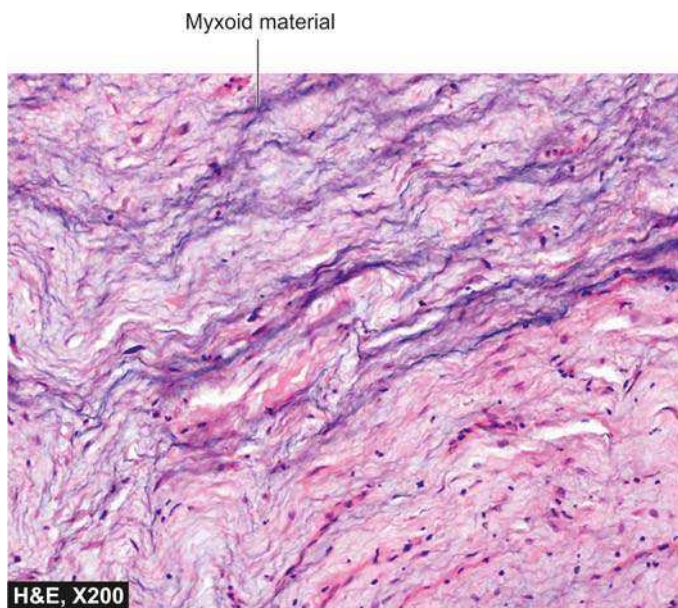

Figure 2.11 Connective tissue mucin (myxoid change) in neurofibroma.

CONNECTIVE TISSUE MUCIN A few examples of disturbances of connective tissue mucin or myxoid change are as under:

1. Mucoïd or myxoid change in some tumours e.g. myxomas, neurofibromas, fibroadenoma, soft tissue sarcomas etc (**Fig. 2.11**).
2. Dissecting aneurysm of the aorta due to Erdheim's medial degeneration and Marfan's syndrome.
3. Myxomatous change in the dermis in myxoedema.
4. Myxoid change in the synovium in ganglion on the wrist.

GIST BOX 2.3

Morphology of Reversibility Cell Injury

- ▣ Degenerations or reversible cell injury depict light microscopic changes occurring at ultrastructural level.
- ▣ Hydropic swelling is the earliest form of cell injury from various etiologies and its main features are cellular swelling due to cytoplasmic vacuoles.
- ▣ Hyaline change is intra- and extracellular deposition of pink, proteinaceous material.
- ▣ Mucoïd change is deposition of mucinous material in epithelial and connective tissues in excessive amounts.

INTRACELLULAR ACCUMULATIONS

Intracellular accumulation of substances in abnormal amounts can occur within the cytoplasm (especially lysosomes) or nucleus of the cell. This phenomenon was previously referred to as *infiltration*, meaning thereby that something unusual has infiltrated the cell from outside which is not always the case. Intracellular accumulation of the substance in mild degree causes reversible cell injury while more severe damage results in irreversible cell injury.

Abnormal intracellular accumulations can be divided into 3 groups:

- i) *Accumulation of constituents of normal cell metabolism produced in excess* e.g. accumulations of lipids (fatty change, cholesterol deposits), proteins and carbohydrates.

- ii) *Accumulation of abnormal substances* produced as a result of abnormal metabolism due to lack of some enzymes e.g. storage diseases or inborn errors of metabolism. These are discussed in Chapter 9.

- iii) *Accumulation of pigments* e.g. endogenous pigments under special circumstances, and exogenous pigments due to lack of enzymatic mechanisms to degrade the substances or transport them to other sites.

These pathologic states are discussed below.

FATTY CHANGE (STEATOSIS)

Fatty change, steatosis or fatty metamorphosis is the intracellular accumulation of neutral fat within parenchymal cells. It includes the older, now abandoned, terms of *fatty degeneration* and *fatty infiltration* because fatty change neither necessarily involves degeneration nor an infiltration. The deposit is in the cytosol and represents an absolute increase in the intracellular lipids. Fatty change is particularly common in the liver but may occur in other non-fatty tissues as well e.g. in the heart, skeletal muscle, kidneys (lipoid nephrosis or minimum change disease) and other organs.

Fatty Liver

Liver is the commonest site for accumulation of fat because it plays central role in fat metabolism. Depending upon the cause and amount of accumulation, fatty change may be mild and reversible, or severe producing irreversible cell injury and cell death.

ETIOLOGY Fatty change in the liver may result from one of the two types of causes:

1. Conditions with excess fat These are conditions in which the capacity of the liver to metabolise fat is exceeded e.g.

- i) Obesity
- ii) Diabetes mellitus
- iii) Congenital hyperlipidaemia

2. Liver cell damage These are conditions in which fat cannot be metabolised due to liver cell injury e.g.

- i) Alcoholic liver disease (most common)
- ii) Starvation
- iii) Protein calorie malnutrition
- iv) Chronic illnesses (e.g. tuberculosis)
- v) Acute fatty liver in late pregnancy
- vi) Hypoxia (e.g. anaemia, cardiac failure)
- vii) Hepatotoxins (e.g. carbon tetrachloride, chloroform, ether, aflatoxins and other poisons)
- viii) Drug-induced liver cell injury (e.g. administration of methotrexate, steroids, CCl_4 , halothane anaesthetic, tetracycline etc)
- ix) Reye's syndrome

PATHOGENESIS Mechanism of fatty liver depends upon the stage at which the etiologic agent acts in the normal fat transport and metabolism. Hence, pathogenesis of fatty liver is best understood in the light of normal fat metabolism in the liver (**Fig. 2.12**).

Lipids as free fatty acids enter the liver cell from either of the following 2 sources:

- ◆ *From diet* as chylomicrons (containing triglycerides and phospholipids) and as free fatty acids.
- ◆ *From adipose tissue* as free fatty acids.

Normally, besides above two sources, a small part of fatty acids is also synthesised from acetate in the liver cells. Most of free fatty acid is esterified to triglycerides by the action of α -glycerophosphate and only a small part is changed into cholesterol, phospholipids and ketone bodies. While cholesterol, phospholipids and ketones are used in the body, intracellular triglycerides are converted into lipoproteins, which require 'lipid acceptor protein'. Lipoproteins are released from the liver cells into circulation as plasma lipoproteins (LDL, VLDL).

In fatty liver, intracellular accumulation of triglycerides occurs due to defect at one or more of the following 6 steps in the normal fat metabolism shown in **Fig. 2.12**:

1. Increased entry of free fatty acids into the liver.
2. Increased synthesis of fatty acids by the liver.
3. Decreased conversion of fatty acids into ketone bodies resulting in increased esterification of fatty acids to triglycerides.
4. Increased α -glycerophosphate causing increased esterification of fatty acids to triglycerides.
5. Decreased synthesis of 'lipid acceptor protein' resulting in decreased formation of lipoprotein from triglycerides.
6. Block in the excretion of lipoprotein from the liver into plasma.

In most cases of fatty liver, one of the above mechanisms is operating. But liver cell injury from chronic alcoholism is multifactorial as follows:

- i) Increased lipolysis
- ii) Increased free fatty acid synthesis
- iii) Decreased triglyceride utilisation
- iv) Decreased fatty acid oxidation to ketone bodies
- v) Block in lipoprotein excretion

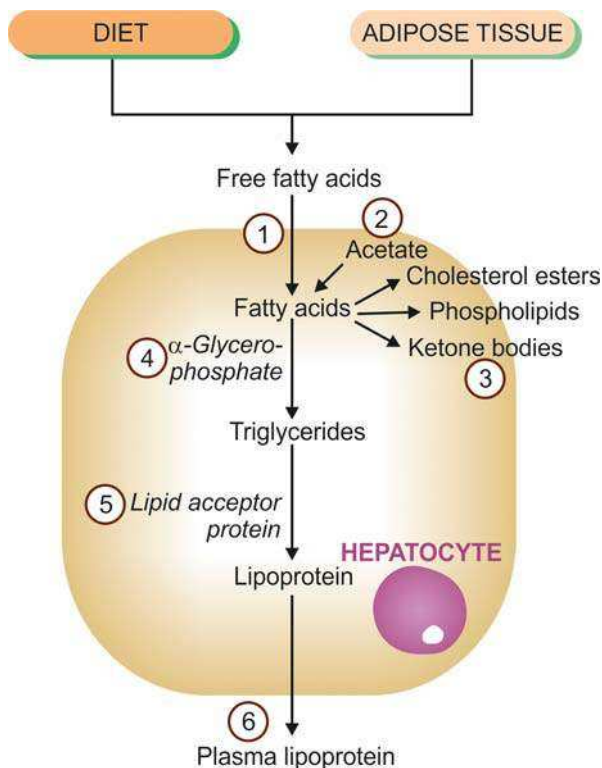

Figure 2.12 Lipid metabolism in the pathogenesis of fatty liver. Defects in any of the six numbered steps (corresponding to the description in the text) can produce fatty liver by different etiologic agents.

Figure 2.13 Fatty liver. Sectioned slice of the liver shows pale yellow parenchyma with rounded borders.

Even a severe form of fatty liver may be reversible if the liver is given time to regenerate and progressive fibrosis has not developed. For example, intermittent drinking is less harmful because the liver cells get time to recover; similarly a chronic alcoholic who becomes teetotaler the enlarged fatty liver may return to normal if fibrosis has not developed. This subject is discussed in detail in Chapter 19.

MORPHOLOGIC FEATURES *Grossly*, the liver in fatty change is enlarged with a tense, glistening capsule and rounded margins. The cut surface bulges slightly and is pale-yellow to yellow and is greasy to touch (**Fig. 2.13**).

Microscopically, characteristic feature is the presence of numerous lipid vacuoles in the cytoplasm of hepatocytes. Fat in H & E stained section prepared by paraffin-embedding technique appear as non-staining vacuoles because it is dissolved in organic solvents used (**Fig. 2.14**):

- i) The vacuoles are initially small and are present around the nucleus (*microvesicular*).
- ii) With progression of the process, the vacuoles become larger pushing the nucleus to the periphery of the cells (*macrovesicular*).
- iii) At times, the hepatocytes laden with large lipid vacuoles may rupture and lipid vacuoles coalesce to form fatty cysts.
- iv) Infrequently, *lipogranulomas* may appear as a reaction to extravasated fat and consist of collections of lymphocytes, macrophages, and some multinucleated giant cells.
- v) Fat can be demonstrated in fresh unfixed tissue by frozen section by *fat stains* e.g. Sudan dyes (Sudan III, IV, Sudan black) and oil red O. Alternatively, osmic acid which is a fixative as well as a stain can be used to demonstrate fat in the tissue.

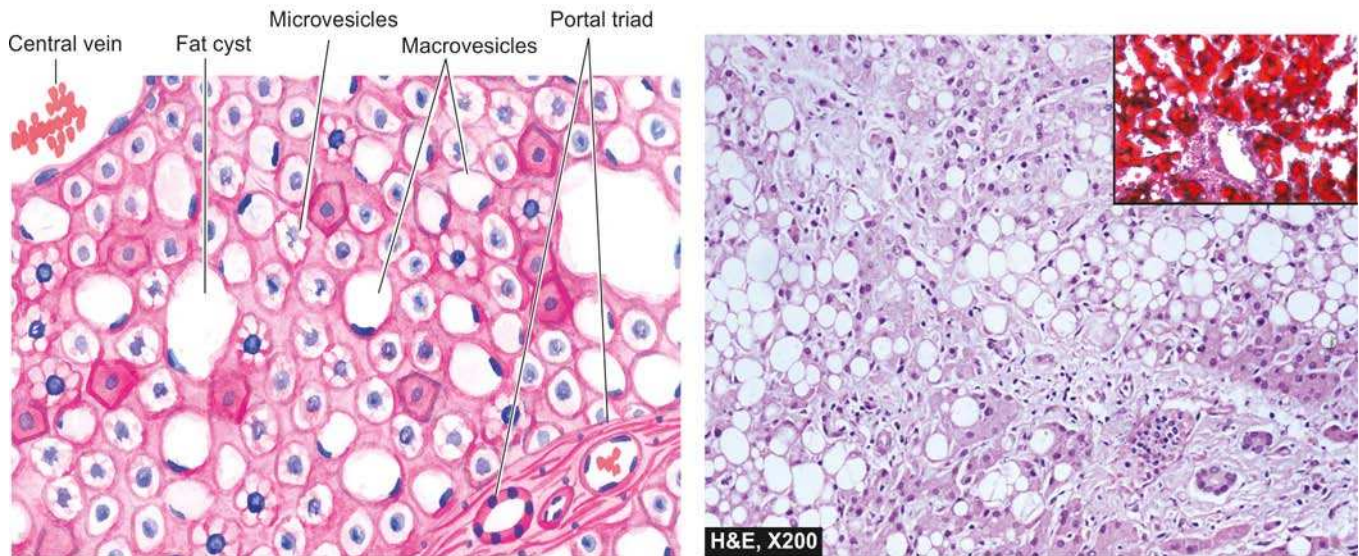

Figure 2.14 Fatty liver. Many of the hepatocytes are distended with large fat vacuoles pushing the nuclei to the periphery (macrovesicles), while others show multiple small vacuoles in the cytoplasm (microvesicles). Inset shows red colour in the cytoplasmic fat in the hepatocytes in Oil Red O stain in frozen section.

Cholesterol Deposits

Intracellular deposits of cholesterol and its esters in macrophages may occur when there is hypercholesterolaemia. This turns macrophages into foam cells. The examples are as follows:

1. *Fibrofatty plaques* of atherosclerosis (Chapter 14).
2. Clusters of foam cells in tumour-like masses called *xanthomas* and *xanthelasma*.

Stromal Fatty Infiltration

This form of lipid accumulation is quite different from parenchymal fatty change just described. Stromal fatty infiltration is the deposition of mature adipose cells in the stromal connective tissue in contrast to intracellular deposition of fat in the parenchymal cells in fatty change. The condition occurs most often in patients with obesity. The two commonly affected organs are the heart and the pancreas. Thus, heart can be the site for intramyocardial fatty change as well as epicardial (stromal) fatty infiltration. The presence of mature adipose cells in the stroma generally does not produce any dysfunction.

INTRACELLULAR ACCUMULATION OF PROTEINS

Pathologic accumulation of proteins in the cytoplasm of cells may occur in the following conditions:

1. In *proteinuria*, there is excessive renal tubular reabsorption of proteins by the proximal tubular epithelial cells which show pink hyaline droplets in their cytoplasm. The change is reversible; with control of proteinuria the protein droplets disappear.
2. The cytoplasm of actively functioning plasma cells shows pink hyaline inclusions called *Russell's bodies* representing synthesised immunoglobulins.
3. In *α 1-antitrypsin deficiency*, the cytoplasm of hepatocytes shows eosinophilic globular deposits of a mutant protein.
4. *Mallory's body* or alcoholic hyaline in the hepatocytes is intracellular accumulation of intermediate filaments of cytokeratin and appear as amorphous pink masses.

INTRACELLULAR ACCUMULATION OF GLYCOGEN

Conditions associated with excessive accumulation of intracellular glycogen are as under:

1. In *diabetes mellitus*, there is intracellular accumulation of glycogen in different tissues because normal cellular uptake of glucose is impaired. Glycogen deposits in diabetes mellitus are seen in epithelium of distal portion of proximal convoluted tubule and descending loop of Henle, in the hepatocytes, in beta cells of pancreatic islets, and in cardiac muscle cells. In routine H & E stained sections, deposits of glycogen produce clear vacuoles in the cytoplasm of the affected cells. Best's carmine and periodic acid-Schiff (PAS) staining may be employed to confirm the presence of glycogen in the cells.
2. In *glycogen storage diseases or glycogenosis*, there is defective metabolism of glycogen due to genetic disorders. These conditions along with other similar genetic disorders are discussed in Chapter 9.

GIST BOX 2.4

Intracellular Accumulations

- ☐ Intracellular accumulations may occur from normal constituents of cell metabolism (e.g. fats, proteins, carbohydrates), or accumulation of abnormal substances due to either absence of some metabolic enzymes or due to pigments.
- ☐ Fatty change is deposition of fat in the parenchymal cells or organs such as liver, kidneys, muscle, pancreas etc.
- ☐ Fatty liver is more common and occurs from various etiologies, most often from alcoholic liver disease; others are obesity, diabetes, starvation, pregnancy, drugs etc.
- ☐ Mechanism for fatty liver is due to excess of free fatty acids, either from diet or from adipose tissues, resulting in intracellular accumulation of triglycerides in the hepatocytes.
- ☐ Fatty liver is characterised by enlarged pale-yellow liver, having cytoplasmic vacuoles (microvesicles or macrovesicles) in the hepatocytes.

- ▣ Fat in the sections can be stained by fat stains e.g. Sudan black, Sudan II, IV, Oil Red O and osmic acid.
- ▣ Stromal fatty infiltration is extracellular accumulation of adipocytes.
- ▣ Intracellular accumulation of proteins may occur in tubular epithelial cells in diabetes, alcoholic hyaline in liver cells, Russells's bodies in the plasma cells.
- ▣ Intracellular glycogen accumulates in tubular cells in diabetes and in parenchymal cells in glycogen storage diseases.

PIGMENTS

Pigments are coloured substances present in most living beings including humans. There are 2 broad categories of pigments: endogenous and exogenous (Table 2.3).

A. ENDOGENOUS PIGMENTS

Endogenous pigments are either normal constituents of cells or accumulate under special circumstances e.g. melanin, alkaptonuria, haemoprotein-derived pigments, and lipofuscin.

Melanin

Melanin is the brown-black, non-haemoglobin-derived pigment normally present in the hair, skin, mucosa at some places, choroid of the eye, meninges and adrenal medulla. In skin, it is synthesised in the melanocytes and dendritic cells, both of which are present in the basal cells of the epidermis and is stored in the form of cytoplasmic granules in the phagocytic cells called the melanophores, present in the underlying dermis. Melanocytes possess the enzyme tyrosinase necessary for synthesis of melanin from tyrosine. However, sometimes tyrosinase is present but is not active and hence no melanin pigment is visible. In such cases, the presence of tyrosinase can be detected by incubation of tissue section in the solution of dihydroxy phenyl alanine (DOPA). If the enzyme is present, dark pigment is identified in pigment cells. This test is called as *DOPA reaction* and may be used for differentiating amelanotic melanoma from other anaplastic tumours.

Various disorders of melanin pigmentation cause generalised and localised hyperpigmentation and hypopigmentation:

i) Generalised hyperpigmentation:

- a) In *Addison's disease*, there is generalised hyperpigmentation of the skin, especially in areas exposed to light, and of buccal mucosa.
- b) *Chloasma* observed during pregnancy is the hyperpigmentation on the skin of face, nipples, and genitalia and occurs under the influence of oestrogen. A similar appearance may be observed in women taking oral contraceptives.
- c) In *chronic arsenical poisoning*, there is characteristic rain-drop pigmentation of the skin.

ii) Focal hyperpigmentation:

- a) *Câfe-au-lait spots* are pigmented patches seen in neurofibromatosis and Albright's syndrome.
- b) *Peutz-Jeghers syndrome* is characterised by focal peri-oral pigmentation.
- c) *Melanosis coli* is pigmentation of the mucosa of the colon.
- d) *Melanotic tumours*, both benign such as pigmented naevi (Fig. 2.15), and malignant such as melanoma, are associated with increased melanogenesis.
- e) *Lentigo* is a pre-malignant condition in which there is focal hyperpigmentation on the skin of hands, face, neck, and arms.
- f) *Dermatopathic lymphadenitis* is an example of deposition of melanin pigment in macrophages of the lymph nodes draining skin lesions.

iii) Generalised hypopigmentation *Albinism* is an extreme degree of generalised hypopigmentation in which tyrosinase enzyme is genetically defective and no melanin is formed in the melanocytes. Oculocutaneous albinos have no pigment in the skin and have blond hair, poor vision and severe photophobia. They are highly sensitive to sunlight. Chronic sun exposure may lead to precancerous lesions and squamous and basal cell cancers of the skin in such individuals.

iv) Localised hypopigmentation:

- a) *Leucoderma* is an autoimmune condition with localised loss of pigmentation of the skin.
- b) *Vitiligo* is also local hypopigmentation of the skin and is more common. It may have familial tendency.
- c) *Acquired focal hypopigmentation* can result from various causes such as leprosy, healing of wounds, DLE, radiation dermatitis etc.

Melanin-like Pigments

ALKAPTONURIA This is a rare autosomal recessive disorder in which there is deficiency of an oxidase enzyme required for break down of homogentisic acid; the latter then accumulates in the tissues and is excreted in the urine (homogentisic aciduria). The urine of patients of alkaptonuria, if allowed to stand for some hours in air, turns black due to oxidation of homogentisic acid. The pigment is melanin-like and is termed *ochronosis*, first described by Virchow. It is deposited both intracellularly and intercellularly, most often in the periarticular tissues such as cartilages, capsules of joints, ligaments and tendons.

DUBIN-JOHNSON SYNDROME Hepatocytes in patients of Dubin-Johnson syndrome, an autosomal recessive form of hereditary conjugated hyperbilirubinaemia, contain melanin-like pigment in the cytoplasm (page 586).

Table 2.3 Pigments of the body.

| | |
|------|------------------------------------|
| A. | ENDOGENOUS PIGMENTS |
| 1. | Melanin |
| 2. | Melanin-like pigment |
| a. | Alkaptonuria |
| b. | Dubin-Johnson syndrome |
| 3. | Haemoprotein-derived pigments |
| i) | Haemosiderin |
| ii) | Acid haematin (Haemozoin) |
| iii) | Bilirubin |
| iv) | Porphyryns |
| 4. | Lipofuscin (Wear and tear pigment) |
| B. | EXOGENOUS PIGMENTS |
| 1. | Inhaled pigments |
| 2. | Ingested pigments |
| 3. | Injected pigments (Tattooing) |

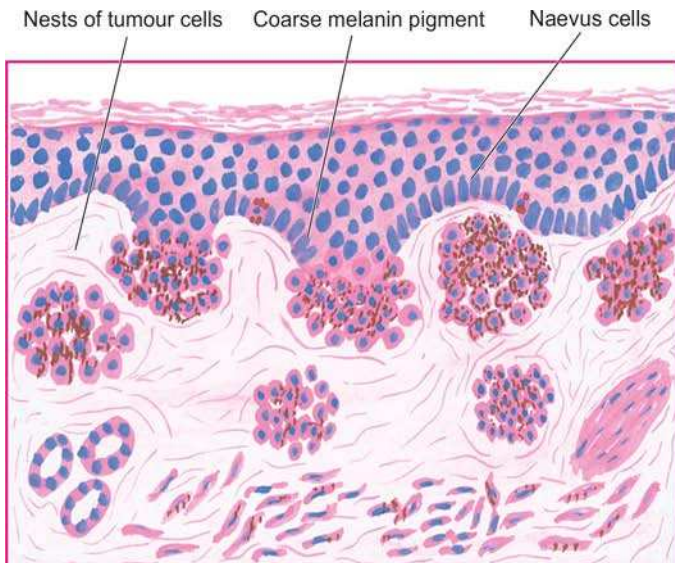

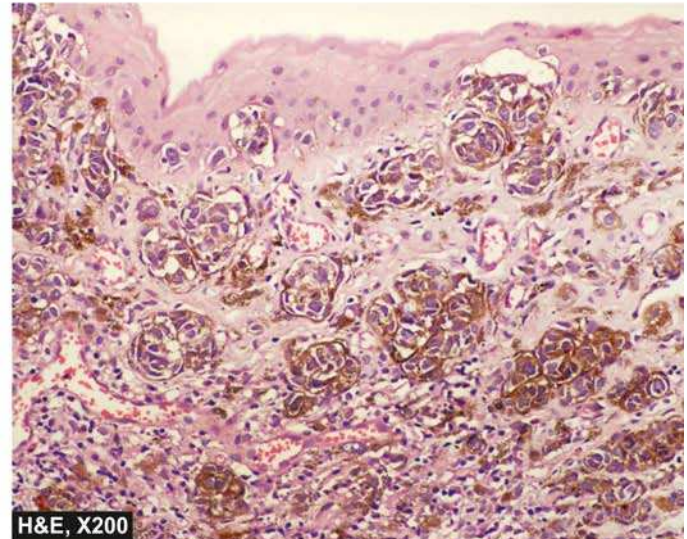

Figure 2.15 Compound naevus showing clusters of benign naevus cells in the dermis as well as in lower epidermis. These cells contain coarse, granular, brown-black melanin pigment.

Haemoprotein-derived Pigments

Haemoproteins are the most important endogenous pigments derived from haemoglobin, cytochromes and their break-down products. For an understanding of disorders of haemoproteins, it is essential to have knowledge of normal iron metabolism and its transport which is described in Chapter 10. In disordered iron metabolism and transport, haemoprotein-derived pigments accumulate in the body. These pigments are haemosiderin, acid haematin (haemozoin), bilirubin, and porphyrins.

- 1. HAEMOSIDERIN** Iron is stored in the tissues in 2 forms:
- ◆ *Ferritin*, which is iron complexed to apoferritin and can be identified by electron microscopy.
 - ◆ *Haemosiderin*, which is formed by aggregates of ferritin and is identifiable by light microscopy as golden-yellow to brown, granular pigment, especially within the mononuclear phagocytes of the bone marrow, spleen and liver where break-down of senescent red cells takes place (**Fig. 2.16, A**). Haemosiderin

is ferric iron that can be demonstrated by Perl's stain that produces Prussian blue reaction. In this reaction, colourless potassium ferrocyanide reacts with ferric ions of haemosiderin to form deep blue *ferric-ferrocyanide* (**Fig. 2.16, B**).

Excessive storage of haemosiderin occurs in conditions when there is increased break-down of red cells systemic overload of iron. This may occur due to primary (idiopathic, hereditary) haemochromatosis, and secondary (acquired) causes such as in chronic haemolytic anaemias (e.g. thalassaemia), sideroblastic anaemia, alcoholic cirrhosis, multiple blood transfusions etc.

Accordingly, the effects of haemosiderin excess are as under (**Fig. 2.17**):

- a) Localised haemosiderosis** This develops whenever there is haemorrhage into the tissues. With lysis of red cells, haemoglobin is liberated which is taken up by macrophages where it is degraded and stored as haemosiderin. A few examples are as under:

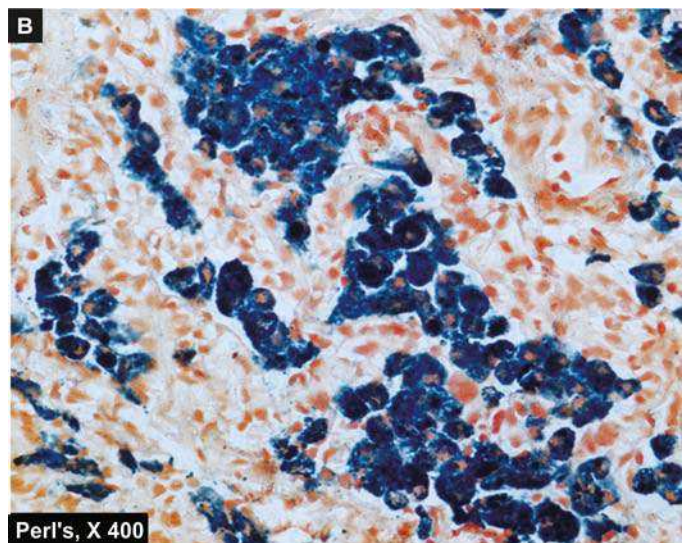

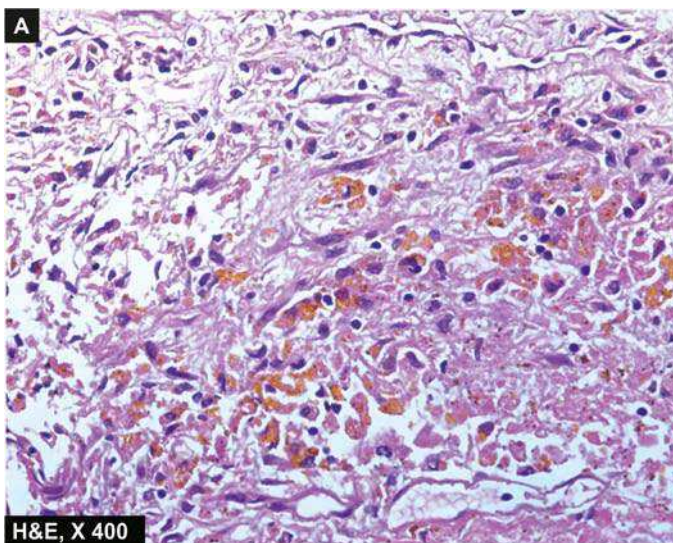

Figure 2.16 Haemosiderin pigment in the cytoplasm. H & E stain shows golden brown granules in the cytoplasm of macrophages (A) which stain positive in Perl's stain as Prussian blue granules (B).

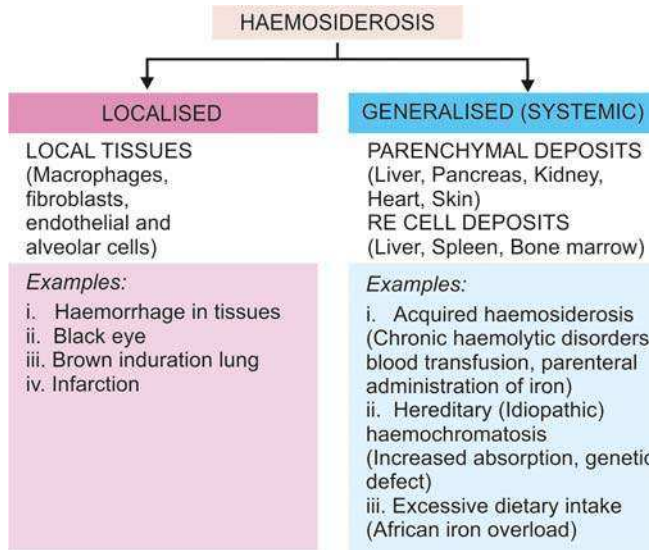

Figure 2.17 Effects of haemosiderosis.

◆ Changing colours of a bruise or a *black eye* are caused by the pigments like biliverdin and bilirubin which are formed during transformation of haemoglobin into haemosiderin.

◆ *Brown induration* of the lungs as a result of small haemorrhages occurring in mitral stenosis and left ventricular failure. Microscopy reveals the presence of 'heart failure cells' in the alveoli which are haemosiderin-laden alveolar macrophages.

b) Generalised (Systemic or Diffuse) haemosiderosis
Systemic overload with iron may result in generalised haemosiderosis. There can be two types of patterns:

◆ *Parenchymatous deposition* occurs in the parenchymal cells of the liver, pancreas, kidney, and heart.

◆ *Reticuloendothelial (RE) deposition* occurs in the RE cells of the liver, spleen, and bone marrow.

Causes for generalised or systemic overload of iron may be as under:

i) Increased erythropoietic activity: In various forms of chronic haemolytic anaemia, there is excessive break-down of haemoglobin and hence iron overload. The problem is further compounded by treating the condition with blood transfusions (transfusional haemosiderosis) or by parenteral iron therapy. The deposits of iron in these cases, termed as *acquired haemosiderosis*, are initially in reticuloendothelial tissues but may eventually affect the parenchymal cells of the organs.

ii) Excessive intestinal absorption of iron: A form of haemosiderosis in which there is excessive intestinal absorption of iron even when the intake is normal, is known as *idiopathic or hereditary haemochromatosis*. It is an autosomal dominant disease associated with much more deposits of iron than in cases of acquired haemosiderosis. Haemochromatosis is characterised by *triad* of features: pigmentary liver cirrhosis, pancreatic damage resulting in diabetes mellitus, and skin pigmentation. On the basis of the last two features, the condition has come to be termed as *bronze diabetes*.

iii) Excessive dietary intake of iron: An example of excessive iron absorption is *African iron overload* (earlier called *Bantu siderosis*) seen in blacks in South Africa. Initially, it was observed in those rural South African communities who consumed alcohol brewed in ungalvanised iron vessels that served as a rich source of additional dietary iron. However,

subsequently it was found that this type of siderosis also occurred in other individuals of African descent who had no history of such alcohol consumption. This led to identification of a gene, ferroportin, which predisposes iron overload in such people of African descent and hence the name. The excess iron gets deposited in various organs including the liver causing pigment cirrhosis.

2. ACID HAEMATIN (HAEMOZOIN) Acid haematin or haemozoin, also called malarial pigment, is a haemoprotein-derived brown-black pigment containing haem iron in ferric form in acidic medium. But it differs from haemosiderin because it cannot be stained by Prussian blue (Perl's) reaction, probably because of formation of complex with a protein so that it is unable to react in the stain. Haematin pigment is seen most commonly in chronic malaria and in mismatched blood transfusions. Besides, the *malarial pigment* can also be deposited in macrophages and in the hepatocytes. Another variety of haematin pigment is *formalin pigment* formed in blood-rich tissues which have been preserved in acidic formalin solution.

3. BILIRUBIN Bilirubin is the normal non-iron containing pigment present in the bile. It is derived from porphyrin ring of the haem moiety of haemoglobin. Normal level of bilirubin in blood is less than 1 mg/dl. Excess of bilirubin or hyperbilirubinaemia causes an important clinical condition called jaundice. Normal bilirubin metabolism and pathogenesis of jaundice are described in Chapter 19. Hyperbilirubinaemia may be unconjugated or conjugated; accordingly jaundice may appear in one of the following 3 ways:

i) An increase in the rate of bilirubin production due to excessive destruction of red cells (predominantly unconjugated hyperbilirubinaemia).

ii) A defect in handling of bilirubin due to hepatocellular injury (biphasic jaundice).

iii) Some defect in bilirubin transport within intrahepatic or extrahepatic biliary system (predominantly conjugated hyperbilirubinaemia).

Excessive accumulation of bilirubin pigment can be seen in different tissues and fluids of the body, especially in the hepatocytes, Kupffer cells and bile sinusoids. Skin and sclerae become distinctly yellow. In infants, rise in unconjugated bilirubin may produce toxic brain injury called *kernicterus*.

4. PORPHYRINS Porphyrins are normal pigment present in haemoglobin, myoglobin and cytochrome. Porphyrin refers to an uncommon disorder of inborn abnormality of porphyrin metabolism. It results from genetic deficiency of one of the enzymes required for the synthesis of haem, resulting in excessive production of porphyrins. Often, the genetic deficiency is precipitated by intake of some drugs. Porphyrins are associated with excretion of intermediate products in the urine—delta-aminolaevulinic acid, porphobilinogen, uroporphyrin, coproporphyrin, and protoporphyrin. Porphyrins are broadly of 2 types—erythropoietic and hepatic.

(a) Erythropoietic porphyrias These have defective synthesis of haem in the red cell precursors in the bone marrow. These may be further of 2 subtypes:

i) *Congenital erythropoietic porphyria*, in which the urine is red due to the presence of uroporphyrin and coproporphyrin.

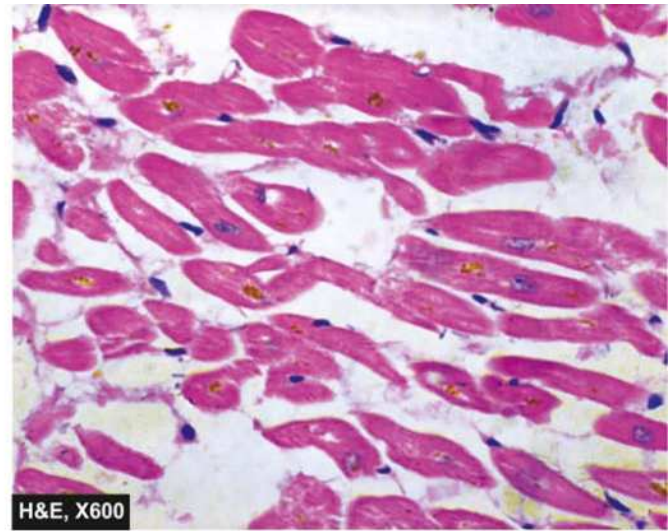

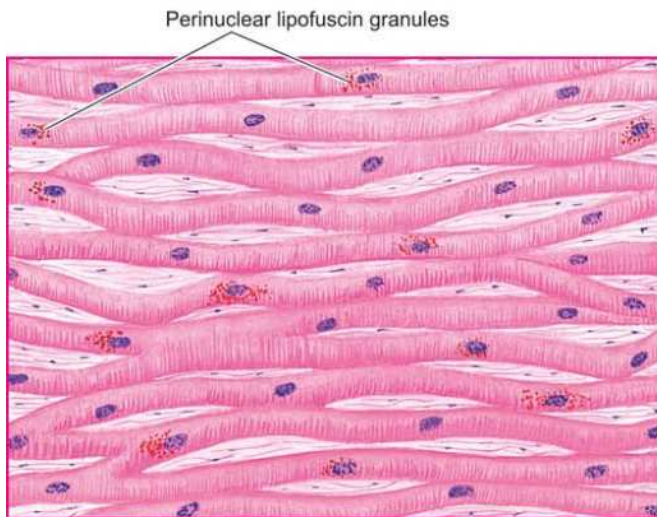

Figure 2.18 Brown atrophy of the heart. The lipofuscin pigment granules are seen in the cytoplasm of the myocardial fibres, especially around the nuclei.

The skin of these infants is highly photosensitive. Bones and skin show red brown discoloration.

ii) *Erythropoietic protoporphyria*, in which there is excess of protoporphyrin but no excess of porphyrin in the urine.

(b) Hepatic porphyrias These are more common and have a normal erythroid precursors but have a defect in synthesis of haem in the liver. Its further subtypes include the following:

i) *Acute intermittent porphyria* is characterised by acute episodes of 3 patterns: abdominal, neurological, and psychotic. These patients do not have photosensitivity. There is excessive delta aminolaevulinic acid and porphobilinogen in the urine.

ii) *Porphyria cutanea tarda* is the most common of all porphyrias. Porphyrins collect in the liver and small quantity is excreted in the urine. Skin lesions are similar to those in variegate porphyria. Most of the patients have associated haemosiderosis with cirrhosis which may eventually develop into hepatocellular carcinoma.

iii) *Mixed (Variegate) porphyrias*. It is rare and combines skin photosensitivity with acute abdominal and neurological manifestations.

Lipofuscin (Wear and Tear Pigment)

Lipofuscin or lipochrome is yellowish-brown intracellular lipid pigment (*lipo* = fat, *fuscus* = brown). The pigment is often found in atrophied cells of old age and hence the name 'wear and tear pigment'. It is seen in the myocardial fibres, hepatocytes, Leydig cells of the testes and in neurons in senile dementia. However, the pigment may, at times, accumulate rapidly in different cells in wasting diseases unrelated to ageing.

By light microscopy, the pigment is coarse, golden-brown granular and often accumulates in the central part of the cells around the nuclei. In the heart muscle, the change is associated with wasting of the muscle and is commonly referred to as 'brown atrophy' (Fig. 2.18). The pigment can be stained by fat stains but differs from other lipids in being fluorescent and having positive acid-fast staining.

By electron microscopy, lipofuscin appears as intra-lysosomal electron-dense granules in perinuclear location.

Lipofuscin granules are composed of lipid-protein complexes. Unlike in normal cells, in ageing or debilitating diseases the phospholipid end-products of membrane damage mediated by oxygen free radicals fail to get eliminated by intracellular lipid peroxidation. These, therefore, persist as collections of indigestible material in the lysosomes; thus lipofuscin is an example of residual bodies.

B. EXOGENOUS PIGMENTS

Exogenous pigments are the pigments introduced into the body from outside such as by inhalation, ingestion or inoculation.

Inhaled Pigments

The lungs of most individuals, especially of those living in urban areas due to atmospheric pollutants and of smokers, show a large number of inhaled pigmented materials. The most commonly inhaled substances are carbon or coal dust; others are silica or stone dust, iron or iron oxide, asbestos and various other organic substances. These substances may produce occupational lung diseases called pneumoconiosis (Chapter 15). The pigment particles after inhalation are taken up by alveolar macrophages. Some of the pigment-laden macrophages are coughed out via bronchi, while some settle in the interstitial tissue of the lung and in the respiratory bronchioles and pass into lymphatics to be deposited in the hilar lymph nodes. *Anthraxosis* (i.e. deposition of carbon particles) is seen in almost every adult lung and generally provokes no reaction of tissue injury (Fig. 2.19). However, extensive deposition of particulate material over many years in coal-miners' pneumoconiosis, silicosis, asbestosis etc. provoke low grade inflammation, fibrosis and impaired respiratory function.

Ingested Pigments

Chronic ingestion of certain metals may produce pigmentation. The examples are as under:

- i) *Argyria* is chronic ingestion of silver compounds and results in brownish pigmentation in the skin, bowel, and kidney.
- ii) *Chronic lead poisoning* may produce the characteristic blue lines on teeth at the gumline.

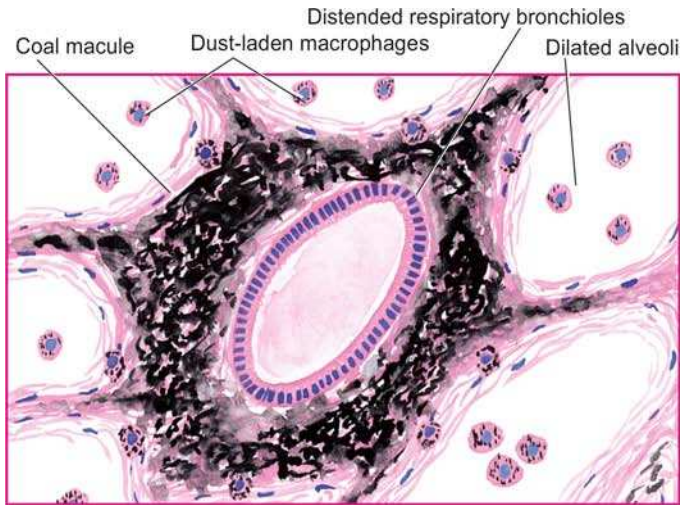

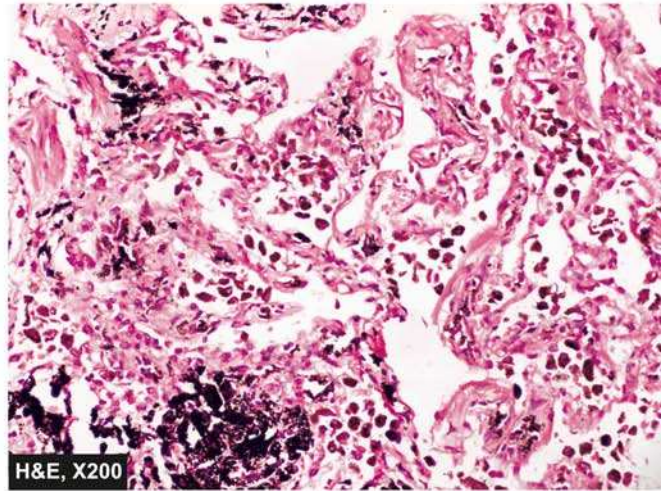

Figure 2.19 Anthracosis lung. There is presence of abundant coarse black carbon pigment in the septal walls and around the bronchiole.

iii) *Melanosis coli* results from prolonged ingestion of certain cathartics.

iv) *Carotenaemia* is yellowish-red colouration of the skin caused by excessive ingestion of carrots which contain carotene.

Injected Pigments (Tattooing)

Pigments like India ink, cinnabar and carbon are introduced into the dermis in the process of tattooing where the pigment is taken up by macrophages and lies permanently in the connective tissue. The examples of injected pigments are prolonged use of ointments containing mercury, dirt left accidentally in a wound, and tattooing by pricking the skin with dyes.

GIST BOX 2.5 Pigments

- ▣ Pigments may be endogenous in origin or exogenously introduced in the body.
- ▣ Most common endogenous pigment is melanin. Disorders of melanin are due to defect in tyrosine metabolism and may give rise to hyper- and hypopigmentation, each of which may be generalised or localised.
- ▣ Haem-derived pigments are haemosiderin, acid haematin, bilirubin and porphyrin.
- ▣ Excess of haemosiderin may get deposited in local tissues, or as generalised deposits in the reticuloendothelial tissues and in parenchymal cells. Haemosiderin in tissues stains positive for Perl's Prussian blue stain.
- ▣ Haemozoin is an acid haematin or malarial pigment which is negative for Perl's Prussian blue stain.
- ▣ Bilirubin is non-iron containing pigment; its increase (conjugated or unconjugated) in the blood causes jaundice. Bilirubin in blood may rise from its increased production, hepatocellular disease or due to obstruction in its excretion.
- ▣ Porphyrins are due to inborn errors in porphyrin metabolism for haem synthesis.
- ▣ Lipofuscin is a golden brown intralysosomal pigment seen in ageing and in debilitating diseases; it is an expression of residual bodies or wear and tear pigment.
- ▣ Exogenous pigments may appear in the body from inhalation (e.g. carbon dust), ingestion (e.g. argyria) and by tattooing.

MORPHOLOGY OF IRREVERSIBLE CELL INJURY (CELL DEATH)

Cell death is a state of irreversible injury. It may occur in the living body as a local or focal change (i.e. autolysis, necrosis and apoptosis) and the changes that follow it (i.e. gangrene and pathologic calcification), or result in end of the life (somatic death). These pathologic processes involved in cell death are described below.

AUTOLYSIS

Autolysis (i.e. *self-digestion*) is disintegration of the cell by its own hydrolytic enzymes liberated from lysosomes. Autolysis can occur in the living body when it is surrounded by inflammatory reaction (*vital reaction*), but the term is generally used for postmortem change in which there is complete absence of surrounding inflammatory response. Autolysis is *rapid* in some tissues rich in hydrolytic enzymes such as in the pancreas, and gastric mucosa; *intermediate* in tissues like the heart, liver and kidney; and *slow* in fibrous tissue.

Morphologically, autolysis is identified by homogeneous and eosinophilic cytoplasm with loss of cellular details and remains of cell as debris.

NECROSIS

Necrosis is defined as a localised area of death of tissue followed later by degradation of tissue by hydrolytic enzymes liberated from dead cells; it is invariably accompanied by inflammatory reaction.

Necrosis can be caused by various agents such as hypoxia, chemical and physical agents, microbial agents, immunological injury, etc.

Based on etiology and morphologic appearance, there are 5 types of necrosis: coagulative, liquefaction (colliquative), caseous, fat, and fibrinoid necrosis.

1. COAGULATIVE NECROSIS This is the most common type of necrosis caused by irreversible focal injury, mostly from sudden cessation of blood flow (ischaemic necrosis), and less often from bacterial and chemical agents. The organs commonly affected are the heart, kidney, and spleen.

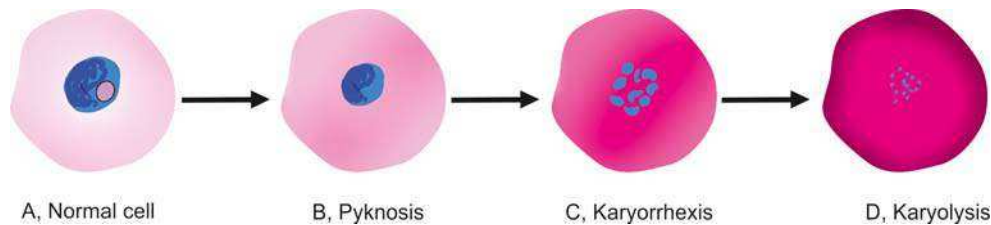

Figure 2.20 Nuclear and cytoplasmic changes in necrosis. A, Normal cell. B, Cytoplasm is more pink and nucleus is shrunken (pyknosis). C, Cytoplasm is more pink and the nucleus is fragmented (karyorrhexis). D, The cytoplasm is intensely pink and nuclear material has disappeared (karyolysis).

Grossly, focus of coagulative necrosis in the early stage is pale, firm, and slightly swollen and is called infarct. With progression, the affected area becomes more yellowish, softer, and shrunken.

Microscopically, the hallmark of coagulative necrosis is the conversion of normal cells into their 'tombstones' i.e. outlines of the cells are retained and the cell type can still be recognised but their cytoplasmic and nuclear details are lost. The necrosed cells are swollen and have more eosinophilic cytoplasm than the normal. These cells show nuclear changes of pyknosis, karyorrhexis and karyolysis (Fig. 2.20). However, cell digestion and liquefaction fail to occur (c.f. liquefaction necrosis). Eventually, the necrosed focus is infiltrated by inflammatory cells and the dead cells are phagocytosed leaving granular debris and fragments of cells (Fig. 2.21).

2. LIQUEFACTION (COLLIQUATIVE) NECROSIS Liquefaction or colliquative necrosis also occurs commonly due to ischaemic injury and bacterial or fungal infections but hydrolytic enzymes in tissue degradation have a dominant role in causing semi-fluid material. The common examples are infarct brain and abscess cavity.

Grossly, the affected area is soft with liquefied centre containing necrotic debris. Later, a cyst wall is formed.

Microscopically, the cystic space contains necrotic cell debris and macrophages filled with phagocytosed

material. The cyst wall is formed by proliferating capillaries, inflammatory cells, and gliosis (proliferating glial cells) in the case of brain and proliferating fibroblasts in the case of abscess cavity (Fig. 2.22).

3. CASEOUS NECROSIS Caseous (caseous= cheese-like) necrosis is found in the centre of foci of tuberculous infections. It combines features of both coagulative and liquefactive necrosis.

Grossly, foci of caseous necrosis resemble dry cheese and are soft, granular and yellowish. This appearance is partly attributed to the histotoxic effects of lipopolysaccharides present in the capsule of the tubercle bacilli, *Mycobacterium tuberculosis*.

Microscopically, centre of the necrosed focus contain structureless, eosinophilic material having scattered granular debris of disintegrated nuclei (Fig. 2.23). The surrounding tissue shows characteristic granulomatous inflammatory reaction consisting of epithelioid cells (modified macrophages having slipper-shaped vesicular nuclei), interspersed giant cells of Langhans' and foreign body type and peripheral mantle of lymphocytes (page 140).

4. FAT NECROSIS Fat necrosis is a special form of cell death occurring at mainly fat-rich anatomic locations in the body. The examples are: traumatic fat necrosis of the breast, especially in heavy and pendulous breasts, and mesenteric fat necrosis due to acute pancreatitis.

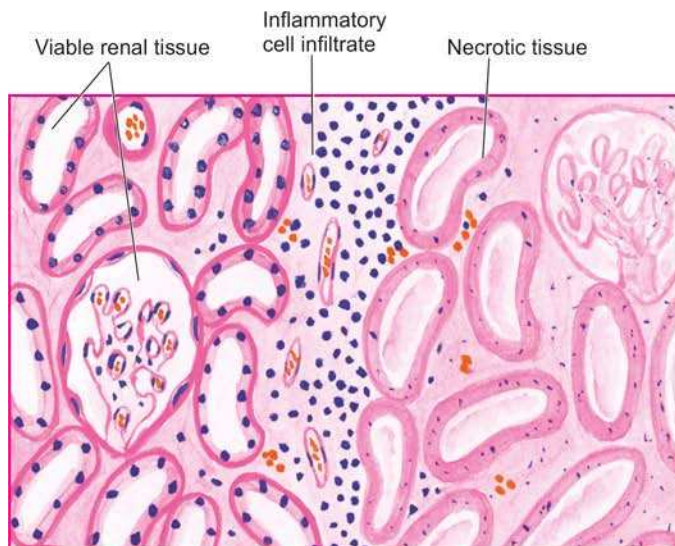

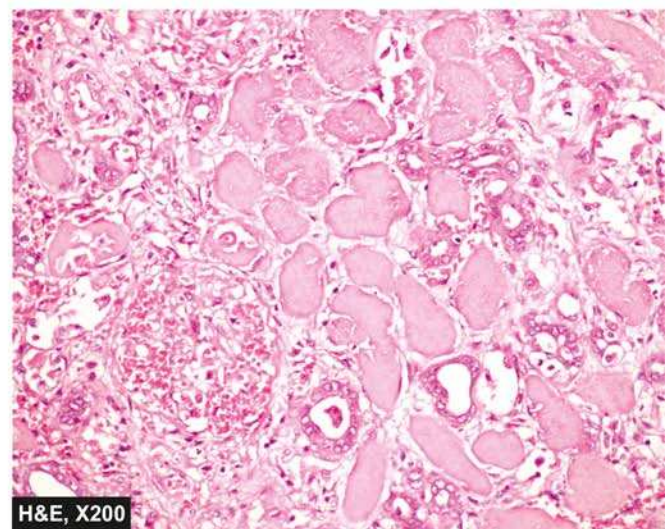

Figure 2.21 Coagulative necrosis in infarct kidney. The affected area on right shows cells with intensely eosinophilic cytoplasm of tubular cells but the outlines of tubules are still maintained. The nuclei show granular debris. The interface between viable and non-viable area shows non-specific chronic inflammation and proliferating vessels.

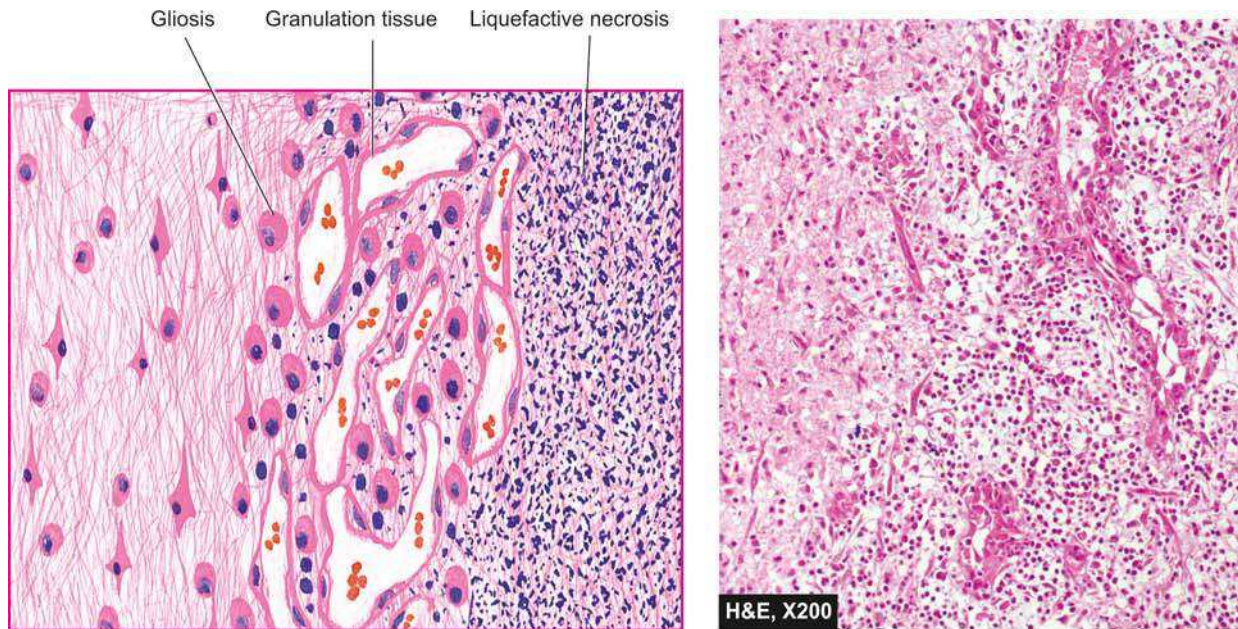

Figure 2.22 Liquefactive necrosis brain. The necrosed area on right side of the field shows a cystic space containing cell debris, while the surrounding zone shows granulation tissue and gliosis.

In the case of acute pancreatitis, there is liberation of pancreatic lipases from injured or inflamed tissue that results in necrosis of the pancreas as well as of the fat depots throughout the peritoneal cavity, and sometimes, even affecting the extra-abdominal adipose tissue.

In fat necrosis, there is hydrolysis and rupture of adipocytes, causing release of neutral fat which changes into glycerol and free fatty acids. The leaked out free fatty acids complex with calcium to form calcium soaps (saponification) discussed later under dystrophic calcification.

Grossly, fat necrosis appears as yellowish-white and firm deposits. Formation of calcium soaps imparts the necrosed foci firmer and chalky white appearance.

Microscopically, the necrosed fat cells have cloudy appearance and are surrounded by an inflammatory

reaction. Formation of calcium soaps is identified in the tissue sections as amorphous, granular and basophilic material (**Fig. 2.24**).

5. FIBRINOID NECROSIS Fibrinoid necrosis is characterized by deposition of fibrin-like material which has the staining properties of fibrin such as phosphotungstic acid haematoxylin (PTAH) stain. It is encountered in various examples of immunologic tissue injury (e.g. in immune complex vasculitis, autoimmune diseases, Arthus reaction etc), arterioles in hypertension, peptic ulcer etc.

Microscopically, fibrinoid necrosis is identified by brightly eosinophilic, hyaline-like deposition in the vessel wall. Necrotic focus is surrounded by nuclear debris of neutrophils (leucocytoclasia) (**Fig. 2.25**). Local haemorrhage may occur due to rupture of the blood vessel.

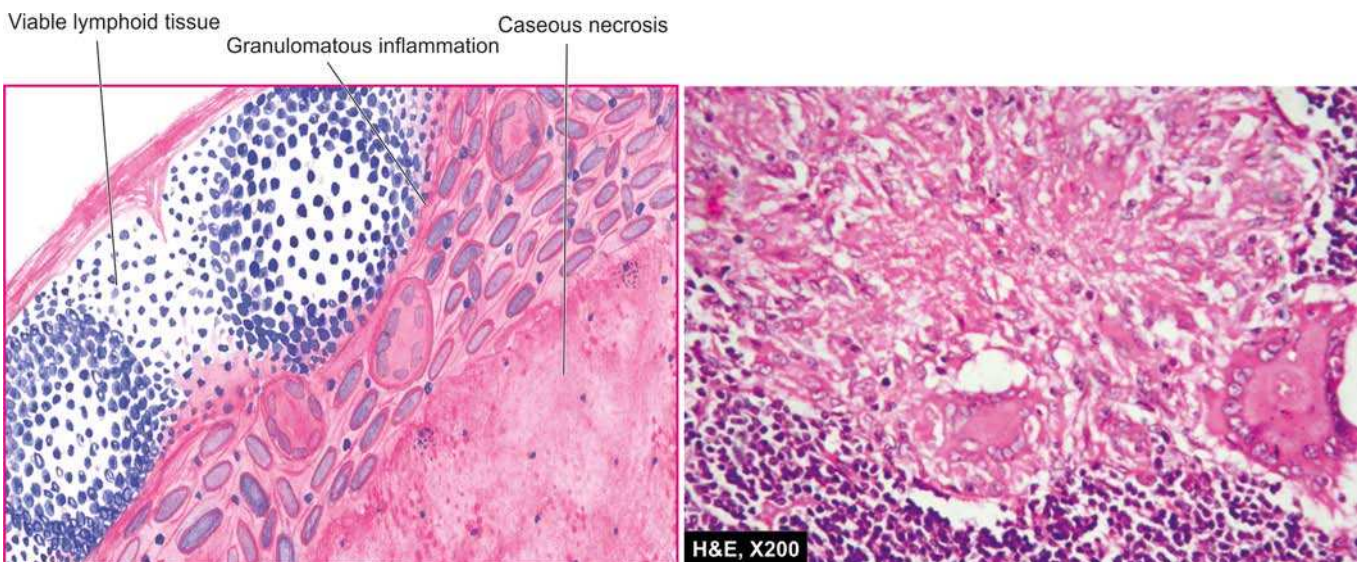

Figure 2.23 Caseous necrosis lymph node. There is eosinophilic, amorphous, granular material, while the periphery shows granulomatous inflammation.

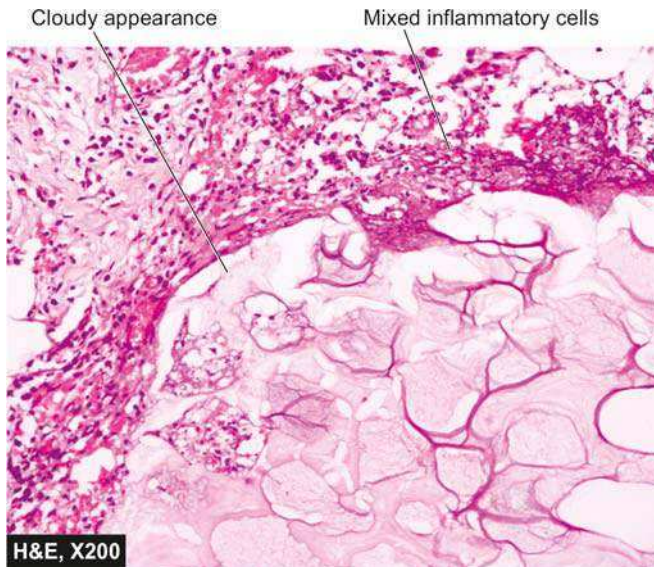

Figure 2.24 Fat necrosis in acute pancreatitis. There is cloudy appearance of adipocytes, coarse basophilic granular debris while the periphery shows a few mixed inflammatory cells.

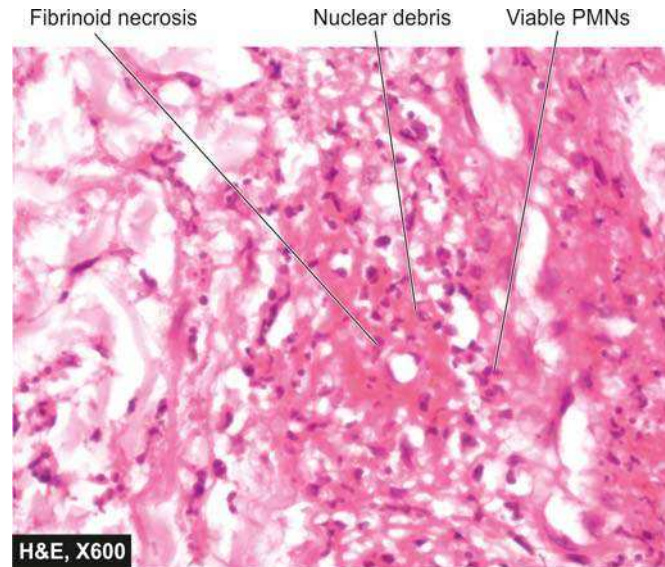

Figure 2.25 Fibrinoid necrosis in autoimmune vasculitis. The vessel wall shows brightly pink amorphous material and nuclear fragments of necrosed neutrophils.

APOPTOSIS

Apoptosis is a form of 'coordinated and internally programmed cell death' having significance in a variety of physiologic and pathologic conditions (*apoptosis*=falling off or dropping off, as that of leaves or petals). The term was first introduced in 1972 distinct from necrosis by being controlled and regulated cell death, and opposed to that of mitosis by having regulated size of the cell turn over. When the cell is not needed, pathway of cell death is activated ('cell suicide'). Unlike necrosis, apoptosis is not accompanied by any inflammation and collateral tissue damage.

APOPTOSIS IN BIOLOGIC PROCESSES Apoptosis is responsible for mediating cell death in a wide variety of physiologic and pathologic processes as under:

Physiologic Processes:

1. Organised cell destruction in sculpting of tissues during *development of embryo*.
2. Physiologic involution of cells in *hormone-dependent tissues* e.g. endometrial shedding, regression of lactating breast after withdrawal of breast-feeding.
3. Normal cell destruction followed by *replacement proliferation* such as in intestinal epithelium.
4. *Involution of the thymus* in early age.

Pathologic Processes:

1. Cell death in tumours exposed to *chemotherapeutic agents*.
2. *Cell death by cytotoxic T cells* in immune mechanisms such as in graft-versus-host disease and rejection reactions.
3. Progressive *depletion of CD4+T cells* in the pathogenesis of AIDS.
4. *Cell death in viral infections* e.g. formation of Councilman bodies in viral hepatitis.
5. *Pathologic atrophy* of organs and tissues on withdrawal of stimuli e.g. prostatic atrophy after orchiectomy, atrophy

of kidney or salivary gland on obstruction of ureter or ducts, respectively.

6. Cell death in response to low dose of *injurious agents* involved in causation of necrosis e.g. radiation, hypoxia and mild thermal injury.
7. In *degenerative diseases of CNS* e.g. in Alzheimer's disease, Parkinson's disease, and chronic infective dementias.
8. *Heart diseases* e.g. in acute myocardial infarction (20% necrosis and 80% apoptosis).

MORPHOLOGIC FEATURES The characteristic morphologic changes in apoptosis by light microscopy and electron microscopy are as under:

1. Involvement of *single cells or small clusters of cells* in the background of viable cells.
2. Apoptotic cells are round to oval *shrunken masses* of intensely eosinophilic cytoplasm (mummified cell) containing shrunken or almost-normal organelles (**Fig. 2.26**).
3. Nuclear chromatin is condensed under the nuclear membrane i.e. *pyknosis*.
4. The cell membrane may show *blebs or projections* on the surface.
5. There may be formation of membrane-bound near-spherical bodies containing condensed organelles around the cell called *apoptotic bodies*.
6. Characteristically, unlike necrosis, there is *no acute inflammatory reaction* around apoptosis.
7. *Phagocytosis* of apoptotic bodies by macrophages takes place at varying speed. There may be swift phagocytosis, or loosely floating apoptotic cells after losing contact with each other and basement membrane as single cells, or may result in major cell loss in the tissue without significant change in the overall tissue structure.

Techniques to identify and count apoptotic cells Apoptotic cells can be identified and counted by following methods:

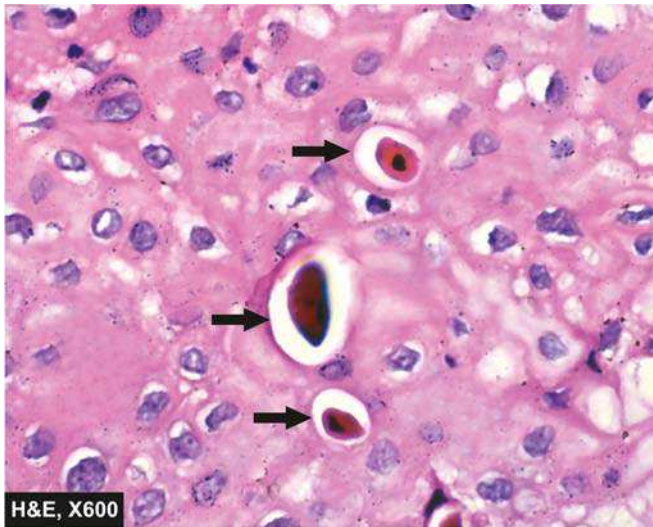

Figure 2.26 Apoptotic bodies in the layer of squamous mucosa (shown by arrows). The dead cell seen in singles, is shrunken, the nucleus has clumped chromatin, while the cytoplasm is intensely eosinophilic. There is no inflammation, unlike necrosis.

1. Staining of chromatin condensation by haematoxylin, Feulgen stain.
2. Fluorescent stain with acridine orange dye.
3. Flow cytometry to visualise rapid cell shrinkage.
4. DNA changes detected by *in situ* techniques or by gel electrophoresis.
5. Immunohistochemical stain with annexin V for plasma membrane of apoptotic cell having phosphatidylserine on the cell exterior.

BIOCHEMICAL CHANGES Biochemical processes underlying the morphologic changes are as under:

1. Proteolysis of cytoskeletal proteins.
2. Protein-protein cross linkages.
3. After initial pyknosis of nucleus, there is fragmentation of chromatin by activation of nuclease.
4. Appearance of phosphatidylserine on the outer surface of cell membrane.
5. In some forms of apoptosis, appearance of an adhesive glycoprotein thrombospondin on the outer surface of apoptotic bodies.
6. Appearance of phosphatidylserine and thrombospondin on the outer surface of apoptotic cell facilitates early recognition by macrophages for phagocytosis prior to appearance of inflammatory cells.

The contrasting features of apoptosis and necrosis are illustrated in **Fig. 2.27** and summarised in **Table 2.4**.

MOLECULAR MECHANISMS OF APOPTOSIS Several physiologic and pathologic processes activate apoptosis in a variety of ways. However, in general the following molecular events sum up the sequence involved in apoptosis:

1. Initiators of apoptosis All cells have inbuilt effector mechanisms for cell survival and signals of cell death; it is the loss of this balance that determines survival or death of a cell. Accordingly, a cell may be initiated to programmed cell death as follows:

i) Withdrawal of normal cell survival signals e.g. absence of certain hormones, growth factors, cytokines.

ii) Agents of cell injury e.g. heat, radiation, hypoxia, toxins, free radicals.

2. Initial steps in apoptosis After the cell has been initiated into self-destruct mode, cell death signaling mechanisms gets activated from *intrinsic (mitochondrial)* and *extrinsic (cell death receptor initiated)* pathways as outlined below. However, finally mediators of cell death are activated caspases. Caspases are a series of proteolytic or protein-splitting enzymes which act on nuclear proteins and organelles containing protein components. The term 'caspase' is derived from: *c* for cysteine protease; *asp* for aspartic acid; and *ase* is used for naming an enzyme.

i) Intrinsic (mitochondrial) pathway: This pathway of cell death signaling is due to increased mitochondrial permeability and is a major mechanism. Mitochondria contain a protein called cytochrome *c* which is its lifeline in an intact mitochondria. But release of this protein from mitochondria into the cytoplasm of the cell triggers the cell into apoptosis. The major mechanism

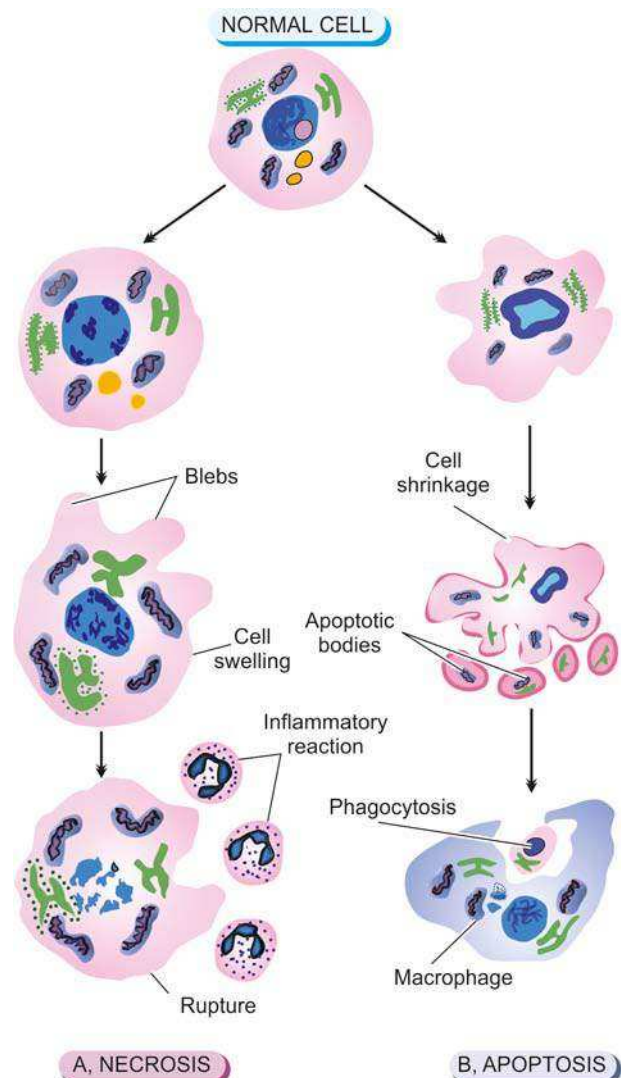

Figure 2.27 Necrosis and apoptosis. A, Cell necrosis is identified by homogeneous, eosinophilic cytoplasm and nuclear changes of pyknosis, karyolysis, and karyorrhexis. B, Apoptosis consists of condensation of nuclear chromatin and fragmentation of the cell into membrane-bound apoptotic bodies which are engulfed by macrophages.

Table 2.4 Contrasting features of apoptosis and necrosis.

| FEATURE | APOPTOSIS | NECROSIS |
|-----------------------------|---|--|
| 1. <i>Definition</i> | Programmed and coordinated cell death | Cell death along with degradation of tissue by hydrolytic enzymes |
| 2. <i>Causative agents</i> | Physiologic and pathologic processes | Hypoxia, toxins |
| 3. <i>Morphology</i> | i) No inflammatory reaction ii) Death of single cells iii) Cell shrinkage iv) Cytoplasmic blebs on membrane v) Apoptotic bodies vi) Chromatin condensation vii) Phagocytosis of apoptotic bodies by macrophages | i) Inflammatory reaction always present ii) Death of many adjacent cells iii) Cell swelling initially iv) Membrane disruption v) Damaged organelles vi) Nuclear disruption vii) Phagocytosis of cell debris by macrophages |
| 4. <i>Molecular changes</i> | i) Lysosomes and other organelles intact ii) Initiation of apoptosis by loss of signals of normal cell survival and by action of agents injurious to the cell iii) Triggered by intrinsic (mitochondrial) pathway (pro- and anti-apoptotic members of Bcl-2 family), extrinsic (cell death receptor initiated) pathway (TNF-R1, Fas, Fas-L) and finally by activated caspases | i) Lysosomal breakdown with liberation of hydrolytic enzymes ii) Initiated by various etiologies (ischaemia hypoxia, chemicals, physical agents, microbes etc). iii) Cell death by ATP depletion, membrane damage, free radical injury |

of regulation of this mitochondrial protein is by pro- and anti-apoptotic members of Bcl proteins. Bcl-2 oncogene was first detected on B-cell lymphoma and hence its name. Bcl-2 gene located on the mitochondrial inner membrane is a human counterpart of *CED-9* (cell death) gene regulating cell growth and cell death of nematode worm *Caenorhabditis elegans* which has been studied in detail. Among about 20 members of Bcl family of oncogenes, the growth promoter (anti-apoptotic) proteins are Bcl-2, Bcl-x and Mcl-1, while pro-apoptotic proteins are Bim, Bid and Bad which contain single Bcl-2 homology domain (also called BH-only proteins). The net effect on the mitochondrial membrane is based on the pro-apoptotic and anti-apoptotic actions of Bcl-2 gene family. Pro-apoptotic mechanism in turn activates Bcl-2 family effectors Bax and Bak which damage mitochondrial membrane and allow leakage of cytochrome c protein into cytoplasm. This, in turn, activates caspase cascade.

ii) Extrinsic (cell death receptor initiated) pathway: This signaling pathway of cell death is by activation of death receptors on the cell membrane. An important cell death receptor is type 1 tumour necrosis factor receptor (TNF-R1) and a related transmembrane protein called Fas (CD95) and its ligand (FasL). Fas is present on cytotoxic (CD 8+) T cells. Binding of Fas and FasL activates Fas-associated death domain (FADD) in the cytoplasm of the cell that activates caspases.

3. Final phase of apoptosis The final culmination of either of the above two mechanisms is activation of caspases. Mitochondrial pathway activates caspase-9 and death receptor pathway activates caspases-8 and 10. Other caspases which actively partake in the apoptotic process are caspases-3 and 6. These caspases act on various components of the cell such as DNAase and nuclear matrix proteins and lead to proteolytic actions on nucleus, chromatin clumping, cytoskeletal damage, disruption of endoplasmic reticulum, mitochondrial damage, and disturbed cell membrane.

4. Phagocytosis The dead apoptotic cells develop membrane changes which promote their phagocytosis. Phosphatidylserine and thrombospondin molecules which are normally present on the inside of the cell membrane, appear

on the outer surface of the cells in apoptosis, which facilitate their identification by adjacent phagocytes and promotes phagocytosis. The phagocytosis is rapid and is unaccompanied by any inflammatory cells.

The mechanism of apoptosis is schematically represented in Fig. 2.28.

**GIST BOX 2.6****Morphology of Irreversible Cell Injury (Cell Death)**

- ☐ *Cell death* is a state of irreversible injury. Examples are autolysis, necrosis and apoptosis.
- ☐ Necrosis is a localised area of death in living tissue and is accompanied by inflammatory reaction.
- ☐ *Coagulative necrosis* is caused by sudden cessation of blood flow (ischaemic necrosis) e.g. infarcts of the heart, kidney, and spleen, or occurs by reduced supply of blood from other causes.
- ☐ *Liquefaction necrosis* also occurs due to ischaemic injury and bacterial or fungal infections but the hydrolytic enzymes in tissue degradation have a dominant role in causing semi-fluid material e.g. infarct brain and abscess cavity.
- ☐ *Caseous necrosis* combines features of both coagulative and liquefactive necrosis. It is found in the centres of foci of tuberculous infections and is accompanied by granulomatous inflammation.
- ☐ *Fat necrosis* is seen in the breast and acute pancreatitis; *fibrinoid necrosis* occurs due to immunologic tissue injury.
- ☐ *Apoptosis* is a coordinated and internally programmed cell death having significance in a variety of physiologic (e.g. endometrial shedding) and pathologic conditions (e.g. viral infections).
- ☐ Morphologically, apoptotic cells appear as round to oval shrunken masses of intensely eosinophilic cytoplasm (*mummified cell*) containing pyknotic nucleus; it is not accompanied by any inflammation.
- ☐ Pathogenetically, apoptosis is triggered by loss of signals of normal cell survival and by action of agents injurious to the cell.

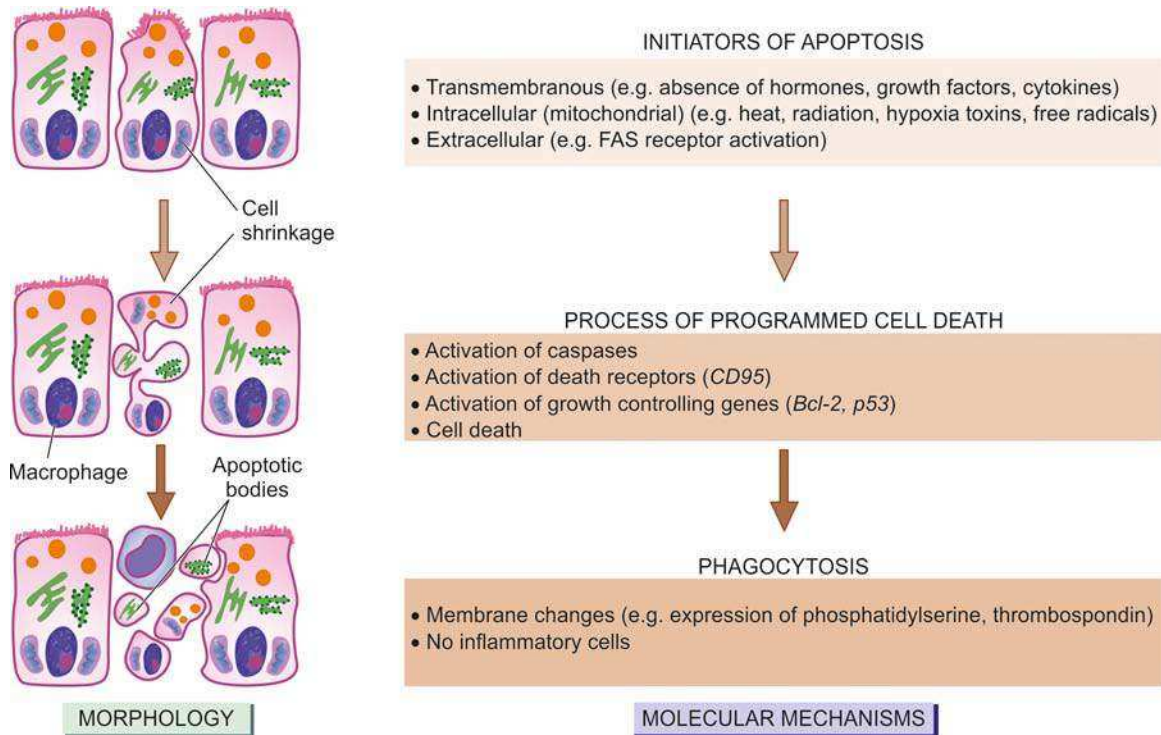

Figure 2.28 Molecular mechanism of apoptosis contrasted with sequence of morphologic changes.

☐ *Molecular mechanism* of apoptosis is under genetic control which may be by intrinsic (mitochondrial) pathway (pro- and anti-apoptotic members of Bcl-2 family), extrinsic (cell death receptor initiated) pathway (TNF-R1, Fas, Fas-L) and finally by activated caspases. This is followed by phagocytosis of apoptotic bodies.

CHANGES AFTER CELL DEATH

Two types of pathologic changes may superimpose following cell injury: gangrene (after necrosis) and pathologic calcification (after degenerations as well as necrosis).

GANGRENE

Gangrene is necrosis of tissue associated with superadded putrefaction, most often following coagulative necrosis due to ischaemia (e.g. in gangrene of the bowel, gangrene of limb). On the other hand, *gangrenous or necrotising inflammation* is characterised primarily by inflammation provoked by virulent bacteria resulting in massive tissue necrosis. Thus, the end-result of necrotising inflammation and gangrene is the same but the way the two are produced, is different. The examples of necrotising inflammation are: gangrenous appendicitis, gangrenous stomatitis (noma, cancrum oris).

There are 2 main types of gangrene—dry and wet, and a variant of wet gangrene called gas gangrene. In all types of gangrene, necrosis undergoes liquefaction by the action of putrefactive bacteria.

Dry Gangrene

This form of gangrene begins in the distal part of a limb due to ischaemia. The typical example is the dry gangrene in the

toes and feet of an old patient due to severe atherosclerosis. Other causes of dry gangrene foot include thromboangiitis obliterans (Buerger's disease), Raynaud's disease, trauma, ergot poisoning. It is usually initiated in one of the toes which is farthest from the blood supply, containing so little blood that even the invading bacteria find it hard to grow in the necrosed tissue. The gangrene spreads slowly upwards until it reaches a point where the blood supply is adequate to keep the tissue viable. A *line of separation* is formed at this point between the gangrenous part and the viable part.

MORPHOLOGIC FEATURES *Grossly*, the affected part is dry, shrunken and dark black, resembling the foot of a mummy. It is black due to liberation of haemoglobin from haemolysed red blood cells which is acted upon by hydrogen disulfide (H_2S) produced by bacteria resulting in formation of black iron sulfide. The line of separation usually brings about complete separation with eventual falling off of the gangrenous tissue if it is not removed surgically (*i.e. spontaneous amputation*) (Fig. 2.29).

Histologically, there is necrosis with smudging of the tissue. The line of separation consists of inflammatory granulation tissue (Fig. 2.30).

Wet Gangrene

Wet gangrene occurs in naturally moist tissues and organs such as the bowel, lung, mouth, cervix, vulva etc. To other examples of wet gangrene having clinical significance are as follows:

- ◆ *Diabetic foot* which is due to high glucose content in the necrosed tissue which favours growth of bacteria.
- ◆ *Bed sores* occurring in a bed-ridden patient due to pressure on sites like the sacrum, buttocks and heel.

Wet gangrene usually develops due to blockage of both venous as well as arterial blood flow and is more rapid.

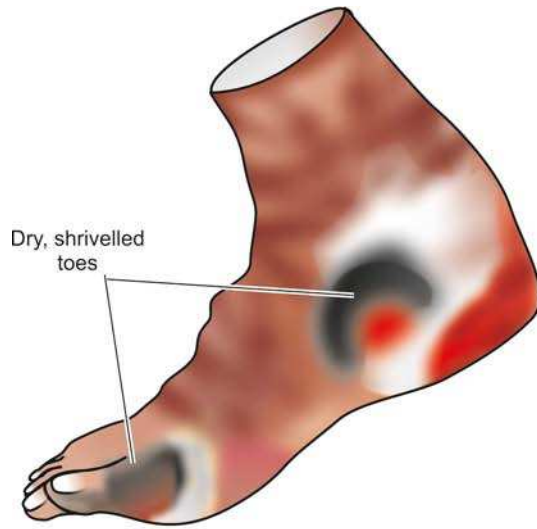

Figure 2.29 Dry gangrene of the foot. The gangrenous area is dry, shrunken and dark and is separated from the viable tissue by clear line of separation.

The affected part is stuffed with blood which favours the rapid growth of putrefactive bacteria. The toxic products formed by bacteria are absorbed causing profound systemic manifestations of septicaemia, and finally death. The spreading wet gangrene generally lacks clear-cut line of demarcation and may spread to peritoneal cavity causing peritonitis.

MORPHOLOGIC FEATURES *Grossly*, the affected part is soft, swollen, putrid, rotten and dark. The classic example is gangrene of the bowel, commonly due to strangulated hernia, volvulus or intussusception. The part is stained dark black due to the same mechanism as in dry gangrene (**Fig. 2.31**).

Histologically, there is coagulative necrosis with stuffing of affected part with blood. The mucosa is ulcerated and sloughed. Lumen of the bowel contains mucus and blood. There is intense acute inflammatory exudates and thrombosed vessels. The line of demarcation between gangrenous segment and viable bowel is generally not clear-cut (**Fig. 2.32**).

Contrasting features of two main forms of gangrene are summarised in **Table 2.5**.

GAS GANGRENE It is a special form of wet gangrene caused by gas-forming clostridia (gram-positive anaerobic bacteria) which gain entry into the tissues through open contaminated wounds, especially in the muscles, or as a complication of operation on colon which normally contains clostridia. Clostridia produce various toxins which produce necrosis and oedema locally and are also absorbed producing profound systemic manifestations.

MORPHOLOGIC FEATURES *Grossly*, the affected area is swollen, oedematous, painful and crepitant due to accumulation of gas bubbles of carbon dioxide within the tissues formed by fermentation of sugars by bacterial toxins.

Subsequently, the affected tissue becomes dark black and is foul smelling.

Microscopically, the muscle fibres undergo coagulative necrosis with liquefaction. Large number of gram-positive bacilli can be identified. At the periphery, a zone of leucocytic infiltration, oedema and congestion are found. Capillary and venous thrombi are common.

PATHOLOGIC CALCIFICATION

Deposition of calcium salts in tissues other than osteoid or enamel is called pathologic or heterotopic calcification. Two distinct types of pathologic calcification are recognised:

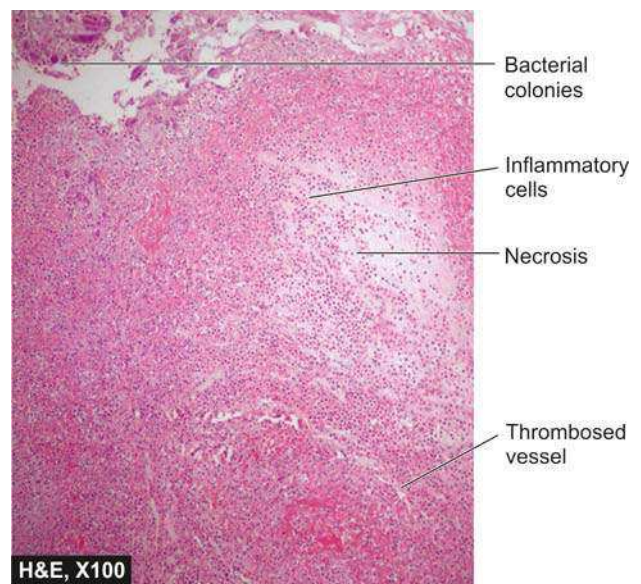

Figure 2.30 Dry gangrene of the foot. Microscopy shows coagulative necrosis of the skin, muscle and other soft tissue, and thrombosed vessels.

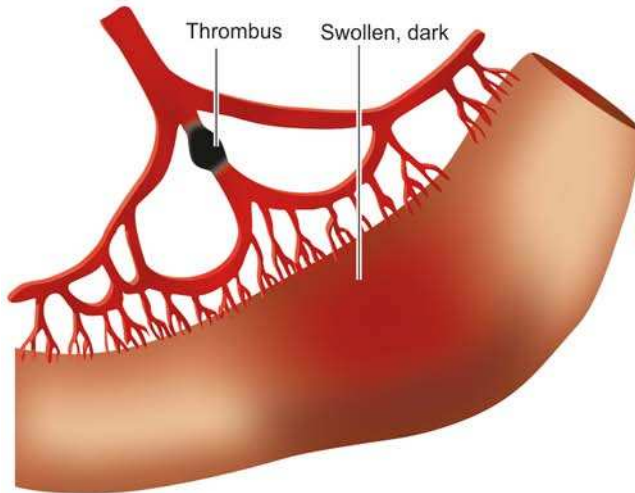

Figure 2.31 Wet gangrene of the small bowel. The affected part is soft, swollen and dark. Line of demarcation between gangrenous segment and the viable bowel is not clear-cut.

◆ *Dystrophic calcification* is characterised by deposition of calcium salts in dead or degenerated tissues with normal calcium metabolism and normal serum calcium level.

◆ *Metastatic calcification*, on the other hand, occurs in apparently normal tissues and is associated with deranged calcium metabolism and hypercalcaemia.

Etiology and pathogenesis of the two are different but morphologically the deposits in both resemble normal minerals of the bone.

Histologically, in routine H & E stained sections, calcium salts appear as deeply basophilic, irregular and granular clumps. The deposits may be intracellular, extracellular, or at both locations. Occasionally, heterotopic bone

formation (ossification) may occur. Calcium deposits can be confirmed by special stains like silver impregnation method of *von-Kossa* producing black colour, and *alizerin red S* that produces red staining. Pathologic calcification is often accompanied by diffuse or granular deposits of iron giving positive Prussian blue reaction in Perl's stain.

Etiopathogenesis

The two types of pathologic calcification result from distinctly different etiologies and mechanisms.

DYSTROPHIC CALCIFICATION As apparent from definition, dystrophic calcification may occur due to 2 types of causes:

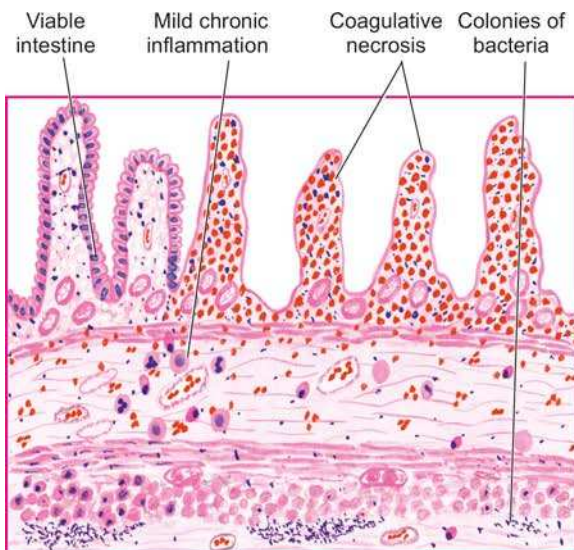

Figure 2.32 Wet gangrene of the small bowel. Microscopy shows coagulative necrosis of the affected bowel wall and thrombosed vessels while the junction with normal intestine is indistinct and shows an inflammatory infiltrate.

Table 2.5 Contrasting features of dry and wet gangrene.

| FEATURE | DRY GANGRENE | WET GANGRENE |
|-------------------------------|---|---|
| 1. <i>Site</i> | Commonly limbs | More common in bowel |
| 2. <i>Mechanisms</i> | Arterial occlusion | Blockage of both venous drainage and arterial obstruction |
| 3. <i>Macroscopy</i> | Organ dry, shrunken and black | Part moist, soft, swollen, rotten and dark |
| 4. <i>Putrefaction</i> | Limited due to very little blood supply | Marked due to stuffing of organ with blood |
| 5. <i>Line of demarcation</i> | Present at the junction between healthy and gangrenous part | No clear line of demarcation |
| 6. <i>Bacteria</i> | Bacteria fail to survive | Numerous present |
| 7. <i>Prognosis</i> | Generally better due to little septicaemia | Generally poor due to profound toxemia |

- ◆ Calcification in dead tissue.
- ◆ Calcification of degenerated tissue.

Calcification in dead tissue

1. *Caseous necrosis* in tuberculosis is the most common site for dystrophic calcification. Living bacilli may be present even in calcified tuberculous lesions, lymph nodes, lungs, etc (Fig. 2.33).
2. *Liquefaction necrosis* in chronic abscesses may get calcified.
3. *Fat necrosis* following acute pancreatitis or traumatic fat necrosis in the breast results in deposition of calcium soaps.
4. *Gamna-Gandy bodies* in chronic venous congestion (CVC) of the spleen is characterised by calcific deposits admixed with haemosiderin on fibrous tissue.
5. *Infarcts* may sometimes undergo dystrophic calcification.
6. *Thrombi*, especially in the veins, may produce phleboliths.
7. *Haematomas* in the vicinity of bones may undergo dystrophic calcification.
8. *Dead parasites* like in hydatid cyst, *Schistosoma* eggs, and cysticercosis are some of the examples showing dystrophic calcification.
9. Microcalcification in *breast cancer* detected by mammo-graphy.

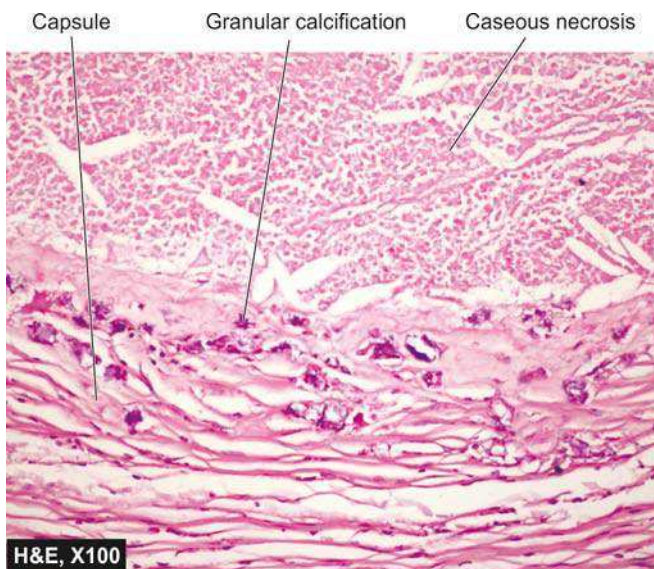

Figure 2.33 Dystrophic calcification in caseous necrosis in tuberculous lymph node. In H & E, the deposits are basophilic granular while the periphery shows healed granulomas.

10. *Congenital toxoplasmosis* involving the central nervous system visualised by calcification in the infant brain.

Calcification in degenerated tissues

1. *Dense old scars* may undergo hyaline degeneration and subsequent calcification.
2. *Atheromas* in the aorta and coronaries frequently undergo calcification.
3. *Mönckeberg's sclerosis* shows calcification in the degenerated tunica media of muscular arteries in elderly people (page 372) (Fig. 2.34).
4. *Stroma of tumours* such as uterine fibroids, breast cancer, thyroid adenoma, goitre etc show calcification.
5. *Goitre* of the thyroid may show presence of calcification in areas of degeneration.
6. Some tumours show characteristic spherules of calcification called *psammoma bodies* or calcospherites such as in meningioma, papillary serous cystadenocarcinoma of the ovary and papillary carcinoma of the thyroid.
7. *Cysts* which have been present for a long time may show calcification of their walls e.g. epidermal and pilar cysts.

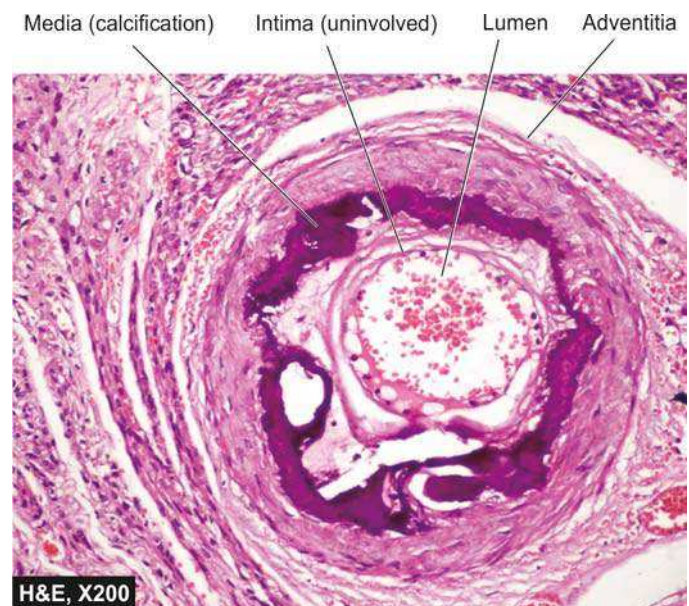

Figure 2.34 Dystrophic calcification in degenerated tunica media of muscular artery of uterine myometrium in Mönckeberg's arteriosclerosis.

8. *Calcinosis cutis* is a condition of unknown cause in which there are irregular nodular deposits of calcium salts in the skin and subcutaneous tissue.

9. *Senile degenerative changes* may be accompanied by dystrophic calcification such as in costal cartilages, tracheal or bronchial cartilages, and pineal gland in the brain etc.

Pathogenesis of dystrophic calcification The process of dystrophic calcification has been likened to the formation of normal hydroxyapatite of bone i.e. binding of phosphate ions with calcium ions to form precipitates of calcium phosphate. It involves phases of initiation and propagation as follows:

◆ **Initiation:** Following cell injury (i.e. degeneration or necrosis), there is membrane damage and release of membrane phospholipids. Phosphatases associated with phospholipids generate phosphate ions. It is also known that there is excess uptake of calcium by injured mitochondria in degeneration and necrosis. Thus, calcium and phosphate so generated from these mechanisms form precipitates of calcium phosphate.

◆ **Propagation:** Simultaneously, some structural changes occur in calcium and phosphate groups which result in further propagation of deposits and form mineral crystals.

METASTATIC CALCIFICATION Since metastatic calcification occurs in normal tissues due to hypercalcaemia, its causes would include either of the following two groups of causes:

- ◆ Excessive mobilisation of calcium from the bone.
- ◆ Excessive absorption of calcium from the gut.

Excessive mobilisation of calcium from the bone These causes are more common and include the following:

1. *Hyperparathyroidism* which may be primary such as due to parathyroid adenoma, or secondary such as from parathyroid hyperplasia, chronic renal failure etc.
2. *Bony destructive lesions* such as multiple myeloma, metastatic carcinoma.
3. *Hypercalcaemia* as a part of paraneoplastic syndrome e.g. in breast cancer.
4. *Prolonged immobilisation* of a patient results in disuse atrophy of the bones and hypercalcaemia.

Excessive absorption of calcium from the gut Less often, excess calcium may be absorbed from the gut causing hypercalcaemia and metastatic calcification. These causes are as under:

1. *Hypervitaminosis D* from excessive intake or in sarcoidosis.
2. *Milk-alkali syndrome* caused by excessive oral intake of calcium in the form of milk and administration of calcium carbonate in the treatment of peptic ulcer.
3. *Idiopathic hypercalcaemia of infancy* (Williams syndrome).
4. *Renal causes* such as in renal tubular acidosis.

Sites of metastatic calcification Metastatic calcification may occur in any normal tissue of the body but preferentially affects the following organs and tissues:

1. *Kidneys*, especially at the basement membrane of tubular epithelium and in the tubular lumina causing nephrocalcinosis (Fig. 2.35).
2. *Lungs*, especially in the alveolar walls.
3. *Stomach*, on the acid-secreting fundal glands.
4. *Blood vessels*, especially on the internal elastic lamina.

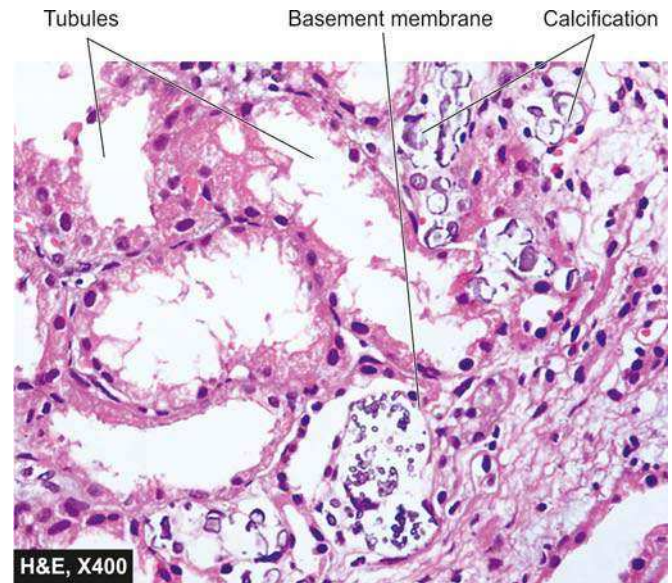

Figure 2.35 Metastatic calcification in tubular basement membrane in nephrocalcinosis due to hypercalcaemia.

5. *Cornea* is another site affected by metastatic calcification.
6. *Synovium* of the joint causing pain and dysfunction.

Pathogenesis of metastatic calcification Metastatic calcification occurs due to excessive binding of inorganic phosphate ions with elevated calcium ions due to underlying metabolic derangement. This leads to precipitates of calcium phosphate at the preferential sites, due to presence of acid secretions or rapid changes in pH levels at these sites. Metastatic calcification is reversible upon correction of underlying metabolic disorder.

The distinguishing features between the two types of pathologic calcification are summarised in **Table 2.6**.

GIST BOX 2.7

Changes after Cell Death

- ☐ **Gangrene** is necrosis of tissue associated with super-added putrefaction, most often following coagulative necrosis due to ischaemia. There are 2 main types of gangrene—dry and wet.
- ☐ **Dry gangrene** begins in the distal part of a limb due to ischaemia e.g. due to severe atherosclerosis and Buerger's disease. A line of separation generally marks the junction of viable and gangrenous tissue e.g. gangrene foot.
- ☐ **Wet gangrene** occurs in naturally moist tissues and organs e.g. gangrene bowel, lungs. A line of separation between viable and non-viable tissue is not distinct.
- ☐ **Diabetic foot** and **bed sores** are also examples of wet gangrene. **Gas gangrene** is a special form of wet gangrene caused by gas-forming clostridia.
- ☐ **Pathologic or heterotopic calcification** is deposition of calcium salts in tissues other than osteoid or enamel. It is of 2 types: dystrophic and metastatic calcification.
- ☐ **Dystrophic calcification** is characterised by deposition of calcium salts in necrotic or degenerated tissues with normal calcium metabolism and normal serum calcium level e.g. in caseous necrosis in tuberculosis, severe atherosclerosis.

Table 2.6 Differences between dystrophic and metastatic calcification.

| FEATURE | DYSTROPHIC CALCIFICATION | METASTATIC CALCIFICATION |
|------------------------|--|--|
| 1. Definition | Deposits of calcium salts in dead and degenerated tissues | Deposits of calcium salts in normal tissues |
| 2. Calcium metabolism | Normal | Deranged |
| 3. Serum calcium level | Normal | Hypercalcaemia |
| 4. Reversibility | Generally irreversible | Reversible upon correction of metabolic disorder |
| 5. Causes | Necrosis (caseous, liquefactive, fat), infarcts, thrombi, haematomas, dead parasites, old scars, atheromas, Mönckeberg's sclerosis, certain tumours, cysts, calcinosis cutis | Hyperparathyroidism (due to adenoma, hyperplasia, CRF), bony destructive lesions (e.g. myeloma, metastatic carcinoma), prolonged immobilisation, hypervitaminosis D, milk-alkali syndrome, hypercalcaemia of infancy |
| 6. Pathogenesis | Increased binding of phosphates with necrotic and degenerative tissue, which in turn binds to calcium forming calcium phosphate precipitates | Increased precipitates of calcium phosphate due to hypercalcaemia at certain sites e.g. in lungs, stomach, blood vessels and cornea |

☐ *Metastatic calcification* occurs in normal tissues and is associated with deranged calcium metabolism and hypercalcaemia e.g. from excessive mobilisation of calcium from bones, and excessive intestinal absorption.

(compared from *hypoplasia* which is the term used for developmentally small size, and *aplasia* for extreme failure of development so that only rudimentary tissue is present).

CAUSES Atrophy may occur from physiologic or pathologic causes:

ADAPTIVE DISORDERS

Adaptive disorders are the adjustments which the cells make in response to stresses which may be for physiologic needs (*physiologic adaptation*) or a response to non-lethal pathologic injury (*pathologic adaptation*). Broadly speaking, such physiologic and pathologic adaptations occur by following processes (Fig. 2.36):

◆ Decreasing or increasing their size i.e. *atrophy* and *hypertrophy* respectively, or by increasing their number i.e. *hyperplasia* (postfix word *-trophy* means nourishment; *-plasia* means growth of new cells).

◆ Changing the pathway of phenotypic differentiation of cells i.e. *metaplasia* and *dysplasia* (prefix word *meta-* means transformation; *dys-* means bad development).

In general, the adaptive responses are reversible on withdrawal of stimulus. However, if the irritant stimulus persists for long time, the cell may not be able to survive and may either die or progress further e.g. cell death may occur in sustained atrophy; dysplasia may progress into carcinoma *in situ*. Thus, the concept of evolution 'survival of the fittest' holds true for adaptation as 'survival of the adaptable'.

Various mechanisms which may be involved in adaptive cellular responses include the following:

1. Altered cell surface receptor binding.
2. Alterations in signal for protein synthesis.
3. Synthesis of new proteins by the target cell such as heat-shock proteins (HSPs).

Common forms of cellular adaptive responses along with examples of physiologic and pathologic adaptations are briefly discussed here.

ATROPHY

Reduction of the number and size of parenchymal cells of an organ or its parts which was once normal is called atrophy

A. Physiologic atrophy Atrophy is a normal process of ageing in some tissues, which could be due to loss of endocrine stimulation or arteriosclerosis. For example:

- i) Atrophy of lymphoid tissue with age.
- ii) Atrophy of thymus in adult life.
- iii) Atrophy of gonads after menopause.
- iv) Atrophy of brain with ageing.
- v) Osteoporosis with reduction in size of bony trabeculae due to ageing.

B. Pathologic atrophy The causes are as under:

1. *Starvation atrophy* In starvation, there is first depletion of carbohydrate and fat stores followed by protein catabolism. There is general weakness, emaciation and anaemia referred to as cachexia seen in cancer and severely ill patients.

2. *Ischaemic atrophy* Gradual diminution of blood supply due to atherosclerosis may result in shrinkage of the affected organ e.g.

- i) Small atrophic kidney in atherosclerosis of renal artery.
- ii) Atrophy of the brain in cerebral atherosclerosis.

3. *Disuse atrophy* Prolonged diminished functional activity is associated with disuse atrophy of the organ e.g.

- i) Wasting of muscles of limb immobilised in cast.
- ii) Atrophy of the pancreas in obstruction of pancreatic duct.

4. *Neuropathic atrophy* Interruption in nerve supply leads to wasting of muscles e.g.

- i) Poliomyelitis
- ii) Motor neuron disease
- iii) Nerve section.

5. *Endocrine atrophy* Loss of endocrine regulatory mechanism results in reduced metabolic activity of tissues and hence atrophy e.g.

- i) Hypopituitarism may lead to atrophy of thyroid, adrenal and gonads.
- ii) Hypothyroidism may cause atrophy of the skin and its adnexal structures.

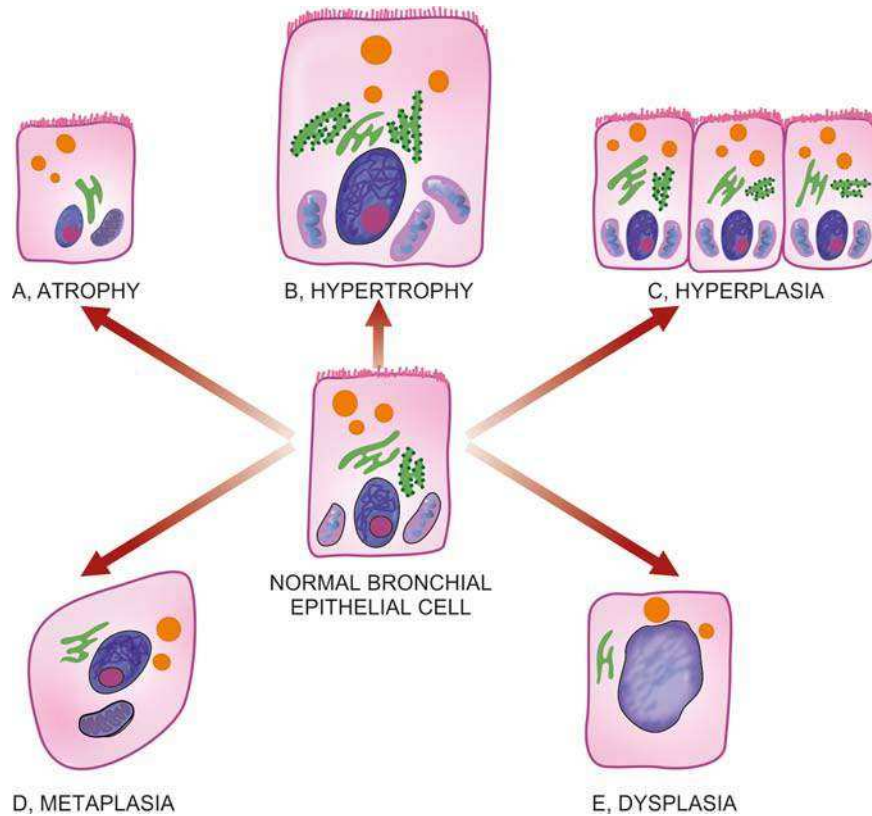

Figure 2.36 Adaptive disorders of growth.

6. *Pressure atrophy* Prolonged pressure from benign tumours or cyst or aneurysm may cause compression and atrophy of the tissues e.g.

- i) Erosion of the spine by tumour in nerve root.
- ii) Erosion of the skull by meningioma arising from pia-arachnoid.
- iii) Erosion of the sternum by aneurysm of arch of aorta.

7. *Idiopathic atrophy* There are some examples of atrophy where no obvious cause is present e.g.

- i) Myopathies.
- ii) Testicular atrophy.

MORPHOLOGIC FEATURES Irrespective of the underlying cause for atrophy, the pathologic changes are similar. The organ is small, often shrunken. The cells become smaller in size but are not dead cells. Shrinkage in cell size is due to reduction in cell organelles, chiefly mitochondria, myofilaments and endoplasmic reticulum. There is often increase in the number of autophagic vacuoles containing cell debris. These autophagic vacuoles may persist to form 'residual bodies' in the cell cytoplasm e.g. lipofuscin pigment granules in brown atrophy (page 25).

HYPERTROPHY

Hypertrophy is an increase in the size of parenchymal cells resulting in enlargement of the organ or tissue, without any change in the number of cells.

CAUSES Hypertrophy may be physiologic or pathologic. In either case, it is caused by increased functional demand or by

hormonal stimulation. Hypertrophy without accompanying hyperplasia affects mainly muscles. In non-dividing cells too, only hypertrophy occurs.

A. Physiologic hypertrophy Enlarged size of the uterus in pregnancy is an example of physiologic hypertrophy as well as hyperplasia.

B. Pathologic hypertrophy Examples of certain diseases associated with hypertrophy are as under:

1. *Hypertrophy of cardiac muscle* may occur in a number of cardiovascular diseases. A few conditions producing left ventricular hypertrophy are as under:

- i) Systemic hypertension
- ii) Aortic valve disease (stenosis and insufficiency)
- iii) Mitral insufficiency

2. *Hypertrophy of smooth muscle* e.g.

- i) Cardiac achalasia (in oesophagus)
- ii) Pyloric stenosis (in stomach)
- iii) Intestinal strictures
- iv) Muscular arteries in hypertension.

3. *Hypertrophy of skeletal muscle* e.g. hypertrophied muscles in athletes and manual labourers.

4. *Compensatory hypertrophy* may occur in an organ when the contralateral organ is removed e.g.

- i) Following nephrectomy on one side in a young patient, there is compensatory hypertrophy as well as hyperplasia of the nephrons of the other kidney.
- ii) Adrenal hyperplasia following removal of one adrenal gland.

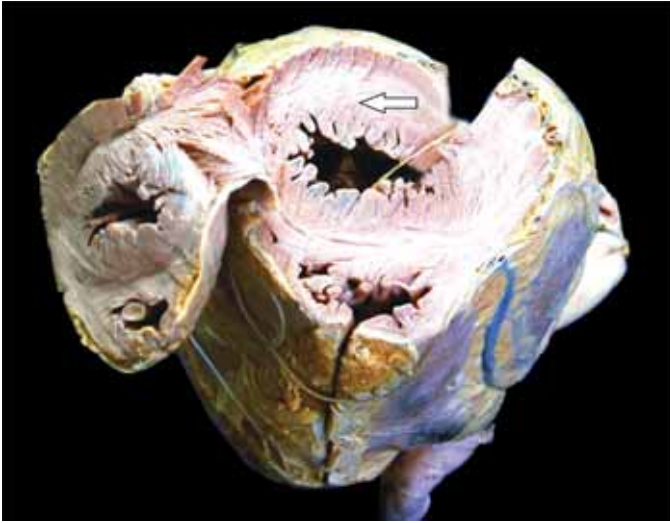

Figure 2.37 Cardiac hypertrophy. Weight of the heart is increased. The chambers opened up at the apex show concentric thickening of left ventricular wall (white arrow) with obliterated lumen (hypertrophy without dilatation).

MORPHOLOGIC FEATURES The affected organ is enlarged and heavy. For example, a hypertrophied heart of a patient with systemic hypertension may weigh 700-800 g as compared to average normal adult weight of 350 g (**Fig. 2.37**). There is enlargement of muscle fibres as well as of nuclei. At ultrastructural level, there is increased synthesis of DNA and RNA, increased protein synthesis and increased number of organelles such as mitochondria, endoplasmic reticulum and myofibrils.

HYPERPLASIA

Hyperplasia is an increase in the number of parenchymal cells resulting in enlargement of the organ or tissue. Quite often, both hyperplasia and hypertrophy occur together. Hyperplasia occurs due to increased recruitment of cells from G₀ (resting) phase of the cell cycle to undergo mitosis, when stimulated. All body cells do not possess hyperplastic growth potential (page 156). Labile cells (e.g. epithelial cells of the skin and mucous membranes, cells of the bone marrow and lymph nodes) and stable cells (e.g. parenchymal cells of the liver, pancreas, kidney, adrenal, and thyroid) can undergo hyperplasia, while permanent cells (e.g. neurons, cardiac and skeletal muscle) have little or no capacity for regenerative hyperplastic growth. Neoplasia differs from hyperplasia in having hyperplastic growth with loss of growth-regulatory mechanism due to change in genetic composition of the cell, while hyperplasia persists so long as stimulus is present.

CAUSES As with other adaptive disorders of growth, hyperplasia may also be physiologic and pathologic.

A. Physiologic hyperplasia The two most common types are hormonal and compensatory:

1. *Hormonal hyperplasia* i.e. hyperplasia occurring under the influence of hormonal stimulation e.g.
 - i) Hyperplasia of female breast at puberty, during pregnancy and lactation.
 - ii) Hyperplasia of pregnant uterus.

- iii) Proliferative activity of normal endometrium after a normal menstrual cycle.

- iv) Prostatic hyperplasia in old age (**Fig. 2.38**).

2. *Compensatory hyperplasia* i.e. hyperplasia occurring following removal of part of an organ or in the contralateral organ in paired organ e.g.

- i) Regeneration of the liver following partial hepatectomy.
- ii) Regeneration of epidermis after skin abrasion.
- iii) Following nephrectomy on one side, there is hyperplasia of nephrons of the other kidney.

B. Pathologic hyperplasia Most examples of pathologic hyperplasia are due to excessive stimulation of hormones or growth factors e.g.

- i) Endometrial hyperplasia following oestrogen excess.
- ii) In wound healing, there is formation of granulation tissue due to proliferation of fibroblasts and endothelial cells.
- iii) Formation of skin warts from hyperplasia of epidermis due to human papilloma virus.
- iv) Pseudocarcinomatous hyperplasia of the skin occurring at the margin of a non-healing ulcer.
- v) Intraductal epithelial hyperplasia in fibrocystic change in the breast.

MORPHOLOGIC FEATURES There is enlargement of the affected organ or tissue and increase in the number of cells. This is due to increased rate of DNA synthesis and hence increased mitoses of the cells.

METAPLASIA

Metaplasia is defined as a reversible change of one type of epithelial or mesenchymal adult cells to another type of adult epithelial or mesenchymal cells, usually in response to abnormal stimuli, and often *reverts back to normal on removal of stimulus*. However, if the stimulus persists for a long time, epithelial metaplasia may progress to dysplasia and further into cancer (**Fig. 2.39**).

Metaplasia is broadly divided into 2 types: epithelial and mesenchymal.

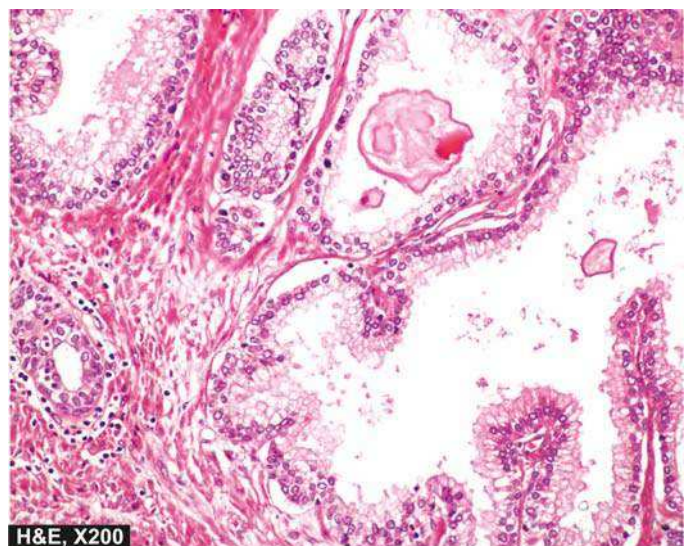

Figure 2.38 Nodular hyperplasia of the prostate. There is hyperplasia of both fibromuscular elements and epithelium seen as areas of intra-acinar papillary infoldings (convolutions) lined by two layers of epithelium with basal polarity of nuclei.

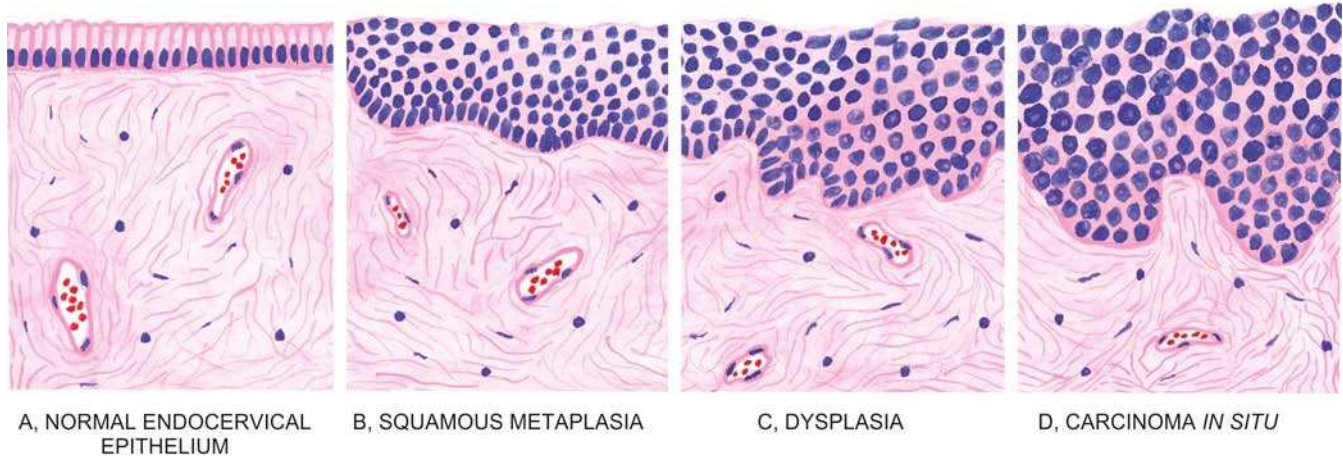

Figure 2.39 Schematic diagram showing sequential changes in uterine cervix from normal epithelium to development of carcinoma *in situ*. A, Normal mucus-secreting endocervical epithelium. B, Squamous metaplasia. C, Dysplastic change. D, Carcinoma *in situ*.

A. EPITHELIAL METAPLASIA This is the more common type. The metaplastic change may be patchy or diffuse and usually results in replacement by stronger but less well-specialised epithelium. However, the metaplastic epithelium being less well-specialised such as squamous type, results in deprivation of protective mucus secretion and hence more prone to infection. Depending upon the type of epithelium transformed, two types of epithelial metaplasia are seen: squamous and columnar.

1. Squamous metaplasia This is more common. Various types of specialised epithelium are capable of undergoing squamous metaplastic change due to chronic irritation that may be mechanical, chemical or infective in origin. Some common examples of squamous metaplasia are seen at following sites:

i) In *bronchus* (normally lined by pseudostratified columnar ciliated epithelium) in chronic smokers.

ii) In *uterine endocervix* (normally lined by simple columnar epithelium) in prolapse of the uterus and in old age (**Fig. 2.40**).

iii) In *gallbladder* (normally lined by simple columnar epithelium) in chronic cholecystitis with cholelithiasis.

iv) In *prostate* (ducts normally lined by simple columnar epithelium) in chronic prostatitis and oestrogen therapy.

v) In *renal pelvis* and *urinary bladder* (normally lined by transitional epithelium) in chronic infection and stones.

vi) In *vitamin A deficiency*, apart from xerophthalmia, there is squamous metaplasia in the nose, bronchi, urinary tract, lacrimal and salivary glands.

2. Columnar metaplasia There are some conditions in which there is transformation to columnar epithelium. For example:

i) Intestinal metaplasia in healed chronic gastric ulcer.

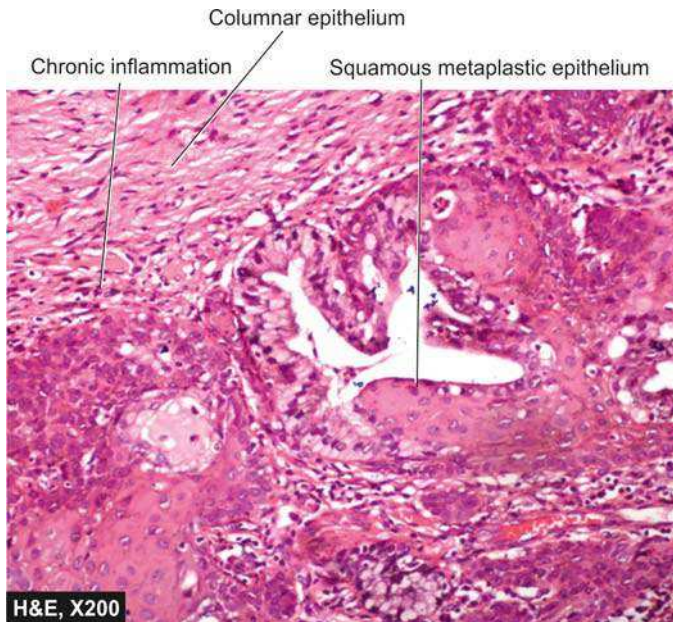

Figure 2.40 Squamous metaplasia of the uterine cervix. Part of the endocervical mucosa is lined by normal columnar epithelium while foci of metaplastic squamous epithelium are seen at other places.

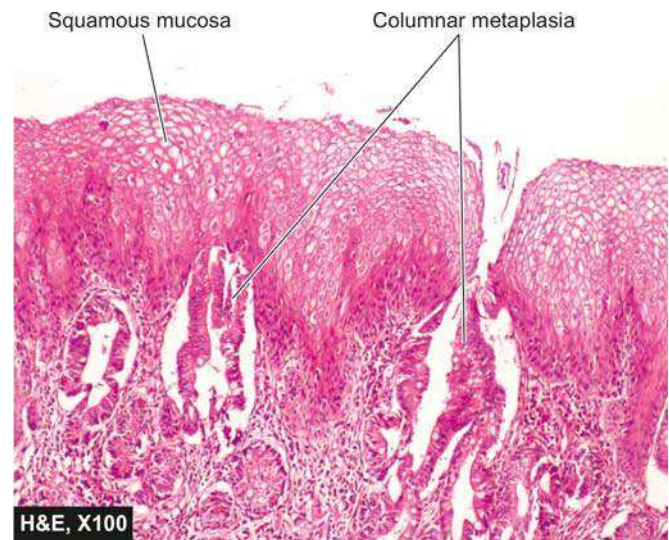

Figure 2.41 Columnar metaplasia oesophagus (Barrett's oesophagus). Part of the oesophagus which is normally lined by squamous epithelium undergoes metaplastic change to columnar epithelium of intestinal type.

ii) Columnar metaplasia in Barrett's oesophagus, in which there is change of normal squamous epithelium to columnar epithelium (Fig. 2.41).

iii) Conversion of pseudostratified ciliated columnar epithelium in chronic bronchitis and bronchiectasis to columnar type.

iv) In cervical erosion (congenital and adult type), there is variable area of endocervical glandular mucosa everted into the vagina.

B. MESENCHYMAL METAPLASIA Less often, there is transformation of one adult type of mesenchymal tissue to another. The examples are as under:

1. Osseous metaplasia Osseous metaplasia is formation of bone in fibrous tissue, cartilage and myxoid tissue. Examples of osseous metaplasia are as under:

i) In arterial wall in old age (Mönckeberg's medial calcific sclerosis)

ii) In soft tissues in myositis ossificans

iii) In cartilage of larynx and bronchi in elderly people

iv) In scar of chronic inflammation of prolonged duration

v) In the fibrous stroma of tumour e.g. in leiomyoma.

2. Cartilaginous metaplasia In healing of fractures, cartilaginous metaplasia may occur where there is undue mobility.

DYSPLASIA

Dysplasia means 'disordered cellular development', often preceded or accompanied with metaplasia and hyperplasia; it is therefore also referred to as *atypical hyperplasia*. Dysplasia occurs most often in epithelial cells. Epithelial dysplasia is characterised by cellular proliferation and cytologic changes as under:

1. Increased number of layers of epithelial cells
2. Disorderly arrangement of cells from basal layer to the surface layer
3. Loss of basal polarity i.e. nuclei lying away from basement membrane
4. Cellular and nuclear pleomorphism
5. Increased nucleocytoplasmic ratio
6. Nuclear hyperchromatism
7. Increased mitotic activity.

The two most common examples of dysplastic changes are the *uterine cervix* (Fig. 2.42) and *respiratory tract*.

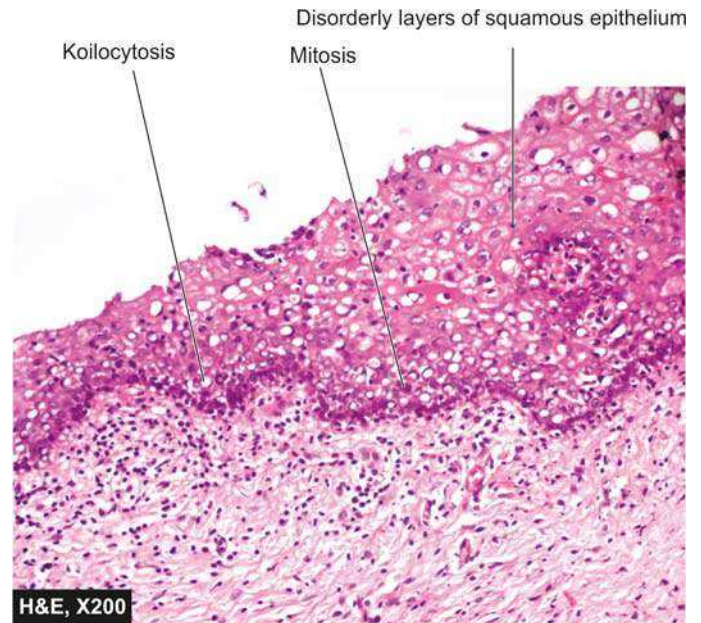

Figure 2.42 Uterine cervical dysplasia, high grade lesion. It shows increased number of layers of squamous epithelium having marked cytologic atypia including mitoses.

Dysplastic changes often occur due to chronic irritation or prolonged inflammation. On removal of the inciting stimulus, the changes may disappear. In a proportion of cases, however, dysplasia may progress into carcinoma *in situ* (cancer confined to layers superficial to basement membrane) or invasive cancer. This concept is further discussed again in details in Chapters 7, 15, and 22.

The differences between dysplasia and metaplasia are contrasted in Table 2.7.

GIST BOX 2.8

Adaptive Disorders

- ☐ **Atrophy** is reduction of the number and size of parenchymal cells of an organ or its parts which was once normal.
- ☐ **Hypertrophy** is an increase in the size of parenchymal cells resulting in enlargement of the organ or tissue, without any change in the number of cells.

Table 2.7 Differences between metaplasia and dysplasia.

| FEATURE | METAPLASIA | DYSPLASIA |
|------------------------------|--|--|
| i) <i>Definition</i> | Change of one type of epithelial or mesenchymal cell to another type of adult epithelial or mesenchymal cell | Disordered cellular development, may be accompanied with hyperplasia or metaplasia |
| ii) <i>Types</i> | Epithelial (squamous, columnar) and mesenchymal (osseous, cartilaginous) | Epithelial only |
| iii) <i>Tissues affected</i> | Most commonly affects bronchial mucosa, uterine endocervix; others mesenchymal tissues (cartilage, arteries) | Uterine cervix, bronchial mucosa |
| iv) <i>Cellular changes</i> | Mature cellular development | Disordered cellular development (pleomorphism, nuclear hyperchromasia, mitosis, loss of polarity) |
| v) <i>Natural history</i> | Reversible on withdrawal of stimulus | May regress on removal of inciting stimulus, or may progress to higher grades of dysplasia or carcinoma <i>in situ</i> |

- ▣ **Hyperplasia** is an increase in the number of parenchymal cells resulting in enlargement of the organ or tissue.
- ▣ **Metaplasia** is defined as a reversible change of one type of epithelial or mesenchymal adult cells to another type of adult epithelial or mesenchymal cells, usually in response to abnormal stimuli, and often reverts back to normal on removal of stimulus.

AGEING

Old age is a concept of longevity in human beings. The consequences of ageing appear after reproductive life when evolutionary role of the individual has been accomplished. However, ageing is distinct from mortality and disease although aged individuals are more vulnerable to disease. With ageing, the mechanism of homeostasis is slow; hence the response to various stresses takes longer to revert back to normal structure and function.

The average age of death of primitive man was barely 20-25 years. However, currently average life-expectancy in the west is about 80 years. In India, due to improved health care, it has gone up from an average of 26 years at the time of independence in 1947 to 64 years at present. In general, survival is longer in women than men (3: 2). About a century ago, the main causes of death were accidents and infections. But now with greater safety and sanitation, the mortality in the middle years has sufficiently declined. However, the maximum human lifespan has remained stable at about 110 years. Higher life expectancy in women is not due to difference in the response of somatic cells of the two sexes but higher mortality rate in men is attributed to violent causes and greater susceptibility to cardiovascular disease, cancer, cirrhosis and respiratory diseases, for which cigarette smoking and alcohol consumption are two most important contributory factors.

In general, the life expectancy of an individual depends upon the following factors:

1. **Intrinsic genetic process** i.e. the genes controlling response to endogenous and exogenous factors initiating apoptosis in senility. It has been seen that long life runs in families and high concordance in lifespan of identical twins has been observed. Studies in centenarians have shown that they lack carrier of apolipoprotein E4 allele which is associated with risk for both heart disease and Alzheimer's disease.
2. **Environmental factors** e.g. consumption and inhalation of harmful substances, type of diet, role of antioxidants etc.
3. **Lifestyle of the individual** such as diseases due to alcoholism (e.g. cirrhosis, hepatocellular carcinoma), smoking (e.g. bronchogenic carcinoma and other respiratory diseases), drug addiction.
4. **Age-related diseases** e.g. atherosclerosis and ischaemic heart disease, diabetes mellitus, hypertension, osteoporosis, Alzheimer's disease, Parkinson's disease etc.

THEORIES OF AGEING

With age, structural and functional changes occur in different organs and systems of the human body. Although no definitive biologic basis of ageing is established, most acceptable theory is the functional decline of non-dividing cells such as neurons and myocytes. The following hypotheses based on investi-

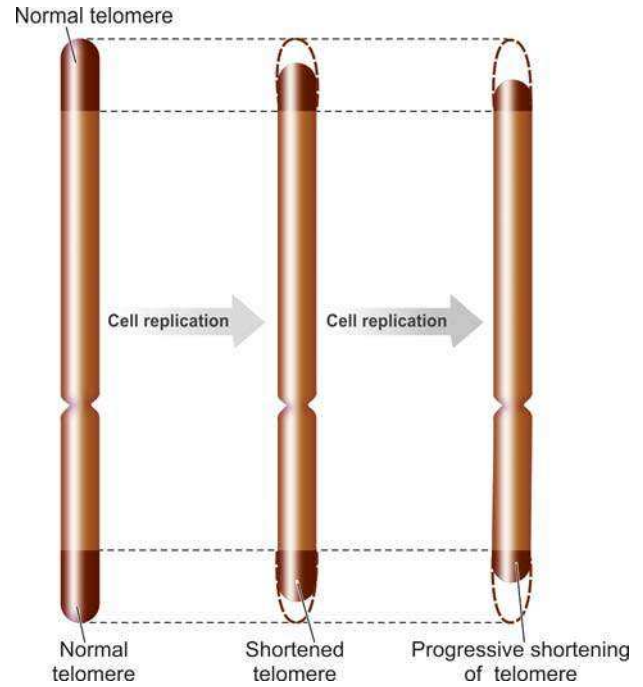

Figure 2.43 Telomeres on chromosomes. In ageing, these end components of chromosome are progressively shortened.

gations mostly in other species explain the cellular basis of ageing:

1. Experimental cellular senescence By *in vitro* studies of tissue culture, it has been observed that cultured human fibroblasts replicate for up to 50 population doublings and then the culture dies out. It means that *in vitro* there is reduced functional capacity to proliferate with age. Studies have shown that there is either loss of chromosome 1 or deletion of its long arm (1q). It has also been observed that with every cell division there is progressive shortening of *telomere* present at the tips of chromosomes, which in normal cell is repaired by the presence of RNA enzyme, *telomerase*. However, due to ageing there is inadequate presence of telomerase enzyme; therefore lost telomere is not repaired resulting in interference in viability of cell (**Fig. 2.43**).

2. Genetic control in invertebrates Clock (*clk*) genes responsible for controlling the rate and time of ageing have been identified in lower invertebrates e.g. *clk-1* gene mutation in the metazoa, *Caenorhabditis elegans*, results in prolonging the lifespan of the worm and slowing of some metabolic functions.

3. Diseases of accelerated ageing A heritable condition associated with signs of accelerated ageing process, *progeria*, seen in children is characterised by baldness, cataracts, and coronary artery disease. Another example is Werner's syndrome, a rare autosomal recessive disease, characterised by similar features of premature ageing, atherosclerosis and risk for development of various cancers.

4. Oxidative stress hypothesis (free radical-mediated injury) Ageing is partly caused by progressive and reversible molecular oxidative damage due to persistent oxidative stress on the human cells. In normal cells, very small amount (3%) of total oxygen consumption by the cell is converted into reactive oxygen species. The rate of generation of reactive

oxygen species is directly correlated with metabolic rate of the organisms. With ageing, there is low metabolic rate with generation of toxic oxygen radicals, which fail to get eliminated causing their accumulation and hence cell damage due to mitochondrial injury. The role of antioxidants in retarding the oxidant damage has been reported in some studies.

5. Hormonal decline With age, there is loss of secretion of some hormones resulting in their functional decline.

6. Defective host defenses Ageing causes impaired immune function and hence reduced ability to respond to microbes and environmental agents.

7. Failure to renew Ageing causes accumulation of senescent cells without corresponding renewal of lost cells.

ORGAN CHANGES IN AGEING

Although all organs start showing deterioration with ageing, following organs show evident morphologic and functional decline:

- 1. Cardiovascular system:** Atherosclerosis, arteriosclerosis with calcification, Mönckeberg's medial calcification, brown atrophy of the heart, loss of elastic tissue from aorta and major arterial trunks causing their dilatation.
- 2. Nervous system:** Atrophy of gyri and sulci, Alzheimer's disease, Parkinson's disease.
- 3. Musculoskeletal system:** Degenerative bone diseases, frequent fractures due to loss of bone density, age-related muscular degeneration.

4. **Eyes:** Deterioration of vision due to cataract and vascular changes in retina.

5. **Hearing:** Disability in hearing due to senility is related to otosclerosis.

6. **Immune system:** Reduced IgG response to antigens, frequent and more severe infections.

7. **Skin:** Laxity of skin due to loss of elastic tissue.

8. **Cancers:** As discussed later in Chapter 7, 80% of cancers occur in the age range of 50-80 years.

GIST BOX 2.9

Ageing

- Life expectancy of an individual depends upon certain factors: genetic, environmental, life style and some age-related diseases.
- There are several hypothesis of ageing. These are: shortening of telomere without replacement of damaged ends, persistent oxidative stress (accumulation of free radicals), hormonal decline, defective host defenses and failure to renew old cells.
- Ageing causes decline in morphology and function of multiple organs: cardiovascular system, nervous system, muscles, bones, eyes, ears, immune system and skin. About 80% of cancers are seen in the age range of 50-80 years.

3

Immunopathology Including Amyloidosis

THE IMMUNE SYSTEM

Immunity and immunopathology are proverbial two edges of 'double-edged sword' i.e. it is a defense mechanism but it can be injurious to the human body in a variety of ways.

Broadly speaking, immunity or body defense mechanism is divided into 2 types, natural (innate) and specific (adaptive), which are interlinked to each other in their functions:

Natural or innate immunity is *non-specific* and is considered as the first line of defense without antigenic specificity. It has 2 major components:

- Humoral*: comprised by complement.
- Cellular*: consists of neutrophils, macrophages, and natural killer (NK) cells.

Specific or adaptive immunity is *specific* and is characterised by antigenic specificity. It too has 2 main components:

- Humoral*: consisting of antibodies formed by B cells.
- Cellular*: mediated by T cells.

The **major functions of immune system** are as under:

- Recognition of self from non-self
- Mounting a specific response against non-self
- Memory of what was earlier recognised as non-self
- Antibody formation
- Cell-mediated reactions

While normal function of immunity is for body defense, its failure or derangement in any way results in diseases of the immune system which are broadly classified into the following 4 groups (**Fig. 3.1**):

1. Immunodeficiency disorders are characterised by deficient or absent cellular and/or humoral immune functions. This group is comprised by a list of *primary and secondary immunodeficiency diseases* including the dreaded *acquired immunodeficiency syndrome (AIDS)*.

2. Hypersensitivity reactions are characterised by hyper-response or inappropriate response of the immune system and cover the various mechanisms of *immunologic tissue injury*.

3. Autoimmune diseases occur when the immune system fails to recognise 'self' from 'non-self'. A growing number of *autoimmune and collagen diseases* are included in this group.

4. Possible immune disorders in which the immunologic mechanisms are suspected in their etiopathogenesis. Classical example of this group is *amyloidosis*.

Before discussing immunopathology of these diseases, it is important to briefly review the normal structure and function of the immune system (immunophysiology) discussed below.

In any discussion of immunity, a few terms and definitions are commonly used as follows:

◆ An **antigen (Ag)** is defined as a substance, usually protein in nature, which when introduced into the tissues stimulates antibody production.

◆ **Hapten** is a non-protein substance which has no antigenic properties, but on combining with a protein can form a new antigen capable of forming antibodies.

◆ An **antibody (Ab)** is a protein substance produced as a result of antigenic stimulation. Circulating antibodies are immunoglobulins (Igs) of which there are 5 classes: IgG, IgA, IgM, IgE and IgD.

◆ An antigen may induce **specifically sensitised cells** having the capacity to recognise, react and neutralise the injurious agent or organisms.

◆ The antigen may combine with antibody to form **antigen-antibody complex**. The reaction of Ag with Ab *in vitro* may be *primary* or *secondary phenomena*; the secondary reaction induces a number of processes such as agglutination, precipitation, immobilisation, neutralisation, lysis and complement fixation. *In vivo*, the Ag-Ab reaction may cause tissue damage.

ORGANS AND CELLS OF IMMUNE SYSTEM

Although functioning as a system, the organs of immune system are distributed at different places in the body. These are as under:

a) Primary lymphoid organs:

- Thymus
- Bone marrow

b) Secondary lymphoid organs:

- Lymph nodes
- Spleen
- MALT (Mucosa-Associated Lymphoid Tissue located in the respiratory tract and GIT).

These organs have been described in the respective chapters in the book.

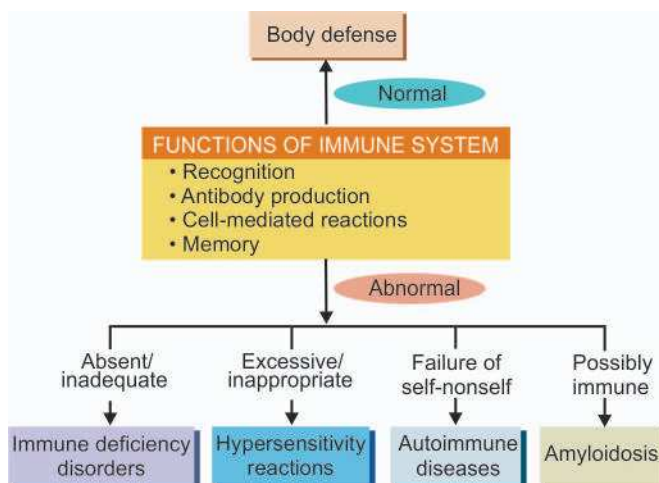

Figure 3.1 Pathophysiology of diseases of immune system.

CELLS OF IMMUNE SYSTEM

The cells comprising immune system are as follows:

- i) Lymphocytes
- ii) Monocytes and macrophages
- iii) Mast cells and basophils
- iv) Neutrophils
- v) Eosinophils

While morphologic aspects of these cells are covered elsewhere in the book, their immune functions are briefly considered below and summarised in **Table 3.1**.

Lymphocytes

Lymphocyte is the master of human immune system. Morphologically, lymphocytes appear as a homogeneous group but functionally two major lymphocyte populations, *T and B lymphocytes*, are identified; while a third type, *NK (natural killer) cells*, comprises a small percentage of circulating lymphocytes having the distinct appearance of *large granular lymphocytes*.

Just as other haematopoietic cells, all three subtypes of lymphocytes are formed from lymphoid precursor cells in the bone marrow. However, unlike other haematopoietic cells, lymphocytes undergo maturation and differentiation in the bone marrow (B cells) and thymus (T cells) and acquire certain genetic and immune surface characters which determine their type and function; this is based on *cluster of differentiation (CD)* molecule on their surface. CD surface protein molecules belong to immunoglobulin superfamily of cell adhesion molecules (CAMs). About 350 different surface CD molecules have been identified so far, which can be identified by 'CD markers' by specific monoclonal antibody stain employing immunohistochemistry or by flow cytometry. B and T lymphocytes proliferate into '*memory cells*' imparting long lasting immunity against specific antigens. While B cells differentiate into plasma cells which form specific antibodies,

T cells get functionally activated on coming in contact with appropriate antigen.

Upon coming in contact with antigen, the macrophage (i.e. specialised antigen-presenting cell such as dendritic cell) and the major histocompatibility complex (MHC) in the macrophage, determine whether the invading antigen is to be presented to B cells or T cells. Some strong antigens that cannot be dealt by antibody response from B cells such as certain microorganisms (e.g. viruses, mycobacteria *M. tuberculosis* and *M. leprae*), cancer cells, tissue transplantation antigen etc, are presented to T cells.

Features and functions of subtypes of lymphocytes are summed up below and illustrated diagrammatically in **Fig. 3.2**.

B CELLS These cells are involved in humoral immunity by inciting antibody response. B cells in circulation comprise about 10-15% of lymphocytes. On coming in contact with antigen (e.g. invading microorganisms), B cells are activated to proliferate and transform into plasmacytoid lymphocytes and then into plasma cells. Depending upon the maturation stage of B cells, specific CD molecules appear on the cell surface which can be identified by CD markers. Common B cell markers are: CD 19, 20, 21, 23. These cells also possess B cell receptors (BCR) for surface immunoglobulins (IgM and IgG) and Fc receptor for attaching to antibody molecule. T cell help is provided to B cells by a subset of T helper cells, $T_H 2$, by elaborated interleukins (IL-4, IL-5, IL-10, IL-13).

T CELLS These cells are implicated in inciting cell-mediated immunity and delayed type of hypersensitivity. T cells in circulation comprise 75-80% of lymphocytes. Pan T cell markers are CD3, CD7 and CD2. Besides, T cells also carry receptor (TCR) for recognition of MHC molecules. Depending upon functional activity, T cells have two major subtypes: *T helper(or CD4+) cells* and *T suppressor(or CD8+) cells*.

T helper cells Abbreviated as T_H cells, these cells promote and enhance the immune reaction and are also termed as

Table 3.1 Cells of the immune system and their functions.

| CELLS | FUNCTIONS |
|--|---|
| 1. Lymphocytes (20-50%) i) B-cells (10-15%) Plasma cells ii) T-cells (75-80%) a) T-helper cells (CD4+) (60%) b) T-suppressor cells (CD8+) (30%) c) NK-cells (10-15%) | Master of immune system Antibody-based humoral reactions, transform to plasma cells Secrete immunoglobulins Cell-mediated immune reactions Promote and enhance immune reaction by elaboration of cytokines Suppress immune reactions but are directly cytotoxic to antigen Part of natural or innate immunity; cause antibody-dependent cell-mediated cytotoxicity (ADCC) |
| 2. Monocytes-macrophages (~5%) | Antigen recognition Phagocytosis Secretory function Antigen presentation |
| 3. Mast cells and basophils (0-1%) | Allergic reactions Wound healing |
| 4. Neutrophils (40-75%) | First line of defense against microorganisms and other small antigens |
| 5. Eosinophils (1-6%) | Allergic reactions Helminthiasis |

The figures in brackets denote percentage of cells in circulation.

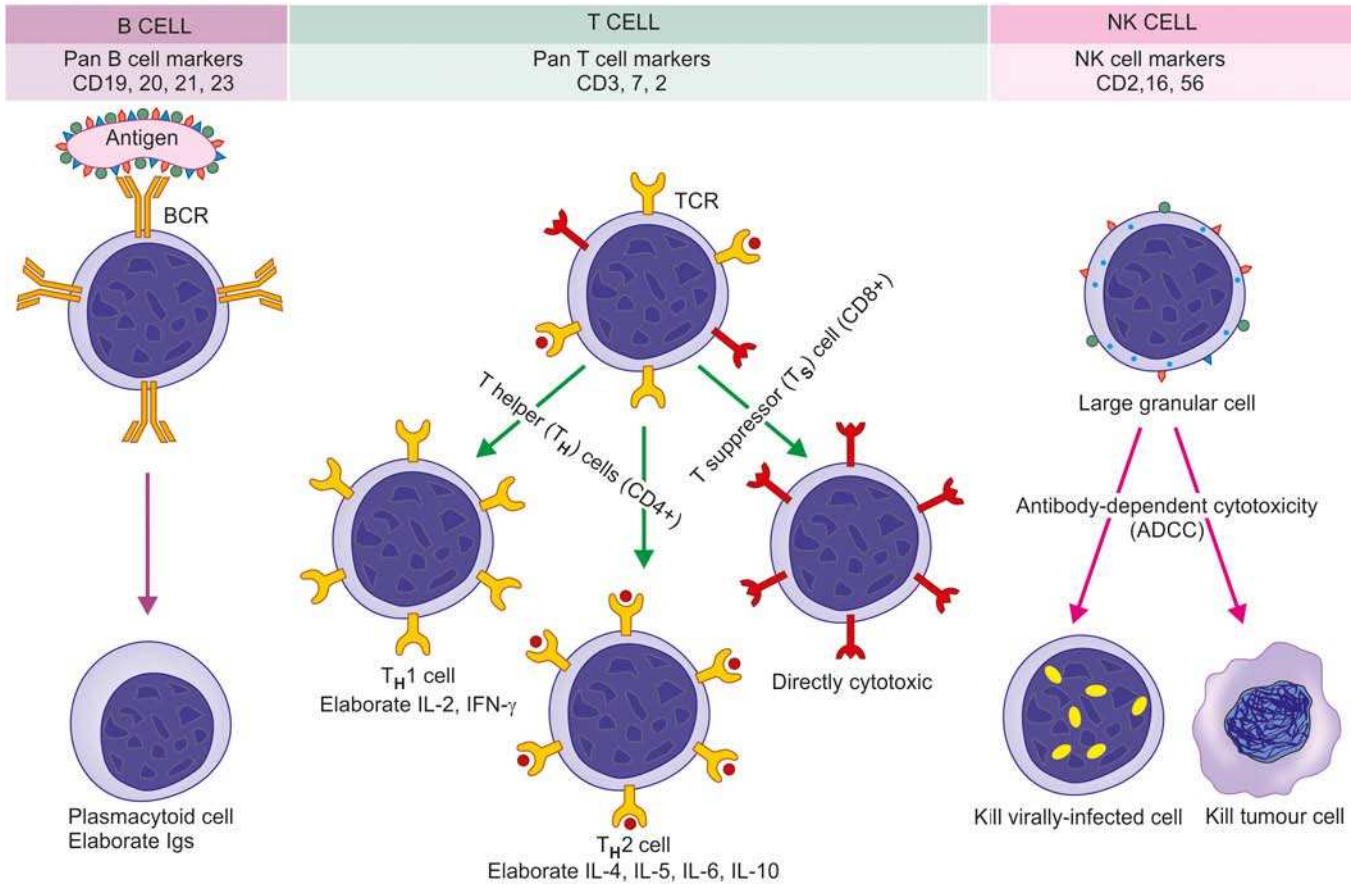

Figure 3.2 Schematic representation of functions of B and T lymphocytes and NK cells. (BCR = B cell receptor, TCR = T cell receptor).

T-regulatory cells. They carry CD4 molecule on their surface and hence are also called *CD4+ cells*. CD4+ cells in circulation are about twice the number of CD8+ cells (CD4+/CD8 ratio 2:1). These cells act by elaboration of variety of cytokines. Depending upon the type of cytokines elaborated, these T_H cells are further of two subclasses: T_H 1 and T_H 2.

- ◆ T_H 1 cells elaborate IL-2 and interferon (IFN)-γ.
- ◆ T_H 2 cells elaborate IL-4, IL-5, IL-6, and IL-10.

CD4+ cells are predominantly involved in cell-mediated reactions to viral infections (e.g. in HIV), tissue transplant reactions and tumour lysis.

T suppressor cells Abbreviated as T_S cells, they suppress immune reactions but are cytotoxic and actually destroy the invading antigen; hence are also termed as *cytotoxic T lymphocytes (CTL)*. These cells carry CD8 molecule on their surface and hence are also called *CD8+ cells*. CD8+ cells in circulation are about half the number of CD4+ cells. Compared to CD4+ cells which act by elaboration of cytokines, CD8+ cells are directly cytotoxic to the antigen.

CD8+ cells are particularly involved in destroying cells infected with viruses, foreign cells and tumour cells.

Contrasting features of B and T cells are given in **Table 3.2**.

NATURAL KILLER (NK) CELLS NK cells comprise about 10-15% of circulating lymphocytes. These lymphocytes do not have B or T cell markers, nor are these cells dependent upon thymus for development unlike CD4+ and CD8+ T cells. NK cells carry surface molecules of CD2, CD16 and CD56, but

negative for T cell marker CD3. NK cells are morphologically distinct from B and T cells in being *large granular lymphocytes*.

NK cells are part of the natural or innate immunity. These cells recognise antibody-coated target cells and bring about killing of the target directly; this process is termed as *antibody-dependent cell-mediated cytotoxicity (ADCC)*. This mechanism is particularly operative against viruses and tumour cells.

Monocytes and Macrophages

The role of macrophages in inflammation consisting of circulating monocytes, organ-specific macrophages and histiocytes has been described in Chapter 5. Circulating monocytes are immature macrophages and constitute about 5% of peripheral leucocytes. They remain in circulation for about 3 days before they enter tissues to become macrophages. The macrophage subpopulations such as the dendritic cells (in the lymphoid tissue) and Langerhans' cells (in the epidermis) are characterised by the presence of dendritic cytoplasmic processes and are active in the immune system.

Salient features and important immune functions of macrophages are as follows:

1. Antigen recognition They possess cell surface receptors to several extracellular molecules—receptor for cytokines, component of complement (C3b), selectins, integrins and Fc (constant fragment) of antibody. These receptors recognise the organisms and initiate intracellular mechanism in macrophages. Antigen to become recognisable can also get coated by antibodies or complement, the process being termed

Table 3.2 Differences between T and B lymphocytes.

| FEATURE | T CELLS | B CELLS |
|-----------------------------------|--|---|
| 1. <i>Origin</i> | Bone marrow → Thymus | Bone marrow → Bursa (in fowl); mucosa-associated lymphoid tissue (MALT) |
| 2. <i>Lifespan</i> | Small T cells: months to years T cell blasts: several days | Small B cells: less than 1 month B cell blasts : several days |
| 3. <i>Location</i> | | |
| (i) Lymph nodes | Perifollicular (paracortical) | Germinal centres, medullary cords |
| (ii) Spleen | Periarteriolar | Germinal centres, red pulp |
| (iii) Peyer's patches | Perifollicular | Central follicles |
| 4. <i>Presence in circulation</i> | 75-80% | 10-15% |
| 5. <i>Surface markers</i> | | |
| (i) Ag receptors | Present | Absent |
| (ii) Surface Ig | Absent | Present |
| (iii) Fc receptor | Absent | Present |
| (iv) Complement receptor | Absent | Present |
| (v) CD markers | T _H cells CD4, 3, 7, 2 T _S cells CD8, 3, 7, 2 | CD19, 20, 21, 23 |
| 6. <i>Functions</i> | (i) CMI via cytotoxic T cells positive for CD3 and CD4 (ii) Delayed hypersensitivity via CD4+ T cells (iii) Immunoregulation of other T cells, B cells and stem cells via T helper (CD4+) or T suppressor (CD8+) cells | (i) Role in humoral immunity by synthesis of specific antibodies (Igs) (ii) Precursors of plasma cells |

as *opsonisation*. Macrophages have capacity to distinguish self from non-self by presence of human leucocyte antigens (HLA) or major histocompatibility complex (MHC) discussed below.

2. Phagocytosis Antigen that has been recognised by the macrophages due to availability of above-mentioned surface receptors, or the opsonised antigen, is ready to be engulfed by the process of cell-eating by macrophages explained on page 120.

3. Secretory function Macrophages secrete important substances as follows:

i) *Cytokines* (IL-1, IL-2, IL-6, IL-8, IL-10, IL-12, tumour necrosis factor- α) and *prostaglandins* (PGE, thromboxane-A, leukotrienes) which are chemical mediators of inflammation and activate other leucocytes.

ii) *Secretion of proteins involved in wound healing* e.g. collagenase, elastase, fibroblast growth factor, angiogenesis factor.

iii) *Acute phase reactants* e.g. fibronectin, microglobulin, complement components.

4. Antigen presentation When macrophages are unable to lyse an antigen or an organism, the next best course adopted by them is to act as antigen-presenting cells for presenting to immunocompetent T cells (subtype CD4+ or CD8+ cells), or to B cells. Accordingly, the lymphoid cell would then deal with such antigen.

Basophils and Mast Cells

Basophils are a type of circulating granulocytes (0-1%) while mast cells are their counterparts seen in tissues, especially in connective tissue around blood vessels and in submucosal location. Basophils and mast cells have IgE surface receptor;

thus on coming in contact with antigen binding to IgE (e.g. allergic reaction to parasites), these cells get activated and release granules i.e. they degranulate. These granules contain active substances such as histamine, platelet activating factor, heparin and certain chemical mediators (e.g. prostaglandins, leukotrienes).

Mast cells and basophils are thus involved in mediating inflammation in allergic reactions and have a role in wound healing.

Neutrophils

Polymorphonuclear neutrophils (PMNs) are normally the most numerous of the circulating leucocytes (40-75%). The cytoplasm of PMNs contains lysosomal granules of three types: primary (azurophilic), secondary, and tertiary.

PMNs have similar function to those of macrophages and are therefore appropriately referred to as '*microphages*' owing to their role as first line of defense against an invading foreign organism in the body. However, these cells have limitation of size and type of organisms to be engulfed e.g. while they are capable of acting against bacteria and small foreign particulate material but not against viruses and large particles.

Eosinophils

Eosinophils are also circulating granulocytes (1-6%). These cells play a role in allergic reactions and in intestinal helminthiasis. The granules of eosinophils contain lysosomal enzymes, peroxidases, and chemical mediators of inflammation (e.g. prostaglandins, leukotrienes). On coming in contact with IgE opsonised antigen (e.g. helminths), eosinophils degranulate and release the chemicals stored in granules and incite inflammation.

CYTOKINES

Cytokines are immunomodulating agents composed of soluble proteins, peptides and glycoproteins secreted by haematopoietic and non-haematopoietic cells in response to various stimuli. Their main role is in molecular interaction between various cells of the immune system described above and are critical in innate as well as in adaptive immune responses.

Cytokines are named according to their presumed targets or possible functions e.g. monokines, colony stimulating factor etc. Presently, about 200 cytokines have been identified. Many of these cytokines have further subtypes as alpha, beta, or are identified by numbers.

CLASSIFICATION Based on structural similarity, cytokines are grouped in following 3 main categories:

- i) *Haematopoietin family*: G-CSF, GM-CSF, erythropoietin, thrombopoietin, Various interleukins (IL) such as IL-2, IL-3, IL-4, IL-5, IL-6, IL-6, IL-7, IL-9.
- ii) *IL-1 α and IL-1 β , tumour necrosis factor (TNF, cachectin), platelet-derived growth factor (PDGF), transforming growth factor (TGF)- β family.*
- iii) *Chemokine family*: These regulate movement of cells and act through G-protein-derived receptors e.g. IL-8, monocyte chemokine protein (MCP), eotaxin, platelet factor (PF) 4.

CYTOKINE RECEPTORS There are 5 members of family of cytokine receptors:

- i) *Immunoglobulin (Ig) superfamily* is the largest group composed of cell surface receptors and extracellular secreted proteins e.g. IL-1 receptors type 1, type 2 etc.
- ii) *Haematopoietic growth factor type 1 receptor family* includes receptors or their subunits shared with several interleukins (IL-3, IL-5, IL-11, IL-12, leukaemia inhibitory factor, granulocyte-monocyte colony stimulating factor receptor).
- iii) *IFN type II receptor family* includes receptors for IFN- γ , IFN- β .
- iv) *TNF receptor family* members are TNF-R1 and TNF-R2, CD40 (B cell marker), CD27 and CD30 (found on activated T and B cells).
- v) *Trans-membrane helix receptor family* is linked to GTP-binding proteins and includes two important chemokines, chemokine receptor type 4 (CXCR4) and β -chemokine receptor type 5 (CCR5), implicated in binding and entry of HIV into CD4+ host cells.

MODE OF ACTION OF CYTOKINES Cytokines may act in one of the following 3 ways:

- 1) *Autocrine* when a cytokine acts on the cell which produced it.
- 2) *Paracrine* when it acts on another target cell in the vicinity.
- 3) *Endocrine* when the cytokine secreted in circulation acts on a distant target.

Cytokines are involved in following actions:

1. Regulation of growth The actions of cytokines in signaling pathways have been studied in detail. They act via haematopoietins and their receptors, which activate Janus family of protein tyrosine kinases (JAK). There is binding of 4 JAK kinases: JAK1, JAK2, JAK3, and tyk2, to receptors causing phosphorylation of target molecules. This promotes mitogen-

activated protein kinase pathway. Besides, a substrate of JAKs, signal transducer and activator of transcription (abbreviated as STAT) family of transcription factors, act on the DNA of the nucleus and thus regulate gene expression.

2. Inflammatory mediators Some cytokines are potent mediators of inflammation e.g. lymphokines, monokines, IL-1, IL-8, TNF- α and β , IFN- γ . This aspect is discussed on page 125.

3. Activation of immune system The immune system is activated by binding of cytokine to specific cell-surface receptors after the cell has interacted with the antigen.

4. Cytokine storm Overstimulation of cytokines can trigger cytokine storm which is a potentially fatal condition.

GIST BOX 3.1

The Immune System

- Body immunity is divided into 2 types, natural (innate) and specific (adaptive), both of which are interlinked and inter-dependent. Each of these has humoral and cellular components.
- The organs of immune system are the thymus, bone marrow, lymph nodes, spleen, and MALT.
- The cells of immune system include lymphocytes, monocytes and macrophages, basophils and mast cells, neutrophils and eosinophils.
- Lymphocytes are the master of immune system. Their functional types are B (10-15%), T (75-80%) and NK (10-15%) cells. T cells have further subpopulations: T helper (type 1 and 2) (CD4+) and T suppressor (CD8+) cells.
- B cells incite antibody response, T cells mediate cellular immunity (CD8+ in cytotoxicity, CD4+ by elaboration of various cytokines) and NK cells are part of innate immunity.
- Monocytes-macrophages are involved in antigen recognition, presentation, phagocytosis and elaboration of certain cytokines.
- Cytokines are immunomodulating proteins or peptides secreted by various cells of the body in response to stimuli. These include haematopoietins, interleukins, interferon, colony stimulating factor, tumour necrosis factor, growth factors, chemokines, and their receptors.
- Cytokines are involved in growth regulation by cell signaling pathways, inflammation and in activation of immune system.

HLA SYSTEM AND MAJOR HISTOCOMPATIBILITY COMPLEX

Though not a component of immune system, HLA system is described here as it is considered important in the regulation of the immune system and is part of immunoglobulin superfamily of cell adhesion molecules (CAMs). HLA stands for *Human Leucocyte Antigens* because these are antigens or genetic proteins in the body that determine one's own tissue from non-self (histocompatibility) and were first discovered on the surface of leucocytes. Subsequently, it was found that HLA are actually gene complexes of proteins on the surface of all nucleated cells of the body and platelets. Since these complexes are of immense importance in matching donor and recipient for organ transplant, they are called *major histocompatibility complex (MHC) or HLA complex*.

Out of various genes for histocompatibility, most of the transplantation antigens or MHC are located on short arm (p) of *chromosome 6*; these genes occupy four regions or loci—A, B, C and D, and exhibit marked variation in allelic genes at each locus. Therefore, the product of HLA antigens is highly polymorphic. The letter w in some of the genes (e.g. Dw3, Cw4, Bw15 etc) refers to the numbers allocated to them at international workshops.

Depending upon the characteristics of MHC, they have been divided into 3 classes (**Fig. 3.3**):

◆ **Class I MHC antigens** have loci as HLA-A, HLA-B and HLA-C. CD8+ (i.e. T suppressor) lymphocytes carry receptors for class I MHC; these cells are used to identify class I antigen on them.

◆ **Class II MHC antigens** have single locus as HLA-D. These antigens have further 3 loci: DR, DQ and DP. Class II MHC is identified by B cells and CD4+ (i.e. T helper) cells.

◆ **Class III MHC antigens** are some components of the complement system (C2 and C4) coded on HLA complex but are not associated with HLA expression and are not used in antigen identification.

In view of high polymorphism of class I and class II genes, they have a number of alleles on loci numbered serially like HLA-A 1, HLA-A 2, HLA-A 3 etc.

MHC antigens present on the cell surface help the macrophage in its function of recognition of bacterial antigen i.e. they help to identify self from foreign, and accordingly present the foreign antigen to T cells (CD4+ or CD8+) or to B cells.

ROLE OF HLA COMPLEX The HLA complex is significant in a number of ways:

1. Organ transplantation Historically, the major importance of HLA system is in matching donor and recipient for tissue transplantation. The recipient's immune system can recognise the histocompatibility antigens on the donor organ and accordingly accept it or reject it. Both humoral as well

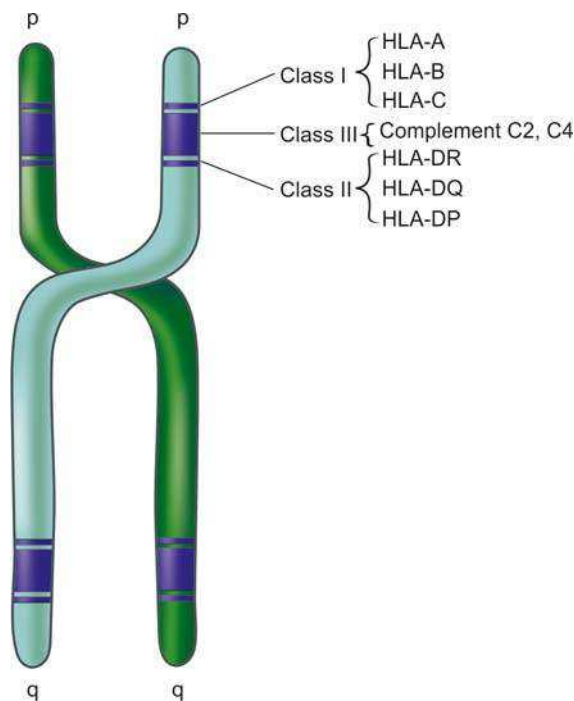

Figure 3.3 HLA system and loci on short arm of chromosome 6.

as cell-mediated immune responses are involved in case of genetically non-identical transplants.

2. Regulation of the immune system Class I and II histocompatibility antigens play a role in regulating both cellular and humoral immunity:

- ◆ **Class I MHC antigens** regulate the function of cytotoxic T cells (CD8+ subpopulation) e.g. in virus infections.
- ◆ **Class II MHC antigens** regulate the function of helper T cells (CD4+ subpopulation).

3. Association of diseases with HLA An increasing number of diseases have been found to have association with some specific histocompatibility antigens. These disorders include the following:

- ◆ **Autoimmune disorders** e.g. rheumatoid arthritis, coeliac disease, Sjogren's syndrome, SLE, chronic active hepatitis.
- ◆ **Spondyloarthropathies** e.g. ankylosing spondylitis, Reiter's syndrome.
- ◆ **Endocrinopathies** e.g. type 1 diabetes mellitus.
- ◆ **Neurologic** e.g. myasthenia gravis

The mechanism of HLA association with diseases is complex and heterogeneous involving multiple steps causing activation of T cells.

GIST BOX 3.2

HLA System and Major Histocompatibility Complex

- ▣ HLA system or MHC is composed of antigenic proteins present on all nucleate cells of the body and platelets.
- ▣ MHC or transplantation antigens are located on short arm of chromosome 6, and has 4 regions or loci: A, B, C and D.
- ▣ There are 3 classes of antigens. Class I antigens are located on CD8+ cells and have loci as HLA-A, HLA-B and HLA-C. Class II antigens have a single locus, HLA-D and is identified on B cells and CD4+ cells. Class III MHC antigens are components of complement, C 2 and C4, but are not used for antigen identification.
- ▣ Main roles of HLA complex are in organ transplantation, regulation of immune system and its association with certain diseases.

TRANSPLANT REJECTION

According to the genetic relationship between donor and recipient, transplantation of tissues is classified into 4 groups:

1. **Autografts** are grafts in which the donor and recipient is the same individual.
2. **Isografts** are grafts between the donor and recipient of the same genotype.
3. **Allografts** are those in which the donor is of the same species but of a different genotype.
4. **Xenografts** are those in which the donor is of a different species from that of the recipient.

All types of grafts have been performed in human beings but xenografts have been found to be rejected invariably due to genetic disparity. Presently, surgical skills exist for skin grafts and for organ transplants such as kidney, heart, lungs, liver, pancreas, cornea and bone marrow. But most commonly practised are skin grafting, and kidney and bone marrow transplantation. For any successful tissue transplant without immunological rejection, matched major histocompatibility

locus antigens (HLA) between the donor and recipient are of paramount importance as discussed already. The greater the genetic disparity between donor and recipient in HLA system, the stronger and more rapid will be the rejection reaction.

Besides the rejection reaction, a peculiar problem occurring especially in bone marrow transplantation is *graft-versus-host (GVH) reaction*. In humans, GVH reaction results when immunocompetent cells are transplanted to an immunodeficient recipient e.g. treating severe combined immunodeficiency by bone marrow transplantation. The clinical features of GVH reaction include: fever, weight loss, anaemia, dermatitis, diarrhoea, intestinal malabsorption, pneumonia and hepatosplenomegaly. The intensity of GVH reaction depends upon the extent of genetic disparity between the donor and recipient.

MECHANISMS OF GRAFT REJECTION

Except for autografts and isografts, an immune response against allografts is inevitable. The development of immunosuppressive drugs has made the survival of allografts in recipients possible. Rejection of allografts involves both cell-mediated and humoral immunity.

1. CELL-MEDIATED IMMUNE REACTIONS These are mainly responsible for graft rejection and are mediated by T cells. The lymphocytes of the recipient on coming in contact with HLA antigens of the donor are sensitised in case of incompatibility. Sensitised T cells in the form of cytotoxic T cells (CD8+) as well as by hypersensitivity reactions initiated by T helper cells (CD4+) attack the graft and destroy it.

2. HUMORAL IMMUNE REACTIONS In addition to the cell-mediated immune reactions, a role for humoral antibodies in certain rejection reactions has been suggested. These include: *preformed circulating antibodies* due to *pre-sensitisation* of the recipient before transplantation e.g. by blood transfusions and previous pregnancies, or in *non-sensitised individuals* by complement dependent cytotoxicity, antibody-dependent cell-mediated cytotoxicity (ADCC) and antigen-antibody complexes.

TYPES OF REJECTION REACTIONS

Based on the underlying mechanism and time period, rejection reactions are classified into 3 types: hyperacute, acute and chronic.

1. HYPERACUTE REJECTION Hyperacute rejection appears within minutes to hours of placing the transplant and destroys it. It is mediated by preformed humoral antibody against donor-antigen. Cross-matching of the donor's lymphocytes with those of the recipient before transplantation has diminished the frequency of hyperacute rejection.

Grossly, hyperacute rejection is recognised by the surgeon soon after the vascular anastomosis of the graft is performed to the recipient's vessels. The organ becomes swollen, oedematous, haemorrhagic, purple and cyanotic rather than gaining pink colour.

Histologically, the characteristics of Arthus reaction are present. There are numerous neutrophils around dilated and obstructed capillaries which are blocked by fibrin and platelet thrombi. Small segments of blood vessel wall may become necrotic and there is necrosis of much of the transplanted organ. Small haemorrhages are common.

2. ACUTE REJECTION This usually becomes evident within a few days to a few months of transplantation. Acute graft rejection may be mediated by cellular or humoral mechanisms. Acute cellular rejection is more common than acute humoral rejection.

Microscopically, the features of the two forms are as under:

i) *Acute cellular rejection* is characterised by extensive infiltration in the interstitium of the transplant by lymphocytes (mainly T cells), a few plasma cells, monocytes and a few polymorphs. There is damage to the blood vessels and there are foci of necrosis in the transplanted tissue.

ii) *Acute humoral rejection* appears due to poor response to immunosuppressive therapy. It is characterised by acute rejection vasculitis and foci of necrosis in small vessels. The mononuclear cell infiltrate is less marked as compared to acute cellular rejection and consists mostly of B lymphocytes.

3. CHRONIC REJECTION Chronic rejection may follow repeated attacks of acute rejection or may develop slowly over a period of months to a year or so. The underlying mechanisms of chronic rejection may be immunologic or ischaemic. Patients with chronic rejection of renal transplant show progressive deterioration in renal function as seen by rising serum creatinine levels.

Microscopically, in chronic rejection of transplanted kidney, the changes are intimal fibrosis, interstitial fibrosis and tubular atrophy. Renal allografts may develop glomerulonephritis by transmission from the host, or rarely may develop *de novo* glomerulonephritis.

GIST BOX 3.3

Transplant Rejection

- ☐ Tissue transplants are most often allografts and are done for skin, bone marrow and various solid organs. HLA matching between donor and recipient is always done before tissue transplantation.
- ☐ Graft versus host (GVH) reaction occurs when bone marrow cells are transplanted from an immunocompetent donor to an immunodeficient host.
- ☐ Graft rejection of other solid organs is mediated mainly by cell-mediated immune reactions via T cells (cytotoxic CD8+ cells and by hypersensitivity reaction initiated by CD4+ cells) and to some extent via humoral immune responses.
- ☐ Rejection reactions may be *hyperacute* appearing within minutes to hours, *acute* becoming evident within a few days to a few months, and *chronic rejection* occurring after repeated attacks of acute rejection or developing slowly.

DISEASES OF IMMUNITY

Failure or deficiency of immune system, which normally plays a protective role against infections, manifests by occurrence of repeated infections in an individual having immunodeficiency diseases.

Traditionally, immunodeficiency diseases are classified into 2 types:

Table 3.3 Immunodeficiency diseases.

| DISEASE | DEFECT |
|---|--|
| A. PRIMARY IMMUNODEFICIENCY DISEASES | |
| 1. Severe combined immunodeficiency diseases (Combined deficiency of T cells, B cells and Igs): | |
| (i) Reticular dysgenesis | Failure to develop primitive marrow reticular cells |
| (ii) Thymic aplasia | No lymphoid stem cells |
| (iii) Agammaglobulinaemia (Swiss type) | No lymphoid stem cells |
| (iv) Wiscott-Aldrich syndrome | Cell membrane defect of haematopoietic stem cells; associated features are thrombocytopenia and eczema |
| (v) Ataxia telangiectasia | Defective T cell maturation |
| 2. T cell defect: DiGeorge's syndrome (thymic hypoplasia) | Epithelial component of thymus fails to develop |
| 3. B cell defects (antibody deficiency diseases): | |
| (i) Bruton's X-linked agammaglobulinaemia | Defective differentiation from pre-B to B cells |
| (ii) Autosomal recessive agammaglobulinaemia | Defective differentiation from pre-B to B cells |
| (iii) IgA deficiency | Defective maturation of IgA synthesising B cells |
| (iv) Selective deficiency of other Ig types | Defective differentiation from B cells to specific Ig-synthesising plasma cells |
| (v) Immune deficiency with thymoma | Defective pre-B cell maturation |
| 4. Common variable immunodeficiencies (characterised by decreased Igs and serum antibodies and variable CMI): | |
| (i) With predominant B cell defect | Defective differentiation of pre-B to mature B cells |
| (ii) With predominant T cell defect | |
| (a) Deficient T helper cells | Defective differentiation of thymocytes to T helper cells |
| (b) Presence of activated T suppressor cells | T cell disorder of unknown origin |
| (iii) With autoantibodies to B and T cells | Unknown differentiation defect |
| B. SECONDARY IMMUNODEFICIENCY DISEASES | |
| 1. Infections | AIDS (HIV virus); other viral, bacterial and protozoal infections |
| 2. Cancer | Chemotherapy by antimetabolites; irradiation |
| 3. Lymphoid neoplasms (lymphomas, lymphoid leukaemias) | Deficient T and B cell functions |
| 4. Malnutrition | Protein deficiency |
| 5. Sarcoidosis | Impaired T cell function |
| 6. Autoimmune diseases | Administration of high dose of steroids toxic to lymphocytes |
| 7. Transplant cases | Immunosuppressive therapy |

A. *Primary immunodeficiencies* are usually the result of genetic or developmental abnormality of the immune system.

B. *Secondary immunodeficiencies* arise from acquired suppression of the immune system, the most important example being acquired immunodeficiency syndrome (AIDS).

Since the first description of a primary immunodeficiency disease was made by Bruton in 1952, more and more primary and secondary immunodeficiency syndromes have been added over the years.

A list of most immunodeficiency diseases with the possible defect in the immune system is given in [Table 3.3](#), while an account of AIDS is given here.

ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS)

Since the initial recognition of AIDS in the United States in 1981, tremendous advances have taken place in the understanding of this dreaded disease as regards its epidemiology, etiology, immunology, pathogenesis, clinical features and morphologic changes in various tissues and organs of the body. Although antiretroviral therapy is being widely used all over the world for such patients, efforts at finding a HIV vaccine have not succeeded so far.

EPIDEMIOLOGY AIDS is pandemic in distribution and is seen in all continents. As per UNAIDS Global Report 2013, an estimated 35 million people are living with AIDS globally (70% in Sub-Saharan Africa), out of which 50% are women and 3.3 million children under 15 years of age. About 1.5 million people are dying from AIDS every year and 2 million cases are being added ever year (about 6000 new cases added per day). Regionwise, besides Sub-Saharan Africa, other countries in order of decreasing incidence of AIDS are South and South-East Asia, Latin America, Eastern Europe, Central Asia, North America, while Oceania region has the lowest incidence. It has been seen there is about 33% decline in the number of new cases in 2012 compared to 2001 and also marginal fall in the number of deaths from HIV. The burden of AIDS in India is estimated at 2.4 million cases; epicentre of the epidemic lies in the states of Maharashtra, Tamil Nadu and Andhra Pradesh which together comprise about 50% of all HIV positive cases (mostly contracted heterosexually), while North-East state of Manipur accounts for 8% of all cases (more often among intravenous drug abusers).

ETIOLOGIC AGENT AIDS is caused by an RNA (retrovirus) virus called human immunodeficiency virus (HIV). There are 4 members of human retroviruses in 2 groups:

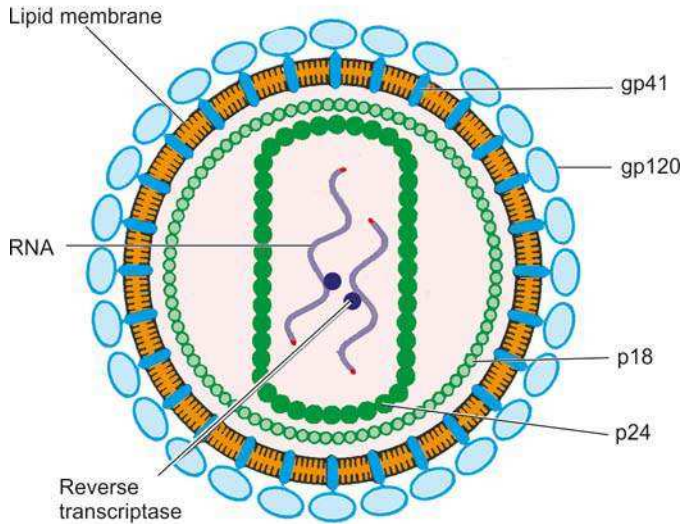

Figure 3.4 Schematic representation of HIV virion or virus particle. The particle has core containing proteins, p24 and p18, two strands of viral RNA, and enzyme reverse transcriptase. Bilayer lipid membrane is studded with 2 viral glycoproteins, gp120 and gp 41, in the positions shown.

◆ **Transforming viruses:** These are human T cell leukaemia-lymphoma virus (HTLV) I and II and are implicated in leukaemia and lymphoma (page 221).

◆ **Cytopathic viruses:** This group includes HIV-1 and HIV-2, causing two forms of AIDS. Most common case of AIDS in the world including US is HIV-1, while HIV-2 is etiologic agent for AIDS in cases from West Africa and parts of India. Both HIV1 and HIV2 are zoonotic infections and their origin can be traced to a species of chimpanzees who are natural reservoir of HIV and most likely source of original infection.

HIV-I virion or virus particle is spherical in shape and 100-140 nm in size (**Fig. 3.4**):

◆ It contains a *core* having *core proteins*, chiefly p24 and p18, two strands of genomic RNA and the enzyme, reverse transcriptase.

◆ The core is covered by a *double layer of lipid membrane* derived from the outer membrane of the infected host cell during budding process of virus. The membrane is studded with 2 *envelope glycoproteins*, gp120 and gp41, in the positions shown.

Besides other genes, **three important genes** code for the respective components of virion:

- i) *gag* (*group antigen*) for core proteins,
- ii) *pol* (*polymerase*) for reverse transcriptase, and
- iii) *env* (*envelope*) for the envelope proteins.

These genes and viral components act as markers for the laboratory diagnosis of HIV infection. Besides, there is *tat* (*transcription activator*) gene for viral functions such as amplification of viral genes, viral budding and replication.

ROUTES OF TRANSMISSION Transmission of HIV infection occurs by one of following three routes and it varies in different populations:

1. Sexual transmission Sexual contact in the main mode of spread and constitutes 75% of all cases of HIV transmission.

Most cases of AIDS in the industrialised world such as in the US occur in *homosexual* or *bisexual males* while *heterosexual promiscuity* seems to be the dominant mode of HIV infection in Africa and Asia. Other sexually transmitted diseases (STDs) may act as cofactors for spread of HIV, in particular gonorrhoeal and chlamydial infection. Transmission from male-to-male and male-to-female is more potent route than that from female-to-male.

2. Transmission via blood and blood products This mode of transmission is the next largest group (25%) and occurs in 3 types of high-risk populations:

i) *Intravenous drug abusers* by sharing needles, syringes etc comprise a large group in the US.

ii) *Haemophiliacs* who have received large amounts of clotting factor concentrates from pooled blood components from multiple donors.

iii) *Recipients of HIV-infected blood and blood products* who have received multiple transfusions of whole blood or components like platelets and plasma.

3. Perinatal transmission HIV infection occurs from infected mother to the newborn during pregnancy *transplacentally*, or in immediate post-partum period *through contamination* with maternal blood, infected amniotic fluid or breast milk.

4. Occupational transmission There have been a small number of health care workers (HCW), laboratory workers and those engaged in disposal of waste of sharps who have developed HIV infection by occupational exposure to HIV-infected material, most often by needle-stick injury. It is imperative that these workers follow the CDC guidelines for *universal precautions* which include disinfecting and sterilising all reusable devices and use of bleaching solution for disinfecting all blood spillage.

5. Transmission by other body fluids Although besides blood, HIV has been isolated and identified from a number of body fluids such as saliva, tears, sweat, urine, semen, vaginal secretions, cervical secretions, breast milk, CSF, synovial, pleural, peritoneal and pericardial fluid, there is no definite evidence that HIV transmission can occur by any of these fluids; isolated cases of such infection reported are in likelihood due to concomitant contamination with HIV-infected blood.

It may, however, be understood regarding spread of HIV infection that *AIDS cannot be transmitted* by casual non-sexual contact like shaking hands, hugging, sharing household facilities like beds, toilets, utensils etc.

It should also be appreciated that HIV contaminated waste products can be *sterilised and disinfected* by most of the chemical germicides used in laboratories at a much lower concentration. These are: sodium hypochlorite (liquid chlorine bleach) (1-10% depending upon amount of contamination with organic material such as blood, mucus), formaldehyde (5%), ethanol (70%), glutaraldehyde (2%), β -propiolactone. HIV is also heat-sensitive and can be inactivated at 56°C for 30 min.

PATHOGENESIS The pathogenesis of HIV infection is largely related to the *depletion of CD4+ T cells (helper T cells) resulting in profound immunosuppression*.

Various aspects in the sequence of events is shown schematically in **Fig. 3.5** and is outlined below:

1. Selective tropism for CD4 molecule receptor gp120 envelope glycoprotein of HIV has selective tropism for cells

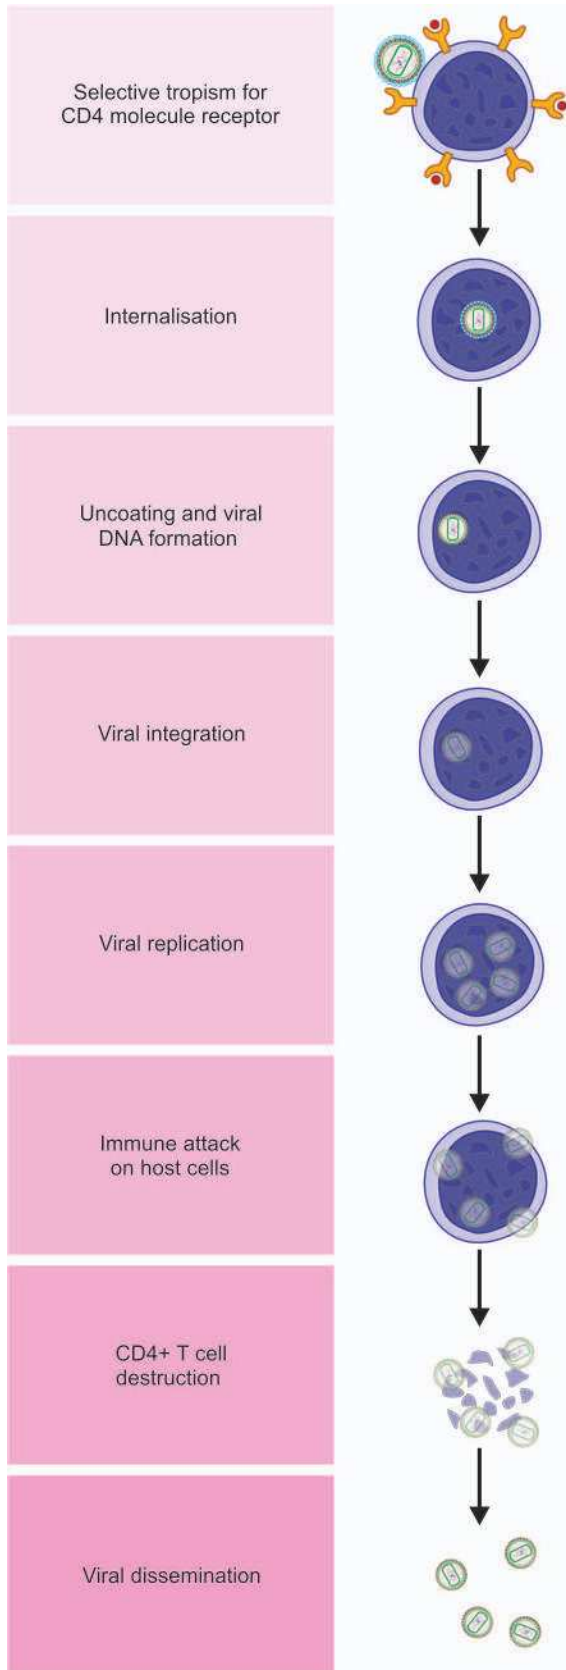

Figure 3.5 Sequence of events in the pathogenesis of HIV infection.

containing CD4 molecule receptor on their surface. These cells most importantly are CD4+ T cells (T helper cells); other such cells include monocyte-macrophages, microglial cells,

epithelial cells of the cervix, Langerhans cells of the skin and follicular dendritic cells. Initially, HIV on entering the body via any route described above has tropism for macrophages (M-tropic) while later it becomes either dual tropic or T-tropic only and thus affects mainly CD4+ T cells which are the main target of attack by HIV.

2. Internalisation gp120 of the virion combines with CD4 receptor, but for fusion of virion with the host cell membrane, a chemokine coreceptor (CCR) is necessary. Once HIV has combined with CD4 receptor and CCR, gp41 glycoprotein of envelope is internalised in the CD4+ T cell membrane.

3. Uncoating and viral DNA formation Once the virion has entered the T cell cytoplasm, reverse transcriptase of the viral RNA forms a single-stranded DNA. Using the single-stranded DNA as a template, DNA polymerase copies it to make it double-stranded DNA, while destroying the original RNA strands. Viral DNA so formed has frequent mutations making the HIV quite resistant to anti-retroviral therapy.

4. Viral integration The viral DNA so formed may initially remain *unintegrated* in the affected cell but later viral integrase protein inserts the viral DNA into nucleus of the host T cell and *integrates* in the host cell DNA. At this stage, viral particle is termed as *HIV provirus*.

5. Viral replication HIV provirus having become part of host cell DNA, host cell DNA transcripts for viral RNA with presence of *tat* gene. Multiplication of viral particles is further facilitated by release of cytokines from T helper cells (CD4+ T cells): $T_H 1$ cells elaborating IL-2 and IFN- γ , and $T_H 2$ cells elaborating IL-4, IL-5, IL6, IL-10. RNA viral particles thus fill the cytoplasm of host T cell where they acquire protein coating. Released cytokines are also responsible for spread of infection to other body sites, in particular to CNS by TNF- α .

6. Latent period and immune attack In an inactive infected T cell, the infection may remain in latent phase for a long time, accounting for the long incubation period. Immune system does act against the virus by participation of CD4+ and CD8+ T cells, macrophages and by formation of antibodies to mount attack against the virus. However, this period is short and the virus soon overpowers the host immune system.

7. CD4+ T cell destruction Viral particles replicated in the CD4+ T cells start forming *buds* from the cell wall of the host cell. As these particles detach from the infected host cell, they damage part of the cell membrane of the host cell and cause death of host CD4+ T cells by apoptosis. Other proposed mechanisms of CD4+ T cell destruction are necrosis of precursors of CD4+ cells by the virus and by formation of syncytial giant cells due to attachment of more and more of gp120 molecules to the surface of CD4+ T cells.

8. Viral dissemination Release of viral particles from infected host cell spreads the infection to more CD4+ host cells and produces viraemia. Through circulation, virus gains entry to the lymphoid tissues (lymph nodes, spleen) where it multiplies further; thus these tissues become the dominant site of virus reservoir rather than circulation.

9. Impact of HIV infection on other immune cells HIV infects other cells of the host immune system and also affects non-infected lymphoid cells.

i) *Other cells of the immune system:* These cells are circulating monocytes, macrophage in tissues and dendritic follicular cells of lymph nodes. HIV-infected monocytes-macrophages

do not get destroyed but instead become a reservoir of HIV infection. Infected dendritic follicular cells of the lymph nodes causes massive enlargement of follicle centres and account for persistent generalised lymphadenopathy in AIDS.

ii) *Non-infected lymphoid cells*: These cells include B cells, NK cells and CD8+ T cells. B cells do not have receptors for HIV but the number of B cells slowly declines, their function of immunoglobulin synthesis is impaired due to lack of their activation by depleting CD4+ T cells, and there may be non-specific hypergammaglobulinaemia. NK cells are also reduced due to lack of cytokines from depleted CD4+ T cells. CD8+ cells show lymphocytosis but the cells having intact function of ADCC are reduced, possibly due to quantitative loss of CD4+ T cell and their qualitative dysfunction (reversal of CD4+ T cells: CD8+ T cell ratio).

The net result of immunological changes in the host due to HIV infection lead to profound immunosuppression rendering the host susceptible to opportunistic infections and tumours, to which the patient ultimately succumbs.

10. HIV infection of nervous system Out of non-lymphoid organ involvement, HIV infection of nervous system is the most serious and 75-90% of AIDS patients may demonstrate some form of neurological involvement at autopsy. It infects microglial cells, astrocytes and oligodendrocytes as under:

i) Infection carried to the microglia of the nervous system by *HIV infected CD4+ monocyte-macrophage subpopulation or endothelial cells*.

ii) *Direct infection* of astrocytes and oligodendrocytes.

iii) Neurons are not invaded by HIV but are affected due to attachment of gp120 and by release of *cytokines* by HIV-infected macrophages.

A summary of major abnormalities in the immune system in AIDS is given in **Table 3.4**.

NATURAL HISTORY HIV infection progresses from an early acute syndrome to a prolonged asymptomatic state to advanced disease. Thus there are different clinical manifestations at different stages. Generally, in an immunocompetent host, the biologic course passes through following 3 phases (**Table 3.5**):

1. Acute HIV syndrome Entry of HIV into the body is heralded by the following sequence of events:

i) High levels of plasma *viraemia* due to replication of the virus.

ii) Virus-specific immune response by formation of anti-HIV antibodies (*seroconversion*) after 3-6 weeks of initial exposure to HIV.

iii) Initially, sudden marked reduction in *CD4+ T cells* (helper T cells) followed by return to normal levels.

iv) Rise in *CD8+ T cells* (cytotoxic T cells).

v) Appearance of self-limited non-specific *acute viral illness* (flu-like or infectious mononucleosis-like) in 50-70% of adults within 3-6 weeks of initial infection. Manifestations include: sore throat, fever, myalgia, skin rash, and sometimes, aseptic meningitis. These symptoms resolve spontaneously in 2-3 weeks.

2. Middle chronic phase The initial acute seroconversion illness is followed by a phase of competition between HIV and the host immune response as under:

i) *Viraemia* due to viral replication in the lymphoid tissue continues which is initially not as high but with passage of time viral load increases due to crumbling host defenses.

Table 3.4 Major abnormalities in immune system in AIDS.

| | |
|----|--|
| 1. | T CELL ABNORMALITIES |
| | (i) Lymphopenia |
| | (ii) CD4+ T cell depletion |
| | (iii) CD8+ T cell lymphocytosis |
| | (iv) Reversal of CD4: CD8 cell ratio |
| | (v) Decreased production of cytokines by CD4+ T cells |
| | (vi) Decreased antibody-dependent cellular cytotoxicity (ADCC) by CD8+ T cells |
| 2. | B CELL ABNORMALITIES |
| | (i) No direct viral damage |
| | (ii) Decreased Ig production |
| | (iii) Polyclonal activation |
| | (iv) Hypergammaglobulinaemia |
| | (v) Circulating immune complexes |
| 3. | NK CELL ABNORMALITIES |
| | (i) No direct viral damage |
| | (ii) Depressed number |
| | (iii) Decreased cytotoxicity |
| 4. | MONOCYTE-MACROPHAGE CELL ABNORMALITIES |
| | (i) No destruction |
| | (ii) Decreased chemotaxis |
| | (iii) Decreased cytotoxicity |

ii) Chronic stage, depending upon host immune system, may continue as long as *10 years*.

iii) Although *CD 4+ T cells* continue to proliferate but net result is moderate fall in CD4+ T cell counts.

iv) Cytotoxic CD8+ T cell count remains high.

v) Clinically, it may be a stage of *latency* and the patient may remain asymptomatic, or may develop mild constitutional symptoms and persistent generalised lymphadenopathy.

3. Final crisis phase This phase is characterised by profound immunosuppression and onset of full-blown AIDS and has the following features:

i) Marked increase in *viraemia*.

ii) The time period from HIV infection through chronic phase into full-blown AIDS may last *7-10 years and culminate in death*.

iii) *CD 4+ T cells* are markedly reduced (below 200 per μ l).

The average survival after the onset of full-blown AIDS is about 2 years.

Children often have a rapidly progressive disease and full-blown AIDS occurring at 4 to 8 years of age.

REVISED CDC HIV CLASSIFICATION SYSTEM The Centers for Disease Control and Prevention (CDC), US in 1993 revised the classification system for HIV infection in adults and children based on 2 parameters: clinical manifestations and CD4+ T cell counts.

According to this system, irrespective of presence of symptoms, any HIV-infected individual having CD4+ T cell count of $<200/\mu$ l is labelled as AIDS.

CDC defining criteria divide AIDS into 3 categories: A, B and C, each of which is further subdivided, based on CD4+ T cell count, into three subtypes: A1, B1, C1 (CD4+ T cell count $\geq 500/\mu$ l), A2, B2, C2 (CD4+ T cell count 200-499/ μ l), and A3, B3, C3 (CD4+ T cell count $<200/\mu$ l) (**Table 3.5**):

Table 3.5 Natural history and revised CDC HIV/AIDS classification.

| PHASE | EARLY, ACUTE | MIDDLE, CHRONIC | FINAL, CRISIS |
|--------------------------------|--|---|---|
| <i>Period after infection</i> | 3-6 weeks | 10 to 12 years | Any period up to death |
| <i>CDC clinical category</i> | Category A: Asymptomatic infection Acute HIV syndrome PGL | Category B: Symptomatic disease (neither A nor C) Condition secondary to impaired CMI | Category C: AIDS indicator defining conditions |
| <i>CD4 + T cell categories</i> | | | |
| ≥ 500/μl | A1 | B1 | C1 |
| 200-499/μl | A2 | B2 | C2 |
| < 200/μl | A3 | B3 | C3 |

(CDC = Centers for Disease Control, Atlanta, USA; PGL = Persistent generalised lymphadenopathy; CME= cell mediated immunity).

Clinical category A Includes a variety of conditions: asymptomatic case, persistent generalised lymphadenopathy (PGL), and acute HIV syndrome.

Clinical category B Includes symptomatic cases and includes conditions secondary to impaired cell-mediated immunity e.g. bacillary dysentery, mucosal candidiasis, fever, oral hairy leukoplakia, ITP, pelvic inflammatory disease, peripheral neuropathy, cervical dysplasia and carcinoma in situ cervix etc.

Clinical category C This category includes conditions listed for AIDS surveillance case definition. These are mucosal candidiasis, cancer uterine cervix, bacterial infections (e.g. tuberculosis), fungal infections (e.g. histoplasmosis), parasitic infections (e.g. *Pneumocystis carinii* pneumonia), malnutrition and wasting of muscles etc.

Similarly, there are revised parameters for *paediatric HIV classification* in which age-adjusted CD4+ T cell counts are given that are relatively higher in each corresponding category.

PATHOLOGICAL LESIONS AND CLINICAL MANIFESTATIONS OF HIV/AIDS HIV/AIDS affects all body organs and systems. In general, clinical manifestations and pathological lesions in different organs and systems are owing to progressive deterioration of body's immune system. Disease progression occurs in all untreated patients, even if the disease is apparently latent. Antiretroviral treatment blocks and slows the progression of the disease.

Pathological lesions and clinical manifestations in HIV disease can be explained by 4 mechanisms:

- i) *Due to viral infection directly*: The major targets are immune system, central nervous system and lymph nodes (persistent generalised lymphadenopathy).
- ii) *Due to opportunistic infections*: Deteriorating immune system provides the body an opportunity to harbour micro-organisms. A list of common opportunistic infectious agents affecting HIV/AIDS is given in **Fig. 3.6**.
- iii) *Due to secondary tumours*: End-stage of HIV/AIDS is characterised by development of certain secondary malignant tumours (**Fig. 3.6**).
- iv) *Due to drug treatment*: Drugs used in the treatment produce toxic effects. These include antiretroviral treatment, aggressive treatment of opportunistic infections and tumours.

Based on above mechanisms, salient clinical features and pathological lesions in different organs and systems are briefly outlined below and illustrated in **Fig. 3.6**. However, it may be

mentioned here that many of the pathological lesions given below may not become clinically apparent during life and may be noted at autopsy alone.

1. Wasting syndrome Most important systemic manifestation corresponding to body's declining immune function is wasting syndrome defined as 'involuntary loss of body weight by more than 10%'. It occurs due to multiple factors such as malnutrition, increased metabolic rate, malabsorption, anorexia, and ill-effects of multiple opportunistic infections.

2. Persistent generalised lymphadenopathy In early asymptomatic stage during the course of disease, some patients may develop persistent generalised lymphadenopathy (PGL). PGL is defined as presence of enlarged lymph nodes >1 cm at two or more extrainguinal sites for >3 months without an obvious cause. There is marked cortical follicular hyperplasia, due to proliferation of CD8+ T cells, B cells and dendritic follicular histiocytes. HIV infected CD4+ T cells are seen in the mantle zone. In advanced cases of AIDS, lymph nodes show progressive depletion of lymphoid cells, or there may be occurrence of opportunistic infection (e.g. *M. avium intracellulare*, *Histoplasma*, *Toxoplasma*) or appearance of secondary tumours in the lymphoid tissue (e.g. Kaposi's sarcoma, lymphoma).

3. GI lesions and manifestations Almost all patients with HIV infection develop gastrointestinal manifestations. These include: chronic watery or bloody diarrhoea, oral, oropharyngeal and oesophageal candidiasis, anorexia, nausea, vomiting, mucosal ulcers, abdominal pain. These features are due to opportunistic infections (e.g. *Candida*, *Clostridium*, *Shigella*, *Salmonella*, *Giardia*, *Entamoeba histolytica*, *Cryptosporium*, CMV). Advanced cases may develop secondary tumours in GIT (e.g. Kaposi's sarcoma, lymphoma).

4. Pulmonary lesions and manifestations Symptoms pertaining to lungs develop in about 50-75% of cases and are a major cause of death in HIV/AIDS. These features are largely due to opportunistic infections causing pneumonia e.g. with *Pneumocystis carinii*, *M. tuberculosis*, CMV, *Histoplasma*, and *Staphylococci*. Lung abscess too may develop. Other pulmonary manifestations include adult respiratory distress syndrome and secondary tumours (e.g. Kaposi's sarcoma, lymphoma).

5. Mucocutaneous lesions and manifestations Symptoms due to mucocutaneous involvement occur in about 50 to

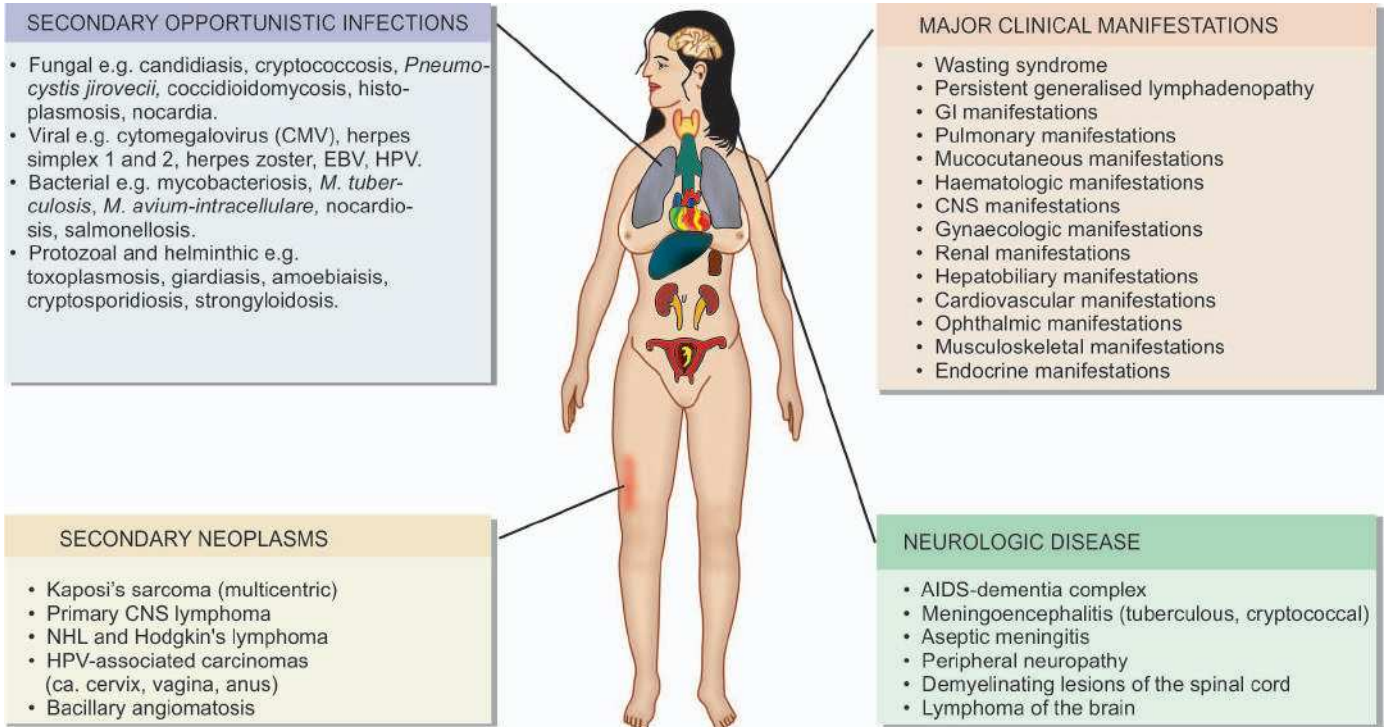

Figure 3.6 Major pathological lesions and clinical manifestations of HIV/AIDS.

75% cases. Mucocutaneous viral exanthem in the form of erythematous rash is seen at the onset of primary infection itself. Other mucocutaneous manifestations are allergic (e.g. drug reaction, seborrhoeic dermatitis), infectious (viral infections such as herpes, varicella zoster, EB virus, HPV; bacterial infections such as *M. avium*, *Staph. aureus*; fungal infections such as *Candida*, *Cryptococcus*, *Histoplasma*) and neoplastic (e.g. Kaposi's sarcoma, squamous cell carcinoma, basal cell carcinoma, cutaneous lymphoma).

6. Haematologic lesions and manifestations Involvement of haematopoietic system is common during the course of HIV/AIDS. These include: anaemia, leucopenia, and thrombocytopenia. These changes are due to bone marrow suppression from several mechanisms: infections such as by HIV, mycobacteria, fungi, and parvoviruses, or by lymphomatous involvement.

7. CNS lesions and manifestations Neurological manifestations occur in almost all cases during the course of disease and are an important cause of mortality and morbidity. These may be inflammatory, demyelinating and degenerative conditions. HIV encephalopathy or AIDS-associated dementia complex, is an AIDS defining condition and manifests clinically with deteriorating cognitive symptoms. Other pathological lesions in HIV/AIDS are meningitis (tuberculous, cryptococcal) demyelinating lesions of the spinal cord, and peripheral neuropathy and lymphoma of the brain.

8. Gynaecologic lesions and manifestations Gynaecologic symptoms are due to monilial (candidal) vaginitis, cervical dysplasia, carcinoma cervix, and pelvic inflammatory disease.

9. Renal lesions and manifestations Features of renal impairment may appear due to HIV-associated nephropathy and genitourinary tract infections including pyelonephritis.

10. Hepatobiliary lesions and manifestations Manifestations of hepatobiliary tract are due to development of coinfection with hepatitis B or C, due to occurrence of other infections and due to drug-induced hepatic injury. The lesions include steatosis, granulomatous hepatitis and opportunistic infections (*M. tuberculosis*, *Mycobacterium avium intracellulare*, *Histoplasma*).

11. Cardiovascular lesions and manifestations Diseases affecting the heart are common autopsy findings and include a form of dilated cardiomyopathy called HIV-associated cardiomyopathy, pericardial effusion in advanced disease as a reaction to opportunistic infection, lymphoma and Kaposi's sarcoma.

12. Ophthalmic lesions HIV associated ocular manifestations occur from opportunistic infections (e.g. CMV retinitis), HIV retinopathy, and secondary tumours.

13. Musculoskeletal lesions These include osteoporosis, osteopaenia, septic arthritis, osteomyelitis and polymyositis.

14. Endocrine lesions Several metabolic derangements may occur during the course of disease. Syndrome of lipodystrophy (buffalo hump) due to dyslipidaemia, hyperinsulinaemia and hyperglycaemia may occur. Besides, abnormality of thyroid function, hypogonadism and inappropriate release of ADH may be associated.

LESIONS AND MANIFESTATIONS IN PAEDIATRIC AIDS Children develop clinical manifestations of AIDS more rapidly than adults. Besides development of opportunistic infections and tumours, neurologic impairment in children cause slowing of development and growth.

DIAGNOSIS OF HIV/AIDS The investigations of a suspected case of HIV/AIDS are categorised into 3 groups: tests for

Table 3.6 Tests for diagnosis of HIV/AIDS.

establishing HIV infection, tests for defects in immunity, and tests for detection of opportunistic infections and secondary tumours. However, usually initial testing for antibodies is done against HIV by ELISA and confirmation by Western blot or immunofluorescence test. These tests are as under (**Table 3.6**):

1. Tests for establishing HIV infection These include antibody tests and direct detection of HIV.

i) Antibody tests These tests are as under:

a) *ELISA* Initial screening is done by serologic test for antibodies by enzyme-linked immunosorbent assay (ELISA) against *gag* and *env* proteins. The term *window period* is used for the initial 2 to 4 weeks period when the patient is infectious but the screening test is negative, while *seroconversion* is the term used for appearance of antibodies. Besides, ELISA may be false positive in autoantibodies, liver disease, recent vaccination against flu, and other viral infections.

b) *Western blot* If ELISA is positive, confirmation is done by Western blot for presence of specific antibodies against all three HIV antigens: *gag*, *pol* and *env*.

ii) Direct detection of HIV These tests are as follows:

a) *p24* antigen capture assay.

b) *HIV RNA* assay methods by reverse transcriptase (RT) PCR, branched DNA, nucleic acid sequence-based amplification (NucliSens).

c) *DNA-PCR* by amplification of proviral DNA.

d) *Culture* of HIV from blood monocytes and CD4+ T cells.

2. Tests for defects in immunity These tests are used for diagnosis as well as for monitoring treatment of cases.

i) *CD4+ T cell counts.* Progressive fall in number of CD4+ T cells is of paramount importance in diagnosis and staging as CDC categories as described above.

ii) Rise in CD8+ T cells.

iii) Reversal of CD4+ to CD8+ T cell ratio.

iv) Lymphopenia.

v) Polyclonal hypergammaglobulinaemia.

vi) Increased β -2 microglobulin levels.

vii) Platelet count revealing thrombocytopenia.

3. Tests for detection of opportunistic infections and secondary tumours Diagnosis of organs involved in opportunistic infection and specific tumours secondary to HIV/AIDS is made by aspiration or biopsy methods as for the corresponding primary disease.

**GIST BOX 3.4****Immunodeficiency Diseases: HIV-AIDS**

- ☐ Immunodeficiency diseases may be *primary* (usually the result of genetic or developmental abnormality of the immune system) or *secondary* (from acquired suppression of the immune system), the most important example being acquired immunodeficiency syndrome (AIDS).
- ☐ AIDS has pandemic distribution and is seen in all continents. As per current estimates, 35 million people are living with AIDS globally, Sub-Saharan Africa having the largest number of cases.
- ☐ It is caused by *retrovirus*, HIV-1 or HIV-2, the former being much more common etiologic agent in most parts of the world.
- ☐ The routes of spread of infection are: sexual (both homo- and heterosexual), via blood route and by use of contaminated blood products, perinatal transmission to the new born from infected mothers, needle stick injuries, and rarely from other body fluids.
- ☐ Mechanism of acquiring disease is by selective tropism of HIV for CD4 molecule located on CD4+ helper T cells and other such cells. The virus internalises in the target cell, uncoats and forms double stranded viral DNA, which then integrates into the host cell DNA, forming HIV provirus. Virus replicates inside the cytoplasm and ultimately destroys the host CD4+T cells. The viral particles then disseminate to the other lymphoid tissues, creating a reservoir of organism in the host.
- ☐ As per CDC, HIV is defined by clinical features and by CD4+ T cell count <200/ μ l. Its categories are: A=asymptomatic case, acute HIV syndrome or with PGL; B=symptomatic case due to impaired CMI; and C=having AIDS indicator conditions.
- ☐ AIDS involves multiple systems and affects almost all organs. The main pathologic lesions in full-blown case are due to opportunistic infections, secondary tumours and CNS manifestations.
- ☐ Diagnosis of AIDS is made by tests to establish infection (antibody testing by ELISA, confirmation by Western blot), and to detect defect in immunity (low CD4 cell counts and reversal of CD4+:CD8+ cells).

HYPERSENSITIVITY REACTIONS (IMMUNOLOGIC TISSUE INJURY)

Hypersensitivity is defined as an exaggerated or inappropriate state of normal immune response with onset of adverse effects on the body. The lesions of hypersensitivity are a form of antigen-antibody reaction. These lesions are termed as hypersensitivity reactions or immunologic tissue injury, of which 4 types are described: type I, II, III and IV. Depending upon the *rapidity, duration and type* of the immune response, these 4 types of

Table 3.7 Comparative features of 4 types of hypersensitivity reactions.

| FEATURE | TYPE I (ANAPHYLACTIC, ATOPIC) | TYPE II (ANTIBODY-MEDIATED, CYTOTOXIC) | TYPE III (IMMUNE-COMPLEX, ARTHUS REACTION) | TYPE IV (DELAYED, T CELL-MEDIATED) |
|----------------------------|--|--|--|---|
| 1. <i>Definition</i> | Rapidly developing immune response in a previously sensitised person | Reaction of humoral antibodies that attack cell surface antigens and cause cell lysis | Results from deposition of antigen-antibody complexes on tissues | Cell-mediated slow and prolonged response |
| 2. <i>Peak action time</i> | 15-30 minutes | 15-30 minutes | Within 6 hours | After 24 hours |
| 3. <i>Mediated by</i> | IgE antibodies | IgG or IgM antibodies | IgG, IgM antibodies | Cell-mediated |
| 4. <i>Etiology</i> | Genetic basis, pollutants, viral infections | HLA-linked, exposure to foreign tissues/cells | Persistence of low grade infection, environmental antigens, autoimmune process | CD8+ T cells, cutaneous antigens |
| 5. <i>Examples</i> | <ul style="list-style-type: none"> i. Systemic anaphylaxis (administration of antisera and drugs, stings) ii. Local anaphylaxis (hay fever, bronchial asthma, food allergy, cutaneous, angioedema) | <ul style="list-style-type: none"> i. Cytotoxic antibodies to blood cells (autoimmune haemolytic anaemia, transfusion reactions, erythroblastosis foetalis, ITP, leucopenia, drug-induced) ii. Cytotoxic antibodies to tissue components (Graves' disease, myasthenia gravis, male sterility, type I DM, hyperacute reaction against organ transplant) | <ul style="list-style-type: none"> i. Immune complex glomerulonephritis ii. Goodpasture's syndrome, iii. Collagen diseases (SLE, rheumatoid arthritis) iv. PAN v. Drug-induced vasculitis | <ul style="list-style-type: none"> i. Reaction against mycobacterial antigen (tuberculin reaction, tuberculosis, tuberculoid leprosy) ii. Reaction against virus-infected cells iii. Reaction against tumour cells |

hypersensitivity reactions are grouped into either immediate or delayed type:

1. Immediate type in which on administration of antigen, the reaction occurs immediately (within seconds to minutes). Immune response in this type is mediated largely by *humoral antibodies* (B cell mediated). Immediate type of hypersensitivity reactions include *type I, II and III*.

2. Delayed type in which the reaction is slower in onset and develops within 24-48 hours and the effect is prolonged. It is mediated by *cellular response* (T cell mediated) and it includes *Type IV reaction*.

The etiopathogenesis and examples of immunologic tissue injury by the 4 types of hypersensitivity reactions are discussed below and are summarised in **Table 3.7**.

TYPE I: ANAPHYLACTIC (ATOPIC) REACTION

Type I hypersensitivity is defined as a state of rapidly developing or anaphylactic type of immune response to an antigen (i.e. allergen) to which the individual is previously sensitised (anaphylaxis is the opposite of prophylaxis). The reaction appears within 15-30 minutes of exposure to antigen.

ETIOLOGY Type I reaction is mediated by *humoral antibodies of IgE type or reagin antibodies* in response to antigen. Following hypotheses have been proposed:

1. Genetic basis There is evidence that ability to respond to antigen and produce IgE are both linked to genetic basis. For example, there is a 50% chance that a child born to both parents allergic to an antigen, may have similar allergy. Further support to this hypothesis comes from observations of high levels of IgE in hypersensitive individuals and low level of suppressor T cells that control the immune response are observed in persons with certain HLA types (in particular HLA-B8).

2. Environmental pollutants Another proposed hypothesis is that environmental pollutants increase mucosal permeability and thus may allow increased entry of allergen into the body, which in turn leads to raised IgE level.

3. Concomitant factors An alternate hypothesis is that allergic response in type I reaction may be linked to simultaneous occurrence of certain viral infections of upper respiratory tract in a susceptible individual.

PATHOGENESIS Type I reaction includes participation by B lymphocytes and plasma cells, mast cells and basophils, neutrophils and eosinophils. The underlying mechanism is as follows (**Fig. 3.7, A**):

i) During *first contact* of the host with the antigen, *sensitisation* takes place. In response to initial contact with antigen, circulating B lymphocytes get activated and differentiate to form IgE-secreting plasma cells. IgE antibodies so formed bind to the Fc receptors present in plenty on the surface of mast cells and basophils, which are the main effector cells of type I reaction. Thus, these cells are now fully sensitised for the next event.

ii) During the *second contact* with the same antigen, IgE antibodies on the surface of mast cells-basophils are so firmly bound to Fc receptors that it sets in cell damage—membrane lysis, influx of sodium and water and *degranulation* of mast cells-basophils.

iii) The released granules contain important chemicals and enzymes with *proinflammatory* properties— histamine, serotonin, vasoactive intestinal peptide (VIP), chemotactic factors of anaphylaxis for neutrophils and eosinophils, leukotrienes B4 and D4, prostaglandins (thromboxane A2, prostaglandin D2 and E2) and platelet activating factor. The effects of these agents are:

i) increased vascular permeability;

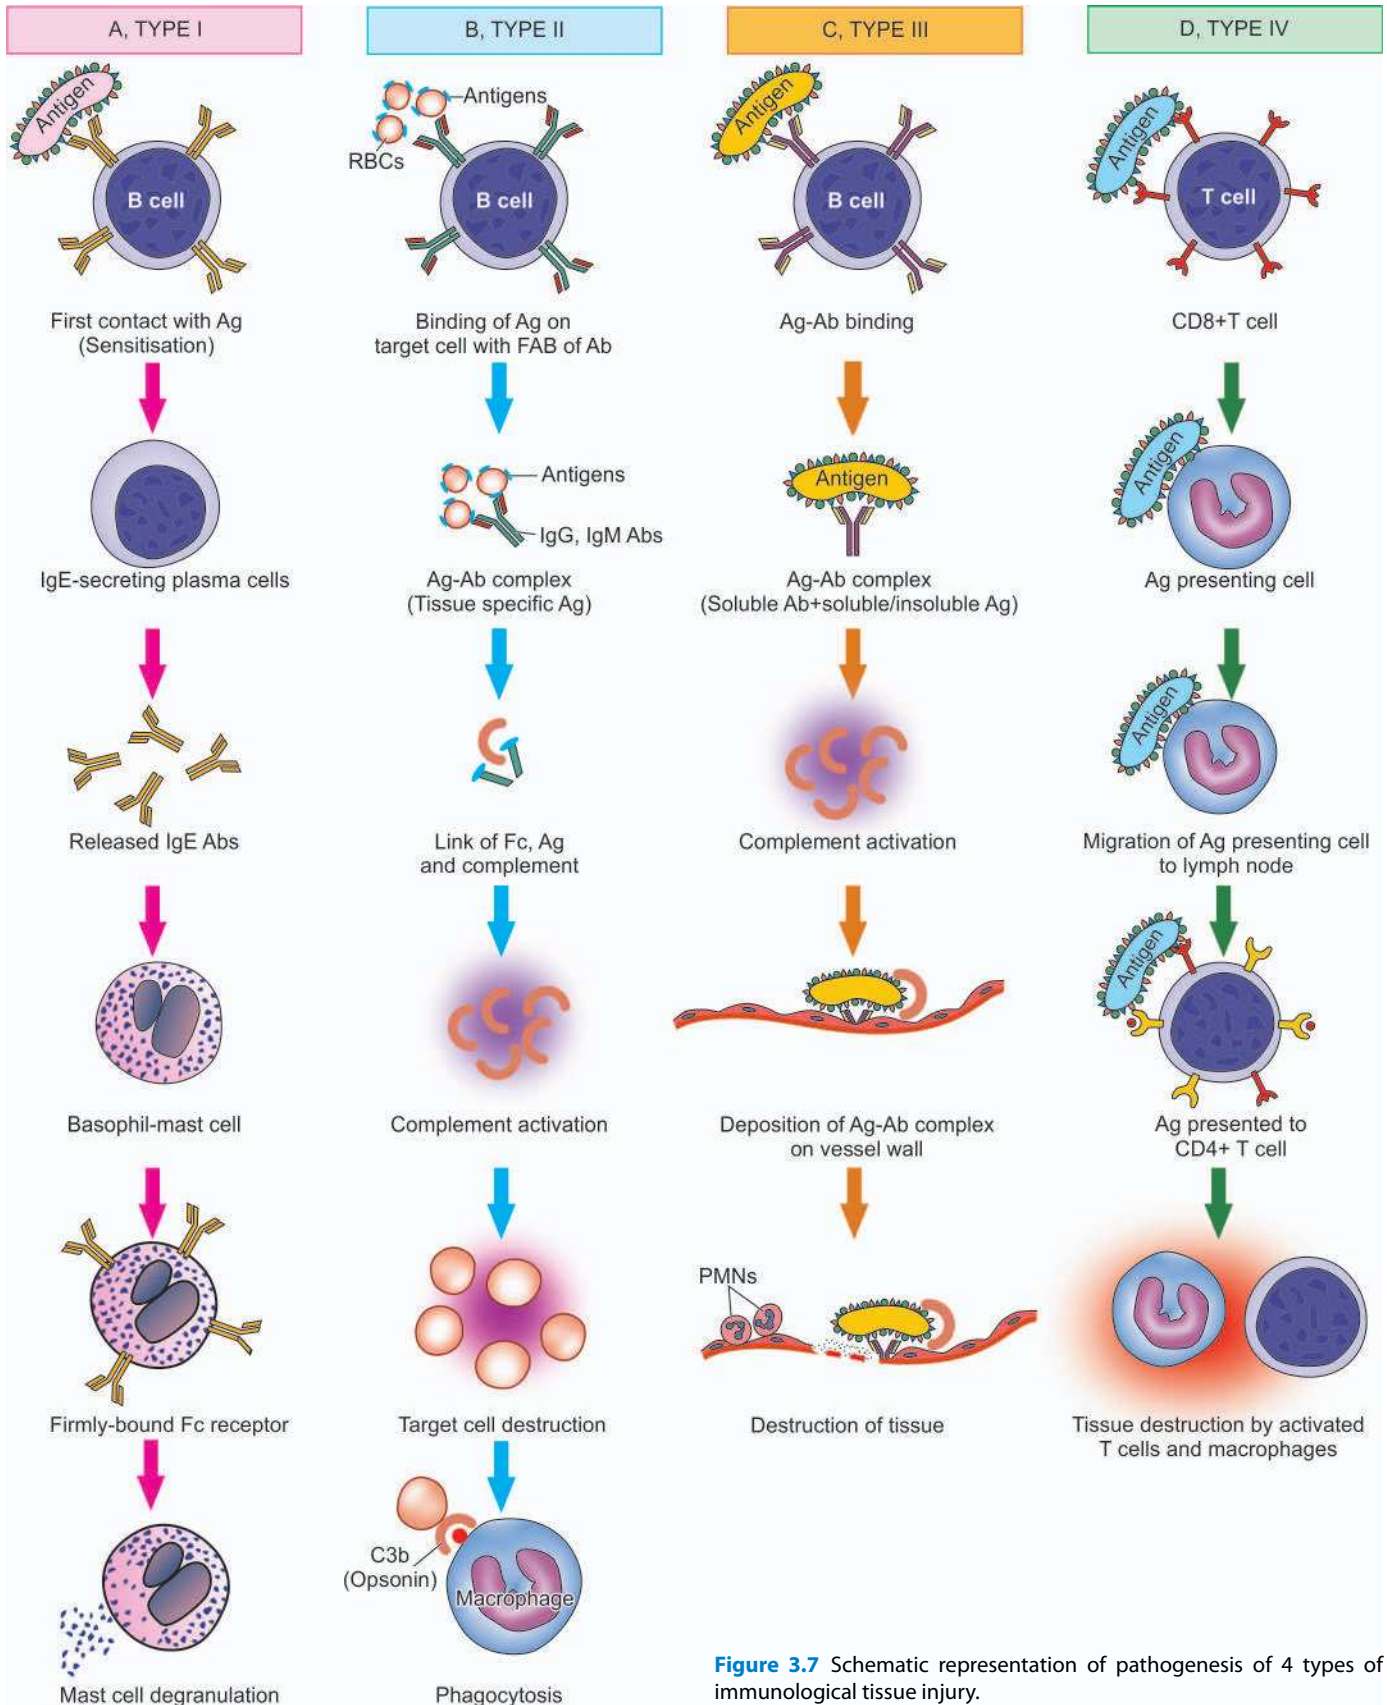

Figure 3.7 Schematic representation of pathogenesis of 4 types of immunological tissue injury.

- ii) smooth muscle contraction;
- iii) early vasoconstriction followed by vasodilatation;
- iv) shock;
- v) increased gastric secretion;

- vi) increased nasal and lacrimal secretions; and
- vii) increased migration of eosinophils and neutrophils at the site of local injury as well as their rise in blood (eosinophilia and neutrophilia).

EXAMPLES OF TYPE I REACTION The manifestations of type I reaction may be variable in severity and intensity. It may manifest as a local irritant (skin, nose, throat, lungs etc), or sometimes may be severe and life-threatening anaphylaxis. Common allergens which may incite local or systemic type I reaction are as under:

Systemic anaphylaxis:

- i) Administration of antisera e.g. anti-tetanus serum (ATS).
- ii) Administration of drugs e.g. penicillin.
- iii) Sting by wasp or bee.

The clinical features of systemic anaphylaxis include itching, erythema, contraction of respiratory bronchioles, diarrhoea, pulmonary oedema, pulmonary haemorrhage, shock and death.

Local anaphylaxis:

- i) Hay fever (seasonal allergic rhinitis) due to pollen sensitisation of conjunctiva and nasal passages.
- ii) Bronchial asthma due to allergy to inhaled allergens like house dust.
- iii) Food allergy to ingested allergens like fish, cow's milk, eggs etc.
- iv) Cutaneous anaphylaxis due to contact of antigen with skin characterised by urticaria, wheal and flare.
- v) Angioedema, an autosomal dominant inherited disorder characterised by laryngeal oedema, oedema of eyelids, lips, tongue and trunk.

TYPE II: ANTIBODY-MEDIATED (CYTOTOXIC) REACTION

Type II or cytotoxic reaction is defined as reaction by humoral antibodies that attack cell surface antigens on the specific cells and tissues and cause lysis of target cells. Type II reaction too appears generally within 15-30 minutes after exposure to antigen but in myasthenia gravis and thyroiditis it may appear after longer duration.

ETIOLOGY AND PATHOGENESIS In general, type II reactions have participation by complement system, tissue macrophages, platelets, natural killer cells, neutrophils and eosinophils while main antibodies are IgG and IgM class. Type II hypersensitivity is tissue-specific and reaction occurs after antibodies bind to tissue specific antigens, most often on blood cells. The mechanism involved is as under (**Fig. 3.7, B**):

- i) The antigen on the surface of target cell (foreign cell) attracts and binds Fab portion of the antibody (IgG or IgM) forming antigen-antibody complex.
- ii) The unattached Fc fragment of antibodies (IgG or IgM) forms a link between the antigen and complement.
- iii) The antigen-antibody binding with Fc forming a link causes activation of classical pathway of serum complement which generates activated complement component, C3b, by splitting C4 and C2 by C1.
- iv) Activated C3b bound to the target cell acts as an opsonin and attracts phagocytes to the site of cell injury and initiates phagocytosis.
- v) Antigen-antibody complex also activates complement system and exposes membrane attack complex (MAC) that attacks and destroys the target cell.

EXAMPLES OF TYPE II REACTION Examples of type II reaction are mainly on blood cells and some other body cells and tissues.

1. Cytotoxic antibodies to blood cells These are more common. Some examples are as under:

- i) *Autoimmune haemolytic anaemia* in which the red cell injury is brought about by autoantibodies reacting with antigens present on red cell membrane. Antiglobulin test (direct Coombs' test) is employed to detect the antibody on red cell surface (page 288).
- ii) *Transfusion reactions* due to incompatible or mismatched blood transfusion.
- iii) Haemolytic disease of the newborn (*erythroblastosis foetalis*) in which the foetal red cells are destroyed by maternal isoantibodies crossing the placenta.
- iv) *Idiopathic thrombocytopenic purpura* (ITP) is the immunologic destruction of platelets by autoantibodies reacting with surface components of normal platelets.
- v) *Leucopenia with agranulocytosis* may be caused by autoantibodies to leucocytes causing their destruction.
- vi) *Drug-induced cytotoxic antibodies* are formed in response to administration of certain drugs like penicillin, methyl dopa, rifampicin etc. The drugs or their metabolites act as haptens binding to the surface of blood cells to which the antibodies combine, bringing about destruction of cells.

2. Cytotoxic antibodies to tissue components Cellular injury may be brought about by autoantibodies reacting with some components of tissue cells in certain diseases.

- i) In *Graves' disease* (primary hyperthyroidism), thyroid autoantibody is formed which reacts with the TSH receptor to cause hyperfunction and proliferation.
- ii) In *myasthenia gravis*, antibody to acetylcholine receptors of skeletal muscle is formed which blocks the neuromuscular transmission at the motor end-plate, resulting in muscle weakness.
- iii) In *male sterility*, antisperm antibody is formed which reacts with spermatozoa and causes impaired motility as well as cellular injury.
- iv) In *type 1 diabetes mellitus*, islet cell autoantibodies are formed which react against islet cell tissue.
- v) In *hyperacute rejection reaction*, antibodies are formed against donor antigen.

TYPE III: IMMUNE COMPLEX MEDIATED (ARTHUS) REACTION

Type III reactions result from deposition of antigen-antibody complexes on tissues, which is followed by activation of the complement system and inflammatory reaction, resulting in cell injury. The onset of type III reaction takes place about 6 hours after exposure to the antigen.

ETIOLOGY Type III reaction is not tissue specific and occurs when antigen-antibody complexes fail to get removed by the body's immune system. There are 3 types of possible etiologic factors precipitating type III reaction:

1. Persistence of low-grade microbial infection A low-grade infection with bacteria or viruses stimulates a somewhat weak antibody response. Persistence of infection (antigen) and corresponding weak antibody response leads to chronic antigen-antibody complex formation. Since these complexes fail to get eliminated from body fluids, they are instead deposited in tissues e.g. in blood vessel wall, glomeruli, joint tissue etc.

2. Extrinsic environmental antigen Exogenous antigens may be inhaled into the lungs e.g. antigens derived from

moulds, plants or animals. The inhaled antigen combines with antibody in the alveolar fluid and forms antigen-antibody complex which is deposited in the alveolar walls.

3. Autoimmune process Another sequence in type III reaction can be formation of autoantibodies against own tissue (self antigen) forming autoantibody-self antigen complex. Such self antigens can be circulating (e.g. IgA) or tissue derived (e.g. DNA). Immune complexes containing both components from body's own system can thus be deposited in tissues.

PATHOGENESIS It may be mentioned here that both type II and type III reactions have antigen-antibody complex formation but the two can be distinguished—antigen in type II is tissue specific while in type III it is not so. Moreover the mechanism of cell injury in type II is direct but in type III it is by deposition of antigen-antibody complex on tissues and subsequent sequence of cell injury takes place.

Type III reaction has participation by IgG and IgM antibodies, neutrophils, mast cells and complement. The sequence of underlying mechanism is as under (**Fig. 3.7, C**):

- i) Immune complexes are formed by interaction of soluble antibody and soluble or insoluble antigen.
- ii) Immune complexes which fail to get removed from body fluid get deposited into tissues. Generally, small and intermediate sized antibodies and antigens precipitate out of the body fluid and get deposited in tissues.
- iii) Fc component of antibody links with complement and activates classical pathway of complement resulting in formation of C3a, C5a and membrane attack complex.
- iv) C3a stimulates release of histamine from mast cells and its resultant effects of increased vascular permeability and oedema.
- v) C5a releases proinflammatory mediators and chemotactic agents for neutrophils.
- vi) Accumulated neutrophils and macrophages in the tissue release cytokines and result in tissue destruction.

EXAMPLES OF TYPE III REACTION Common examples of cell injury by type III injury are as under:

- i) Immune complex glomerulonephritis in which the antigen may be glomerular basement membrane (GBM) or exogenous agents (e.g. Streptococcal antigen).
- ii) Goodpasture syndrome having GBM as antigen.
- iii) SLE in which there is nuclear antigen (DNA, RNA) and there is formation of anti-nuclear and anti-DNA autoantibodies.
- iv) Rheumatoid arthritis in which there is nuclear antigen.
- v) Farmer's lung in which actinomycetes-contaminated hay acts as antigen.
- vi) Polyarteritis nodosa and Wegener's granulomatosis with antineutrophil cytoplasmic antigen.
- vii) Henoch-Schönlein purpura in which respiratory viruses act as antigen.
- viii) Drug-induced vasculitis in which the drug acts as antigen.

TYPE IV: DELAYED HYPERSENSITIVITY (T CELL-MEDIATED) REACTION

Type IV or delayed hypersensitivity reaction is tissue injury by T cell-mediated immune response without formation of antibodies (contrary to type I, II and III) but is instead a slow and prolonged response. The reaction occurs about 24 hours after exposure to antigen and the effect is prolonged which may last up to 14 days.

ETIOLOGY AND PATHOGENESIS Type IV reaction involves role of mast cells and basophils, macrophages and CD8+ T cells. Briefly, the mechanism of type IV reaction is as under (**Fig. 3.7, D**):

- i) The antigen is recognised by CD8+ T cells (cytotoxic T cells) and is processed by antigen presenting cells.
- ii) Antigen-presenting cells migrate to lymph node where antigen is presented to helper T cells (CD4+ T cells).
- iii) Helper T cells release cytokines that stimulate T cell proliferation and activate macrophages.
- iv) Activated T cells and macrophages release proinflammatory mediators and cause cell destruction.

EXAMPLES OF TYPE IV REACTION Type IV reaction can explain tissue injury in following common examples:

1. Reaction against mycobacterial infection e.g. tuberculin reaction, granulomatous reaction in tuberculosis, leprosy.
2. Reaction against virally infected cells.
3. Reaction against malignant cells in the body.
4. Reaction against organ transplantation e.g. transplant rejection, graft versus host reaction.

GIST BOX 3.5

Hypersensitivity Reactions (Immunologic Tissue Injury)

- Depending upon the *rapidity, duration and type* of the immune response, there are 4 types of hypersensitivity reactions grouped into two categories: immediate (type I, II, and III) and delayed type (type IV).
- *Type I (or anaphylactic) hypersensitivity* is a state of rapidly developing or anaphylactic type of immune response to an antigen (i.e. allergen) to which the individual is previously sensitised. The reaction appears within 15-30 minutes of exposure to antigen. It is mediated by humoral antibodies of IgE type for which mast cells and basophils play a key role.
- *Type II or cytotoxic reaction* is a reaction by humoral antibodies that attack cell surface antigens on the specific cells and tissues and cause lysis of target cells. Type II reaction is tissue-specific and occurs after antibodies (IgG or IgM) bind to tissue specific antigens, most often on blood cells.
- *Type III reactions* result from deposition of antigen-antibody complexes on tissues, which is followed by activation of the complement system and inflammatory reaction and tissue injury. Antigen in type II reaction is not tissue specific.
- *Type IV or delayed hypersensitivity* is tissue injury by T cell-mediated immune response without formation of antibodies. The reaction occurs about 24 hours (delayed) after exposure to antigen and the response is prolonged.

AUTOIMMUNE DISEASES

Autoimmunity is a state in which the body's immune system fails to distinguish between 'self' and 'non-self' and reacts by formation of autoantibodies against one's own tissue antigens. In other words, there is loss of tolerance to one's own tissues; *autoimmunity is the opposite of immune tolerance.*

Immune tolerance is a normal phenomenon present since foetal life and is defined as the ability of an individual to recognise self tissues and antigens. Normally, the immune

system of the body is able to distinguish self from non-self antigens by the following mechanisms:

1. **Clonal elimination** According to this theory, during embryonic development, T cells maturing in the thymus acquire the ability to distinguish self from non-self. These T cells are then eliminated by apoptosis for the tolerant individual.
2. **Concept of clonal anergy** According to this mechanism, T lymphocytes which have acquired the ability to distinguish self from non-self are not eliminated but instead become non-responsive and inactive.
3. **Suppressor T cells** According to this mechanism, the tolerance is achieved by a population of specific suppressor T cells which do not allow the antigen-responsive cells to proliferate and differentiate.

PATHOGENESIS (THEORIES) OF AUTOIMMUNITY

Normally, the body's response to self antigens (autoimmunity) is prevented by three major processes:

1. **Sequestration** of autoantigens and thus their unavailability for autoimmune response.
2. **Generation and maintenance** of tolerance or anergy by T and B lymphocytes in the body.
3. **Regulatory mechanisms** limiting response by the immune system.

The mechanisms by which the immune tolerance of the body is broken causes autoimmunity. These mechanisms or theories of autoimmunity may be exogenous or endogenous, and include immunological, genetic, and microbial factors, which may be interacting:

1. Immunological factors Failure of immunological mechanisms of tolerance initiates autoimmunity as follows:

- i) **Polyclonal activation of B cells** B cells may be directly activated by stimuli such as infection with microorganisms and their products leading to bypassing of T cell tolerance.
- ii) **Generation of self-reacting B cell clones** may also lead to bypassing of T cell tolerance.
- iii) **Decreased T suppressor and increased T helper cell activity.** Loss of T suppressor cell and increase in T helper cell activities may lead to high levels of autoantibody production by B cells contributing to autoimmunity.
- iv) **Fluctuation of anti-idiotypic network control** may cause failure of mechanisms of immune tolerance.
- v) **Sequestered antigen released from tissues** 'Self-antigen' which is completely sequestered may act as 'foreign-antigen' if introduced into the circulation later. For example, in trauma to the testis, there is formation of anti-sperm antibodies against spermatozoa; similar is the formation of autoantibodies against lens crystallin.

2. Genetic factors There is evidence in support of genetic factors in the pathogenesis of autoimmunity as under:

- i) There is increased expression of **Class II HLA antigens** on tissues involved in autoimmunity.
- ii) There is increased **familial incidence** of some forms of the autoimmune disorders.
- iii) There is higher incidence of autoimmune diseases in **twins** favouring genetic basis.

3. Microbial factors Infection with microorganisms, particularly viruses (e.g. EBV infection), and less often bacteria (e.g. streptococci, *Klebsiella*) and mycoplasma, has been

Table 3.8 Criteria for diagnosis of autoimmune diseases.

LABORATORY EVIDENCE

1. Presence and documentation of relevant autoantibodies in the serum
2. Demonstration of T cell reactivity to self antigen
3. Lymphocytic infiltrate in the pathologic lesion
4. Production of cytokines by helper T cells e.g. interferon γ , interleukin 4
5. Evidence to support production of pathologic lesions in the tissues by transplacental transmission
6. Transfer of an autoimmune disease to an experimental animal by administration of autoantibodies

CLINICAL EVIDENCE

1. Association of other autoimmune disease
2. Improved therapeutic response to immunosuppressive agents
3. Family history of autoimmune disease

implicated in triggering the pathogenesis of autoimmune diseases. However, a definite evidence in support is lacking.

TYPES AND EXAMPLES OF AUTOIMMUNE DISEASES

Autoimmune diseases are a growing number of such diseases in which autoimmunity is either mediated by formation of immune complexes or they are mediated by T cells. In order to classify a disease as autoimmune, it is necessary to demonstrate that immune response in the body is elicited by self antigen and has caused the specific pathologic change. In general, presumptive evidence of autoimmune disease is made based on a few criteria, both laboratory and clinical, listed in **Table 3.8**.

Depending upon the type of autoantibody formation, the autoimmune diseases are broadly classified into 2 groups:

1. Organ specific (Localised) diseases In these, the autoantibodies formed react specifically against an organ or target tissue component and cause its chronic inflammatory destruction. The tissues affected are endocrine glands (e.g. thyroid, pancreatic islets of Langerhans, adrenal cortex), alimentary tract, blood cells and various other tissues and organs.

2. Organ non-specific (Systemic) diseases These are diseases in which a number of autoantibodies are formed which react with antigens in many tissues and thus cause systemic lesions. The examples of this group are various systemic collagen diseases.

However, a few autoimmune diseases overlap between these two main categories.

Based on these 2 main groups, a list of common autoimmune (or immune-mediated inflammatory) diseases is presented in **Table 3.9** and illustrated in **Fig. 3.8**. Some of the systemic autoimmune diseases (*marked with asterisk*) are discussed in this chapter while others from both the groups are described later in the relevant chapters.

Systemic Lupus Erythematosus (SLE)

SLE is the classical example of systemic autoimmune or collagen diseases. The disease derives its name '*lupus*' from the Latin word meaning 'wolf' since initially this disease was believed to affect skin only and eat away skin like a wolf. However, now 2 forms of lupus erythematosus are described:

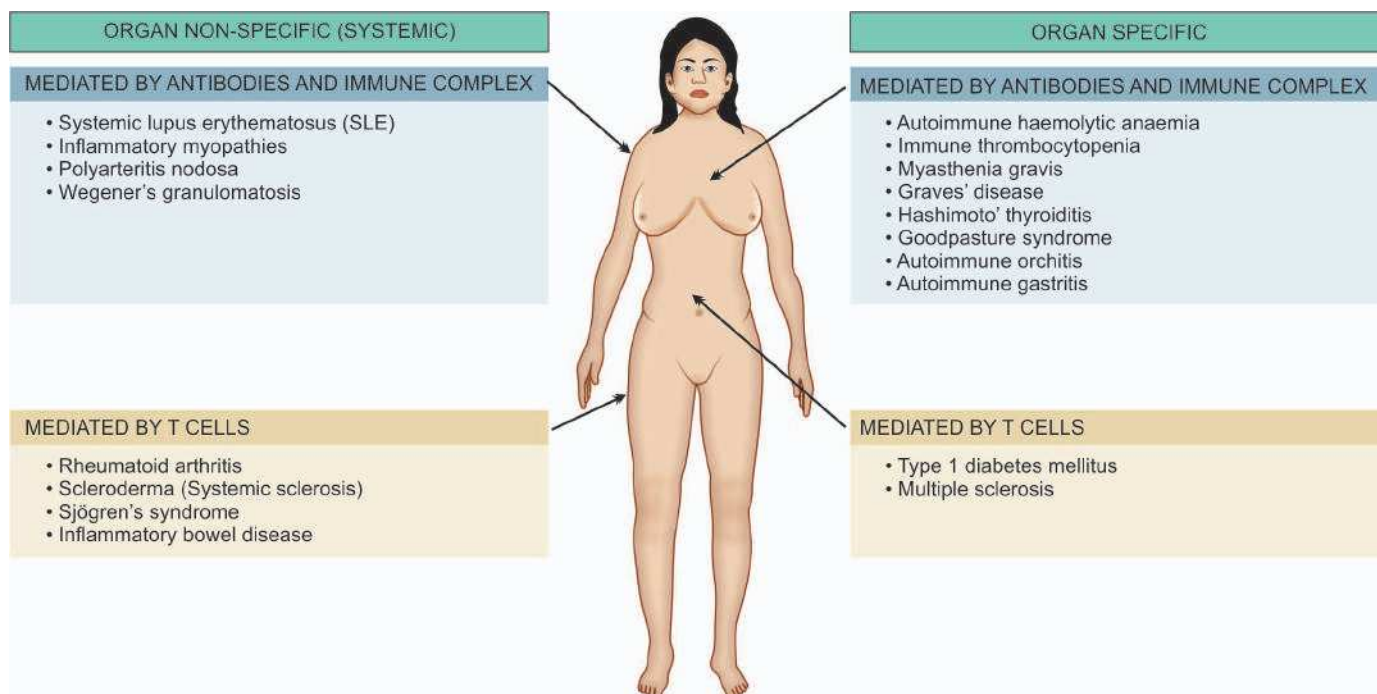

Figure 3.8 Organ specific and systemic autoimmune diseases.

Table 3.9 Autoimmune diseases.

ORGAN NON-SPECIFIC (SYSTEMIC)

1. Systemic lupus erythematosus*
2. Rheumatoid arthritis
3. Scleroderma (Systemic sclerosis)*
4. Inflammatory myopathies (polymyositis, dermatomyositis, inclusion body myositis)*
5. Polyarteritis nodosa (PAN)
6. Sjögren's syndrome*
7. Wegener's granulomatosis

ORGAN SPECIFIC (LOCALISED)

1. **ENDOCRINE GLANDS**
 - (i) Hashimoto's (autoimmune) thyroiditis
 - (ii) Graves' disease
 - (iii) Type 1 diabetes mellitus
 - (iv) Idiopathic Addison's disease
2. **ALIMENTARY TRACT**
 - (i) Autoimmune atrophic gastritis in pernicious anaemia
 - (ii) Ulcerative colitis
 - (iii) Crohn's disease
3. **BLOOD CELLS**
 - (i) Autoimmune haemolytic anaemia
 - (ii) Autoimmune thrombocytopenia
 - (iii) Pernicious anaemia
4. **OTHERS**
 - (i) Myasthenia gravis
 - (ii) Autoimmune orchitis
 - (iii) Autoimmune encephalomyelitis
 - (iv) Goodpasture's syndrome
 - (v) Primary biliary cirrhosis
 - (vi) Lupoid hepatitis
 - (vii) Membranous glomerulonephritis
 - (viii) Autoimmune skin diseases

*Diseases discussed in this chapter.

1. Systemic or disseminated form is characterised by acute and chronic inflammatory lesions widely scattered in the body and there is presence of various nuclear and cytoplasmic autoantibodies in the plasma.

2. Discoid form is characterised by chronic and localised skin lesions involving the bridge of nose and adjacent cheeks without any systemic manifestations. Rarely, discoid form may develop into disseminated form.

ETIOLOGY The exact etiology of SLE is not known. However, there is role of heredity and certain environmental factors:

2. **Genetic factors.** Genetic predisposition to develop autoantibodies to nuclear and cytoplasmic antigens in SLE is due to the immunoregulatory function of class II HLA genes implicated in the pathogenesis of SLE.

3. **Environmental factors.** Various other factors express the genetic susceptibility of an individual to develop clinical disease. These factors are:

- i) certain drugs e.g. penicillamine D;
- ii) certain viral infections e.g. EBV infection; and
- iii) certain hormones e.g. oestrogen.

PATHOGENESIS Interaction between susceptibility genes and environmental factors results in abnormal immune responses by formation of various autoantibodies. Autoantibodies against nuclear and cytoplasmic components of the cells are demonstrable in plasma by immunofluorescence tests in almost all cases of SLE. Some of the important **antinuclear antibodies (ANAs)** or antinuclear factors (ANFs) against different nuclear antigens are as under:

i) Antinuclear antibodies (ANA) These are the antibodies against common nuclear antigen that includes DNA as well as RNA. These are demonstrable in about 98% cases and are used as screening test.

ii) Antibodies to double-stranded (anti-dsDNA) This is the most specific for SLE, especially in high titres, and is present in 70% cases.

iii) Anti-Smith antibodies (anti-Sm) These antibodies appear against Smith antigen which is part of ribonucleoproteins. It is also specific for SLE but is seen in about 25% cases.

iv) Other non-specific antibodies Besides above, there are several other antibody tests which lack specificity for SLE. These are as follows:

- Anti-ribonucleoproteins (anti-RNP)* seen in 40% cases of SLE but seen more often in Sjögren's syndrome.
- Anti-histone antibody*, which is antibody against histone associated with DNA in chromatin, is seen particularly in cases of drug-induced lupus than in SLE.
- Antiphospholipid antibodies (APLA) or lupus anticoagulant* are tests for thrombotic complications in cases of SLE.
- Anti-ribosomal P antibody* is antibody against protein in ribosomes and is seen in CNS lupus.

The source of these autoantibodies as well as hypergamma-globulinaemia seen in SLE is the **polyclonal activation of B cells** brought about by following immunologic derangements:

- an inherited defect in B cells;
- stimulation of B cells by micro-organisms;
- T helper cell hyperactivity; and
- T suppressor cell defect.

Two types of immunologic tissue injury can occur in SLE:

- Type II hypersensitivity* is characterised by formation of autoantibodies against blood cells (red blood cells, platelets, leucocytes) and results in haematologic derangement in SLE.
- Type III hypersensitivity* is characterised by antigen-antibody complex (commonly DNA-anti-DNA antibody; sometimes Ig-anti-Ig antibody complex) which is deposited at sites such as renal glomeruli, walls of small blood vessels etc.

LE CELL PHENOMENON This was the first diagnostic laboratory test described for SLE. The test is based on the principle that ANAs cannot penetrate the intact cells and thus cell nuclei should be exposed to bind them with the ANAs. The binding of exposed nucleus with ANAs results in homogeneous mass of nuclear chromatin material which is called *LE body* or *haematoxylin body*.

LE cell is a phagocytic leucocyte, commonly polymorphonuclear neutrophil, and sometimes a monocyte, which engulfs the homogeneous nuclear material of the injured cell. For demonstration of LE cell phenomenon *in vitro*, the blood sample is traumatised to expose the nuclei of blood leucocytes to ANAs. This results in binding of denatured and damaged nucleus with ANAs. The ANA-coated denatured nucleus is chemotactic for phagocytic cells.

◆ If this mass is engulfed by a neutrophil, displacing the nucleus of neutrophil to the rim of the cell, it is called *LE cell* (Fig. 3.9).

◆ If the mass, more often an intact lymphocyte, is phagocytosed by a monocyte, it is called *Tart cell*.

LE cell test is positive in 70% cases of SLE while newer and more sensitive immunofluorescence tests for autoantibodies listed above are positive in almost all cases of SLE. A few other conditions may also show positive LE test e.g. rheumatoid arthritis, lupoid hepatitis, penicillin sensitivity etc.

MORPHOLOGIC FEATURES The manifestations of SLE are widespread in different visceral organs and as erythematous cutaneous eruptions. The principal lesions

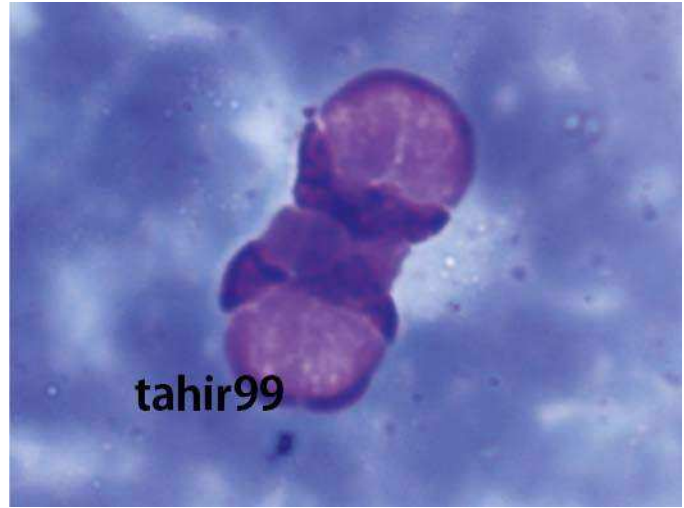

Figure 3.9 Typical LE cell. There are two LE cells having rounded masses of amorphous nuclear material (LE body) which has displaced the lobes of neutrophil to the rim of the cell.

are renal, vascular, cutaneous and cardiac; other organs and tissues involved are serosal linings (pleuritis, pericarditis), joints (synovitis), spleen (vasculitis), liver (portal triaditis), lungs (interstitial pneumonitis, fibrosing alveolitis), CNS (vasculitis) and in blood (autoimmune haemolytic anaemia, thrombocytopaenia).

Histologically, the characteristic lesion in SLE is *fibrinoid necrosis* which may be seen in the connective tissue, beneath the endothelium in small blood vessels, under the mesothelial lining of pleura and pericardium, under the endothelium in endocardium, or under the synovial lining cells of joints.

Table 3.10 summarises the morphology of lesions in different organs and tissues in SLE.

CLINICAL FEATURES SLE, like most other autoimmune diseases, is more common in women in their 2nd to 3rd decades of life. As obvious from **Table 3.10**, SLE is a multisystem disease and thus a wide variety of clinical features may be present. The severity of disease varies from mild to intermittent to severe and fulminant. Usually targeted organs are musculoskeletal system, skin, kidneys, nervous system, lungs, heart and blood vessels, GI system, and haematopoietic system. Fatigue and myalgia are present in most cases throughout the course of disease. Severe form of illness occurs with fever, weight loss, anaemia and organ related manifestations.

The disease usually runs a long course of flare-ups and remissions; renal failure is the most frequent cause of death.

Scleroderma (Systemic Sclerosis)

Just like SLE, scleroderma was initially described as a skin disease characterised by progressive fibrosis. But now, 2 main types are recognised:

- Diffuse scleroderma* in which the skin shows widespread involvement and may progress to involve visceral structures.
- CREST syndrome* characterised by Calcinosis (C), Raynaud's phenomenon (R), Esophageal hypomotility (E), Sclerodactyly (S) and Telangiectasia (T).

Table 3.10 Morphology of major lesions in SLE.

- RENAL LESIONS (LUPUS NEPHRITIS)**
EM-shows large deposits in mesangium, subepithelium or subendothelium.
IM-shows granular deposits of immune complex (IgG and C3) on capillaries, mesangium and tubular basement membranes. Six WHO classes of lupus nephritis based on patterns:

Class I: Minimal disease lupus nephritis: Seen in <5% cases. LM shows no change. IF shows mesangial deposits.

Class II: Mesangial proliferative lupus nephritis: Seen in 10-25% cases. LM shows mesangial expansion; pure mesangial hypercellularity. IF shows subepithelial or subendothelial deposits.

Class III: Focal lupus nephritis: Seen in 20-35% cases. LM shows focal or segmental endothelial and mesangial cell proliferation in <50% glomeruli. IF shows focal subendothelial deposits. Three subclasses:

Class IIIA: Active lesions (focal proliferative).
Class IIIA/C: Active on chronic lesions (focal proliferative and sclerosing).
Class IIIC: Chronic inactive lesions with scars (focal sclerosing).

Class IV: Diffuse lupus nephritis: Seen in 35-60% cases. LM shows diffuse, segmental or global involvement of $\geq 50\%$ glomeruli; proliferation of endothelial, mesangial and epithelial cells; epithelial crescents. IF shows diffuse subendothelial deposits. Two subclasses:

Class IV-S: 50% of involved glomeruli have segmental lesions.
Class IV-G: 50% of involved glomeruli have global lesions. Each of these subclasses (IV-S and IV-G) has active, active on chronic, and chronic lesions.

Class V: Membranous lupus nephritis: Seen in 10-15% cases. LM shows diffuse basement membrane thickening. IF shows global or segmental subepithelial deposits. May be seen in combination with class III or IV.

Class VI: Advanced sclerotic lupus nephritis: Seen as end-stage disease. LM shows global sclerosis of $\geq 90\%$ of glomeruli.
- LESIONS OF SMALL BLOOD VESSELS (ACUTE NECROTISING VASCULITIS)**
Affects all tissues; commonly skin and muscles involved. LM shows fibrinoid deposits in the vessel wall; perivascular infiltrate of mononuclear cells.
- CUTANEOUS LESIONS (ERYTHEMATOUS ERUPTIONS)**
Butterfly area on nose and cheek. LM shows liquefactive degeneration of basal layer of epidermis, oedema at dermoepidermal junction; acute necrotising vasculitis in dermis. IF shows immune complex deposits (IgG and C3) at dermoepidermal junction.
- CARDIAC LESIONS (LIBMAN-SACKS ENDOCARDITIS)**
Vegetations on mitral and tricuspid valves, may extend to mural endocardium, chordae tendinae. LM of vegetations shows fibrinoid material, necrotic debris, inflammatory cells, haematoxylin bodies may be present; connective tissue of endocardium and myocardium may show focal inflammation and necrotising vasculitis.

(LM = Light microscopy; IF = Immunofluorescence microscopy).

ETIOPATHOGENESIS There is role of following 2 factors in its etiology:

1. *Susceptibility genes* as seen in occurrence of disease in families and in twins.

2. *Certain environmental factors* e.g. CMV infection, and role of common shared environmental exposure of certain agents as seen by prevalence of disease in some geographic location.

Antinuclear antibodies are detected in majority of cases of systemic sclerosis. Thus, immunologic mechanisms have been implicated in the pathogenesis of lesions in systemic sclerosis which finally cause activation of fibroblasts. The *immune mechanisms* leading to stimulation of fibroblasts act in the following ways:

i) *Elaboration of cytokines* such as by fibroblast growth factor and chemotactic factors by activated T cells and macrophages.

ii) *Endothelial cell injury* due to cytotoxic damage to endothelium from autoantibodies or antigen-antibody complexes. This results in aggregation and activation of platelets which increases vascular permeability and stimulates fibroblastic proliferation.

MORPHOLOGIC FEATURES Disseminated visceral involvement as well as cutaneous lesions are seen in systemic sclerosis.

1. Skin changes Skin is involved diffusely, beginning distally from fingers and extending proximally to arms, shoulders, neck and face. In advanced stage, the fingers become claw-like and face mask-like.

Microscopically, changes are progressive from early to late stage.

◆ *Early stage* shows oedema and degeneration of collagen. The small-sized blood vessels are occluded and there is perivascular infiltrate of mononuclear cells.

◆ *Late stage* reveals thin and flat epidermis. Dermis is largely replaced by compact collagen and there is hyaline thickening of walls of dermal blood vessels. In advanced cases subcutaneous calcification may occur.

2. Kidney changes Involvement of kidneys is seen in majority of cases of systemic sclerosis. The lesions are prominent in the walls of interlobular arteries which develop changes resembling malignant hypertension. There is thickening of tunica intima due to concentric proliferation of intimal cells and fibrinoid necrosis of vessel wall.

3. Smooth muscle of GIT Muscularis of the alimentary tract, particularly oesophagus, is progressively atrophied and replaced by fibrous tissue.

4. Skeletal muscle The interstitium of skeletal muscle shows progressive fibrosis and degeneration of muscle fibres with associated inflammatory changes.

5. Cardiac muscle Involvement of interstitium of the heart may result in heart failure.

6. Lungs Diffuse fibrosis may lead to contraction of the lung substance. There may be epithelium-lined honey-combed cysts of bronchioles.

7. Small arteries The lesions in small arteries show endarteritis due to intimal proliferation and may be the cause for Raynaud's phenomenon.

CLINICAL FEATURES Systemic sclerosis is more common in middle-aged women. The clinical manifestations include:

- i) claw-like flexion deformity of hands;
- ii) Raynaud's phenomenon;
- iii) oesophageal fibrosis causing dysphagia and hypomotility;
- iv) malabsorption syndrome;
- v) respiratory distress;
- vi) malignant hypertension;
- vii) pulmonary hypertension; and
- viii) biliary cirrhosis.

Inflammatory Myopathies

This group includes three conditions having common clinical feature of progressive skeletal muscle weakness: polymyositis, dermatomyositis and inclusion body myositis.

ETIOPATHOGENESIS All the three forms of inflammatory myositis appear to have an autoimmune etiology. This is supported by following:

1. Association with other autoimmune (collagen) diseases.
2. Presence of various autoantibodies against nuclear and cytoplasmic antigens in 20% cases.
3. Presence of humoral immune mechanism in dermatomyositis as observed by B cell infiltration in the lesions.
4. In polymyositis and inclusion body myositis, T-cell mediated cytotoxicity is implicated as seen by CD8+ T cells along with macrophages in the lesions.
5. Some non-immune factors such as viral infection with coxsackie B, influenza, Epstein-Barr, CMV etc in triggering autoimmune mechanism has been suggested.

MORPHOLOGIC FEATURES There is symmetric involvement of skeletal muscles such as those of pelvis, shoulders, neck, chest and diaphragm.

Histologically, vacuolisation and fragmentation of muscle fibres and numerous inflammatory cells are present. In late stage, muscle fibres are replaced by fat and fibrous tissue.

CLINICAL FEATURES It is a multi-system disease characterised by:

- i) progressive muscle weakness, mainly proximal;
- ii) skin rash, typically with heliotropic erythema and peri-orbital oedema;
- iii) dysphagia due to involvement of pharyngeal muscles;
- iv) respiratory dysfunction; and
- v) association with deep-seated malignancies.

Sjögren's Syndrome

Sjögren's syndrome is characterised by the *triad* of dry eyes (*keratoconjunctivitis sicca*), dry mouth (*xerostomia*), and *rheumatoid arthritis*. The combination of the former two symptoms is called *sicca syndrome*.

ETIOPATHOGENESIS Both humoral and cellular immune mechanisms have been implicated in the etiopathogenesis of lesions in Sjögren's syndrome:

- i) There is B lymphocyte hyperactivity as seen by rise of monoclonal immunoglobulins in 255 cases.
- ii) Presence of antinuclear antibodies in about 90% of cases.
- iii) Positive rheumatoid factor in 25% of cases.
- iv) Infiltration by T lymphocytes in exocrine glands.

- v) Association of disease with certain HLA class II genes.
- vi) Association with other autoimmune diseases.

MORPHOLOGIC FEATURES In early stage, the lacrimal and salivary glands show periductal infiltration by lymphocytes and plasma cells, which at times may form lymphoid follicles (pseudolymphoma). In late stage, glandular parenchyma is replaced by fat and fibrous tissue. The ducts are also fibrosed and hyalinised.

CLINICAL FEATURES The disease is common in women in 4th to 6th decades of life. It is clinically characterised by the following:

- i) Symptoms referable to eyes such as blurred vision, burning and itching.
- ii) Symptoms referable to xerostomia such as fissured oral mucosa, dryness, and difficulty in swallowing.
- iii) Symptoms due to glandular involvement such as enlarged and inflamed lacrimal gland (Mikulicz's syndrome is involvement of parotid alongwith lacrimal gland).
- iv) Symptoms due to systemic involvement referable to lungs, CNS and skin.

GIST BOX 3.6

Autoimmune Diseases

- ☐ Depending upon the type of autoantibody formation, the autoimmune diseases are broadly classified into 2 groups: organ specific (localised) and organ non-specific (or systemic).
- ☐ SLE is the classical example of systemic autoimmune or collagen diseases. Autoantibodies against nuclear (ANAs) and cytoplasmic components of the cells are demonstrable in plasma by immunofluorescence tests in almost all cases of SLE e.g. ANA, anti-ds-DNA, antiSm etc. LE cell test is positive in 70% cases. SLE is a multisystem disease and affects chiefly kidneys (lupus nephritis), skin, small blood vessels, and heart.
- ☐ Scleroderma or systemic sclerosis may occur as diffuse form or as CREST syndrome. The disease involves skin, kidneys, GIT, skeletal muscle, heart and lungs.
- ☐ Inflammatory myopathies are a group of 3 diseases having common clinical feature of progressive skeletal muscle weakness: polymyositis, dermatomyositis and inclusion body myositis.
- ☐ Sjögren's syndrome is characterised by the triad of dry eyes (keratoconjunctivitis sicca), dry mouth (xerostomia), and rheumatoid arthritis.

AMYLOIDOSIS

Amyloidosis is the term used for a group of diseases characterised by extracellular deposition of fibrillar insoluble proteinaceous substance called amyloid having common morphological appearance, staining properties and physical structure but with variable protein (or biochemical) composition.

First described by Rokitansky in 1842, the substance was subsequently named by Virchow as 'amyloid' under the mistaken belief that the material was starch-like (*amylon* = starch). This property was demonstrable grossly on the cut surface of an organ containing amyloid which stained brown

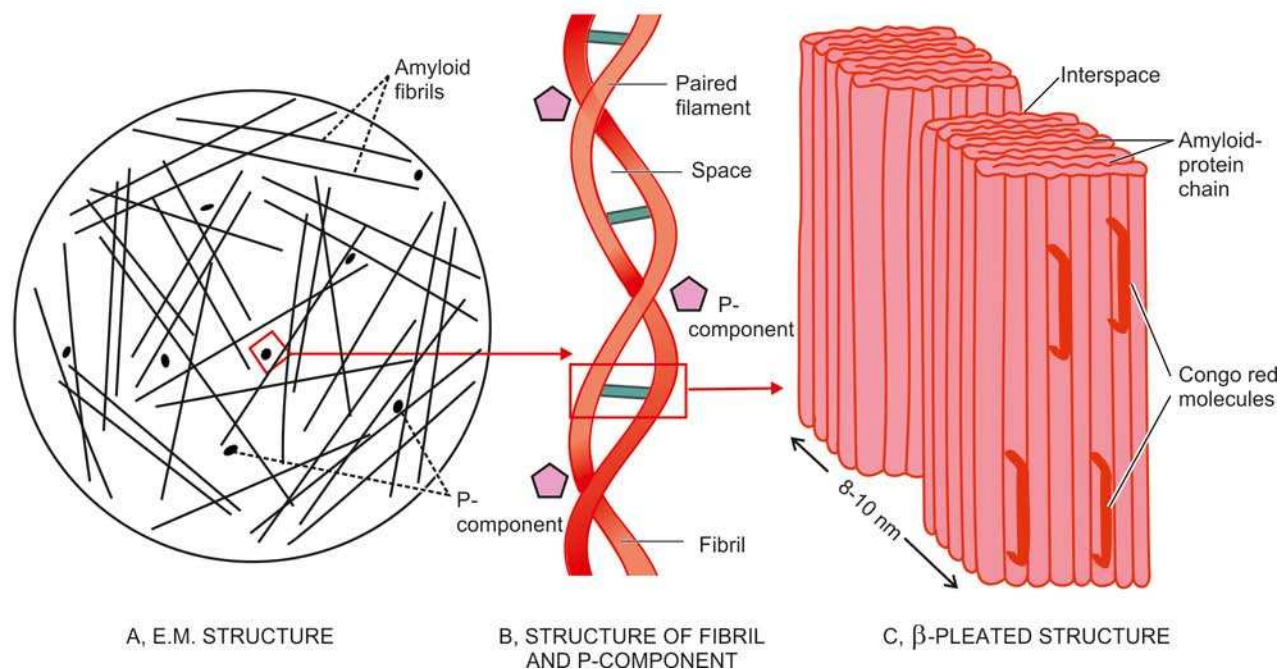

Figure 3.10 Diagrammatic representation of the ultrastructure of amyloid. A, Electron microscopy shows major part consisting of amyloid fibrils (95%) randomly oriented, while the minor part is essentially P-component (5%) B, Each fibril is further composed of double helix of two pleated sheets in the form of *twin filaments* separated by a clear space. P-component has a pentagonal or doughnut profile. C, X-ray crystallography and infra-red spectroscopy shows fibrils having *cross-β-pleated* sheet configuration which produces periodicity that gives the characteristic staining properties of amyloid with Congo red and birefringence under polarising microscopy.

with iodine and turned violet on addition of dilute sulfuric acid. By H&E staining under *light microscopy*, amyloid appears as extracellular, homogeneous, structureless and eosinophilic hyaline material; it stains *positive with Congo red* staining and shows apple-green birefringence on *polarising microscopy*.

The nomenclature of different forms of amyloid is done by putting the alphabet A (A for amyloid), followed by the suffix derived from the name of specific protein constituting amyloid of that type e.g. AL (A for amyloid, L for light chain-derived), AA, ATTR etc.

PHYSICAL AND CHEMICAL NATURE OF AMYLOID

Ultrastructural examination and chemical analysis reveal the complex nature of amyloid. *It emerges that on the basis of morphology and physical characteristics, all forms of amyloid are similar in appearance, but they are chemically heterogeneous.* Based on analysis, amyloid is composed of 2 main types of complex proteins (**Fig. 3.10**):

- I. *Fibril proteins* comprise about 95% of amyloid.
- II. *Non-fibrillar components* which include *P-component* predominantly; and there are several other different proteins which together constitute the remaining 5% of amyloid.

I. Fibril Proteins

By electron microscopy, it became apparent that major component of all forms of amyloid (about 95%) consists of meshwork of fibril proteins. These consist of delicate, randomly dispersed, non-branching amyloid fibres having 4-6 *fibrils*, each measuring 7.5-10 nm in diameter and having indefinite length. These fibrils are wound on each other and are separated by a clear space which contains regularly placed binding sites

for Congo red dye. By X-ray crystallography and infra-red spectroscopy, the fibrils are shown to have *cross-β-pleated* sheet configuration which produces 1000 Å periodicity. These properties give amyloid its characteristic staining properties with Congo red dye and birefringence under polarising microscopy. Based on these features amyloid is given an alternate name of *β-fibrillosis*.

Chemical analysis of fibril proteins of amyloid reveals heterogeneous nature of amyloid. Chemically, following two major forms of amyloid fibril proteins were first identified in 1970s while currently there are 20 other biochemically different proteins which form amyloid fibrils in humans in different clinicopathologic settings. Thus, these proteins can be categorised as under:

- i) AL (amyloid light chain) protein
- ii) AA (amyloid associated) protein
- iii) Other proteins

AL PROTEIN AL amyloid fibril protein is derived from immunoglobulin light chain, which may be complete light chain, or may include amino-terminal segment and part of C region of the immunoglobulin light chain. AL fibril protein is more frequently derived from the lambda (λ) light chain (twice more common) than kappa (κ). However, in any given case, there is amino acid sequence homology.

AL type of fibril protein is produced by immunoglobulin-secreting cells and is therefore seen in association with plasma cell dyscrasias and is included in primary systemic amyloidosis.

AA PROTEIN AA fibril protein is composed of protein with molecular weight of 8.5-kD which is derived from larger precursor protein in the serum called SAA (serum amyloid-associated protein) with a molecular weight of 12.5-kD. Unlike

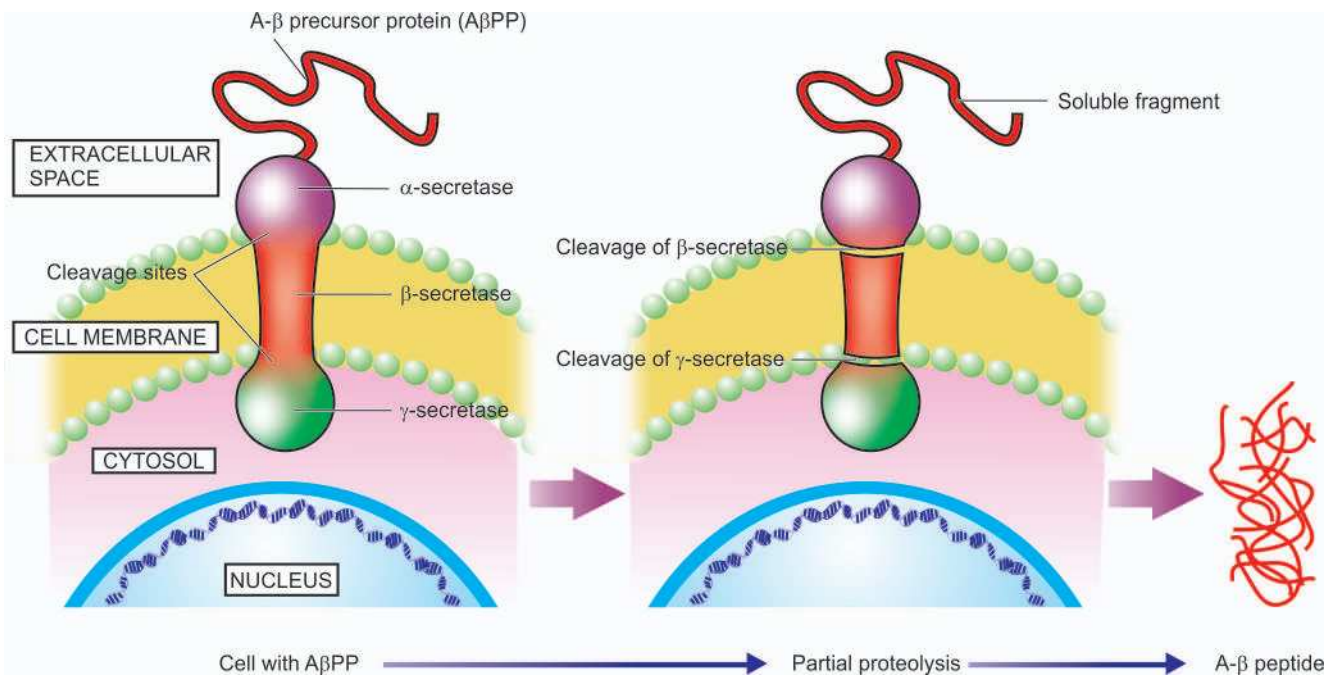

Figure 3.11 Mechanism of amyloid deposits in Alzheimer's disease.

AL amyloid, the deposits of AA amyloid do not have sequence homology. In the plasma, SAA circulates in association with HDL3 (high-density lipoprotein). SAA is an acute phase reactant protein synthesised in the liver, in response to chronic inflammatory and traumatic conditions, and thus the level of SAA is high in these conditions.

AA fibril protein is found in secondary amyloidosis which is seen in association with several examples of chronic infectious and autoimmune inflammatory diseases and disseminated malignancies.

OTHER PROTEINS Apart from the two major forms of amyloid fibril proteins, a few other forms of proteins are found in different clinical states:

1. Transthyretin (TTR) It is a serum protein synthesised in the liver and normally transports thyroxine and retinol (trans-thy-retin). Single amino acid substitution mutations in the structure of TTR results in variant form of protein which is responsible for this form of amyloidosis termed as ATTR.

ATTR is the most common form of hereditary amyloidosis seen in familial amyloid polyneuropathies. However, the deposits of ATTR in the elderly in the heart (senile cardiac amyloidosis) consists of normal TTR without any mutation. Another interesting aspect in ATTR is that despite being inherited, the disease appears in middle age or elderly.

2. Aβ₂-microglobulin (Aβ₂M) This form of amyloid is seen in cases of long-term haemodialysis (for 10-12 years). As the name suggests, β₂M is a small protein which is a normal component of major histocompatibility complex (MHC) class I and has β-pleated sheet structure. β₂M is 11.8 kDa protein that is not filtered by the haemodialysis membrane and thus there is high serum concentration of β₂M protein in these patients. Although the deposit due to Aβ₂M may be systemic in distribution, it has predilection for bones and joints.

3. Amyloid β-peptide (Aβ) Aβ is distinct from Aβ₂M and is deposited in cerebral amyloid angiopathy and neurofibrillary

tangles in Alzheimer's disease. Aβ is derived from amyloid beta precursor protein (AβPP). The latter is a cell surface protein having a single transmembranous domain that functions as a receptor. The Aβ portion of this protein is seen extending into extracellular region. Out of three intramembranous cleavage sites—secretase α, β and γ, partial proteolysis of AβPP due to cleavage of β-secretase and γ-secretase sites generates Aβ i.e. amyloidogenic protein in Alzheimer's disease (Fig. 3.11).

4. Endocrine amyloid from hormone precursor proteins. It includes examples such as amyloid derived from pro-calcitonin (ACal), islet amyloid polypeptide (AIAPP, amylin), pro-insulin (AIns), prolactin (APro) etc.

5. Amyloid of prion protein (APrP) It is derived from precursor prion protein which is a plasma membrane glycoprotein. Prion proteins are proteinaceous infectious particles lacking in RNA or DNA. Amyloid in prionosis occurs due to abnormally folded isoform of the PrP.

II. Non-fibrillar Components

Non-fibrillar components comprise about 5% of the amyloid material. These components include the following:

1. Amyloid P (AP)-component It is synthesised in the liver and is present in all types of amyloid. It is derived from circulating serum amyloid P-component, a glycoprotein resembling the normal serum α₁-glycoprotein and is PAS-positive. It is structurally related to C-reactive protein, an acute phase reactant, but is not similar to it. By electron microscopy, it has a pentagonal profile (P-component) or doughnut-shape with an external diameter of 9 nm and internal diameter of 4 nm.

2. Apolipoprotein-E (apoE) It is a regulator of lipoprotein metabolism and is found in all types of amyloid. One allele, apoE4, increases the risk of Alzheimer precursor protein (APP) deposition in Alzheimer's disease but not in all other types of amyloid deposits.

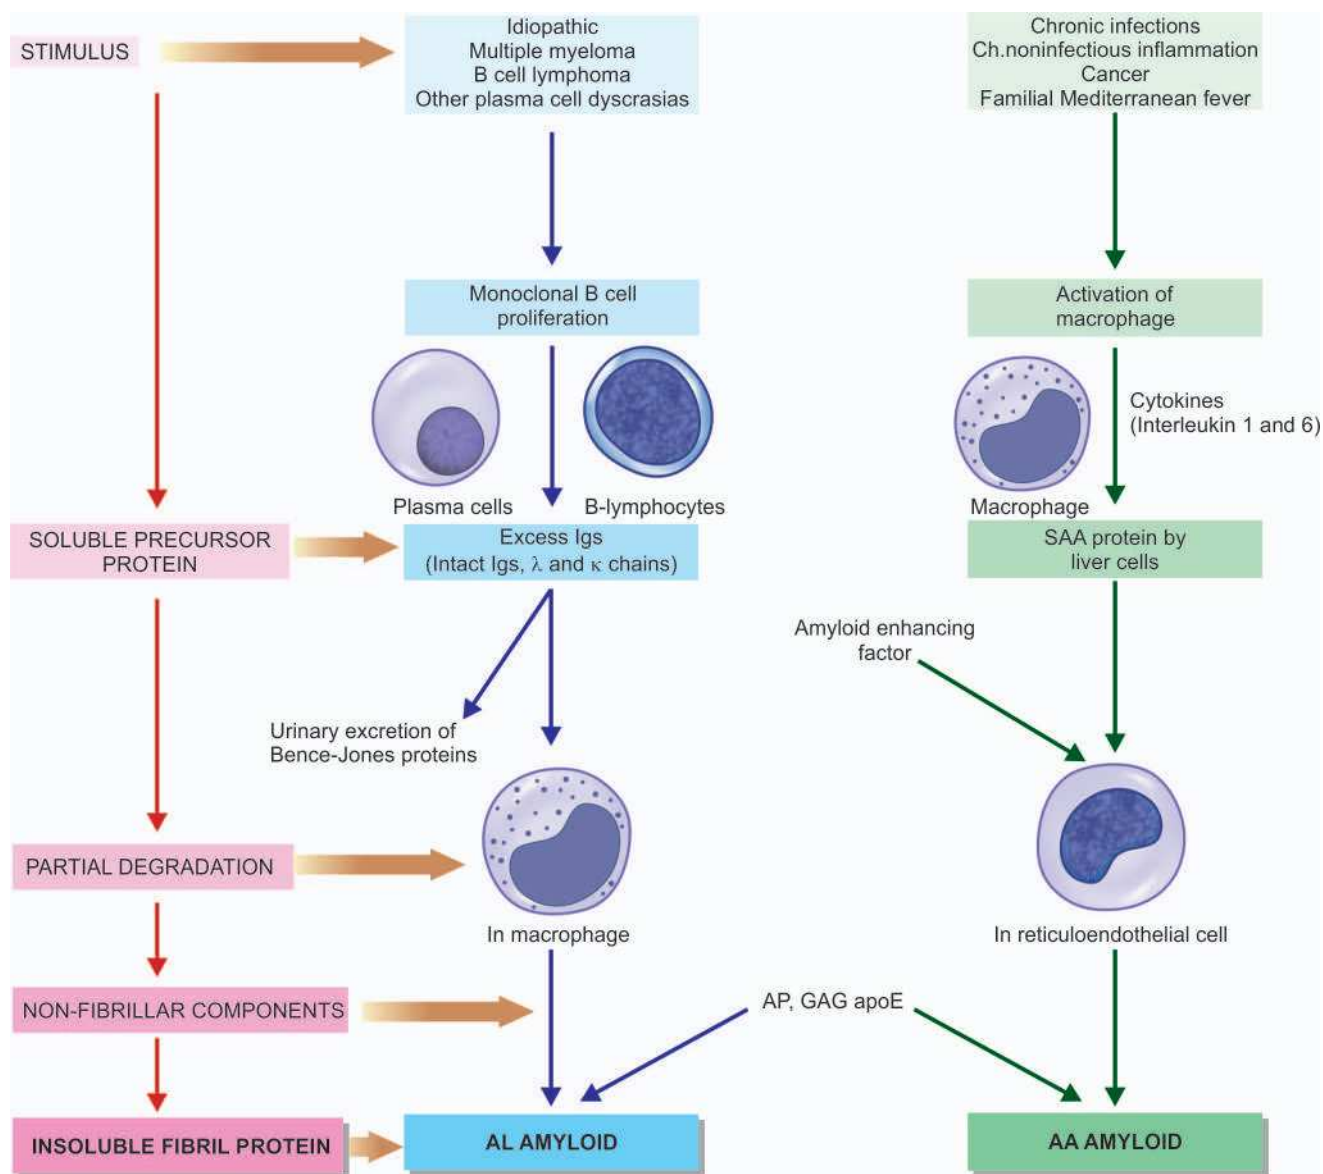

Figure 3.12 Pathogenesis of two main forms of amyloid deposition (AL = Amyloid light chain; AA = Amyloid-associated protein; GAG = Glycosaminoglycan; AP = Amyloid P component). The sequence on left shows general schematic representation common to both major forms of amyloidogenesis.

3. Sulfated glycosaminoglycans (GAGs) These are constituents of matrix proteins, particularly associated is heparan sulfate in all types of tissue amyloid.

4. Other components Besides above, other components such as α -1 anti-chymotrypsin, protein X, components of complement, proteases, and membrane constituents may be seen in the amyloid deposits.

PATHOGENESIS OF AMYLOIDOSIS

The earliest observation that amyloidosis developed in experimental animals who were injected repeatedly with antigen to raise antisera for human use led to the concept that amyloidogenesis was the result of immunologic mechanisms. Thus, AL variety of amyloid protein was isolated first. It is now appreciated that amyloidosis or fibrillogenesis is multifactorial and that different mechanisms are involved in various types of amyloid.

Irrespective of the type of amyloid, amyloidogenesis in general *in vivo*, occurs in the following sequence (**Fig. 3.12**):

1. *Pool of amyloidogenic precursor protein* is present in circulation in different clinical settings and in response to stimuli e.g. increased hepatic synthesis of AA or ATTR, increased synthesis of AL etc.

2. *A nidus for fibrillogenesis*, meaning thereby an alteration in microenvironment, to stimulate deposition of amyloid protein is formed. This alteration involves changes and interaction between basement membrane proteins and amyloidogenic protein.

3. *Partial degradation or proteolysis* occurs prior to deposition of fibrillar protein which may occur in macrophages or reticuloendothelial cells. However, there are exceptions to this generalisation when there is no degradation of proteins such as in ATTR (heredofamilial type in which there are amino acid mutations in most cases), A β 2M (in which there are elevated

levels of normal β_2M protein which remain unfiltered during haemodialysis) and prionosis (in which β -pleated sheet is formed *de novo*).

4. The role of *non-fibrillar components* (e.g. AP, apoE and GAGs) in amyloidosis is fibril stabilisation by protein aggregation and protein folding in a way that it is protected from solubilisation or degradation.

Based on this general pathogenesis, deposition of AL and AA amyloid is briefly outlined below:

Deposition of AL Amyloid

1. The stimulus for production of AL amyloid is some disorder of *immunoglobulin synthesis* e.g. multiple myeloma, B cell lymphoma, other plasma cell dyscrasias.
2. Excessive immunoglobulin production is in the form of *monoclonal gammopathy* i.e. there is production of either intact immunoglobulin, or λ light chain, or κ light chain, or rarely heavy chains. This takes place by monoclonal proliferation of plasma cells, B lymphocytes, or their precursors.
3. *Partial degradation* in the form of limited proteolysis of larger protein molecules occurs in macrophages that are anatomically closely associated with AL amyloid.
4. *Non-fibrillar components* like AP and GAGs play role in folding and aggregation of fibril proteins.

Deposition of AA Amyloid

1. AA amyloid is directly related to *SAA levels*, a high-density lipoprotein. SAA is synthesised by the liver in response to *cytokines*, notably interleukin 1 and 6, released from activated macrophages.
2. The levels of SAA are elevated in *long-standing tissue destruction* e.g. in chronic inflammation, cancers. However, SAA levels in isolation do not always lead to AA amyloid.

3. As in AL amyloid, *partial degradation* in the form of limited proteolysis takes place in reticuloendothelial cells.

4. In AA amyloid, a significant role is played by another glycoprotein, *amyloid enhancing factor (AEF)*. AEF is elaborated in chronic inflammation, cancer and familial Mediterranean fever. AEF acts as a nidus and accelerates AA amyloid deposition.

5. As in AL amyloid, there is a role of *AP component and glycosaminoglycans* in the fibril protein aggregation and its protection from disaggregation again.

CLASSIFICATION OF AMYLOIDOSIS

Over the years, amyloidosis has been classified in a number of ways:

- ◆ **Based on cause**, into *primary* (with unknown cause and the deposition is in the disease itself) and *secondary* (as a complication of some underlying known disease) amyloidosis.
- ◆ **Based on extent of amyloid deposition**, into *systemic (generalised)* involving multiple organs and *localised amyloidosis* involving one or two organs or sites.
- ◆ **Based on clinical location**, into *pattern I* (involving tongue, heart, bowel, skeletal and smooth muscle, skin and nerves), *pattern II* (principally involving liver, spleen, kidney and adrenals) and *mixed pattern* (involving sites of both pattern I and II).
- ◆ **Based on precursor biochemical proteins**, into specific type of serum amyloid proteins.

With availability of biochemical composition of various forms of amyloid and diverse clinical settings in which these specific biochemical forms of amyloid are deposited, a *clinicopathologic classification* has been proposed which is widely accepted (**Table 3.11**). According to this classification, amyloidosis can be divided into 2 major categories and their subtypes depending upon clinical settings:

Table 3.11 Classification of amyloidosis.

| CATEGORY | ASSOCIATED DISEASE | BIOCHEMICAL TYPE | ORGANS COMMONLY INVOLVED |
|--|---|----------------------------------|--|
| A. SYSTEMIC (GENERALISED) AMYLOIDOSIS | | | |
| 1. <i>Primary</i> | Plasma cell dyscrasias | AL type | Heart, bowel, skin, nerves, kidney |
| 2. <i>Secondary (Reactive)</i> | Chronic inflammation, cancers | AA type | Liver, spleen, kidneys, adrenals |
| 3. <i>Haemodialysis-associated</i> | Chronic renal failure | A β_2 M | Synovium, joints, tendon sheaths |
| 4. <i>Heredofamilial</i> | | | |
| i. <i>Hereditary polyneuropathies</i> | — | ATTR | Peripheral and autonomic nerves, heart |
| ii. <i>Familial Mediterranean fever</i> | — | AA type | Liver, spleen, kidneys, adrenals |
| iii. <i>Rare hereditary forms</i> | — | AApoAI, AGel ALys, AFib, ACys | Systemic amyloidosis |
| B. LOCALISED AMYLOIDOSIS | | | |
| 1. <i>Senile cardiac</i> | Senility | ATTR | Heart |
| 2. <i>Senile cerebral</i> | Alzheimer's, transmissible encephalopathy | A β , APrP | Cerebral vessels, plaques, neurofibrillary tangles |
| 3. <i>Endocrine</i> | Medullary carcinoma Type 2 diabetes mellitus | Procalcitonin Proinsulin | Thyroid Islets of Langerhans |
| 4. <i>Tumour-forming</i> | Lungs, larynx, skin, urinary bladder, tongue, eye | AL | Respective anatomic location |

(AL= Amyloid light chain; AA= Amyloid-associated protein; A β_2 M= Amyloid β_2 -microglobulin; ATTR= Amyloid transthyretin; APrP= Amyloid of prion proteins, A β = β -amyloid protein).

- A. *Systemic (generalised) amyloidosis:*
1. Primary (AL)
 2. Secondary/reactive/ inflammatory (AA)
 3. Haemodialysis-associated (A β 2M)
 4. Heredofamilial (ATTR, AA, Others)
- B. *Localised amyloidosis:*
1. Senile cardiac (ATTR)
 2. Senile cerebral (A β , APrP)
 3. Endocrine (Hormone precursors)
 4. Tumour-forming (AL)

A. SYSTEMIC AMYLOIDOSIS

1. Primary Systemic (AL) Amyloidosis

Primary amyloidosis consisting of AL fibril proteins is systemic or generalised in distribution. About 30% cases of AL amyloid have some form of plasma cell dyscrasias, most commonly multiple myeloma (in about 15-20% cases), and less often other monoclonal gammopathies such as Waldenström's macroglobulinaemia, heavy chain disease, solitary plasmacytoma and B cell lymphoma. The neoplastic plasma cells usually are a single clone and, therefore, produce the same type of immunoglobulin light chain or part of light chain. Almost all cases of multiple myeloma have either λ or κ light chains (Bence Jones proteins) in the serum and are excreted in the urine. However, in contrast to normal or myeloma light chains, AL is twice more frequently derived from λ light chains.

The remaining 70% cases of AL amyloid do not have evident B-cell proliferative disorder or any other associated diseases and thus are cases of true 'primary' (idiopathic) amyloidosis. However, by more sensitive methods, some plasma cell dyscrasias are detectable in virtually all patients with AL. Majority of these cases too have a single type of abnormal immunoglobulin in their serum (monoclonal) and that these patients have some degree of plasmacytosis in the bone marrow, suggesting the origin of AL amyloid from precursor plasma cells.

AL amyloid is most prevalent type of systemic amyloidosis in North America and Europe and is seen in individuals past the

age of 40 years and is rapidly progressive disease if not treated. Primary amyloidosis is often severe in the heart, kidney, bowel, skin, peripheral nerves, respiratory tract, skeletal muscle and tongue (macroglossia).

Treatment of AL amyloid is targetted at reducing the underlying clonal expansion of plasma cells. Median survival with no treatment after diagnosis is about one year.

2. Secondary/Reactive (AA) Systemic Amyloidosis

The second form of systemic or generalised amyloidosis is reactive or inflammatory or secondary in which the fibril proteins contain AA amyloid. Secondary or reactive amyloidosis occurs typically as a complication of chronic infectious (e.g. tuberculosis, bronchiectasis, chronic osteomyelitis, chronic pyelonephritis, leprosy, chronic skin infections), non-infectious chronic inflammatory conditions associated with tissue destruction (e.g. autoimmune disorders such as rheumatoid arthritis, lupus, inflammatory bowel disease), some tumours (e.g. renal cell carcinoma, Hodgkin's disease) and in familial Mediterranean fever, an inherited disorder (discussed below).

Secondary amyloidosis is typically distributed in solid abdominal viscera like the kidney, liver, spleen and adrenals. Secondary reactive amyloidosis is seen less frequently in developed countries due to containment of infections before they become chronic but this is the more common type of amyloidosis in underdeveloped and developing countries of the world.

Secondary systemic amyloidosis can occur at any age and is the only form of amyloid which can occur in children. Treatment lies in treating the underlying infectious or inflammatory disorder resulting in lowering of SAA protein in blood.

The contrasting features of the two main forms of systemic amyloidosis are given in **Table 3.12**.

3. Haemodialysis-Associated (A β 2M) Amyloidosis

Patients on long-term dialysis for more than 10 years for chronic renal failure may develop systemic amyloidosis derived from

Table 3.12 Contrasting features of primary and secondary amyloidosis.

| FEATURE | PRIMARY AMYLOID | SECONDARY AMYLOID |
|-----------------------------------|---|---|
| 1. <i>Biochemical composition</i> | AL (Light chain proteins); lambda chains more common than kappa; sequence homology of chains | AA (Amyloid associated proteins); derived from larger precursor protein SAA; no sequence homology of polypeptide chain |
| 2. <i>Associated diseases</i> | Plasma cell dyscrasias e.g. multiple myeloma, B cell lymphomas, others | Chronic inflammation e.g. infections (TB, leprosy, osteomyelitis, bronchiectasis), autoimmune diseases (rheumatoid arthritis, IBD), cancers (RCC, Hodgkin's disease), FMF |
| 3. <i>Pathogenesis</i> | Stimulus \rightarrow Monoclonal B cell proliferation \rightarrow Excess of Igs and light chains \rightarrow Partial degradation \rightarrow Insoluble AL fibril | Stimulus \rightarrow Chronic inflammation \rightarrow Activation of macrophages \rightarrow Cytokines (IL1,6) \rightarrow Partial degradation \rightarrow AEF \rightarrow Insoluble AA fibril |
| 4. <i>Incidence</i> | Most common in US and other developed countries | Most common worldwide, particularly in developing countries |
| 5. <i>Age</i> | >40 years | Any age including children |
| 6. <i>Course and prognosis</i> | Rapidly progressive, dismal | Better, treat the underlying cause |
| 7. <i>Organ distribution</i> | Kidney, heart, bowel, nerves | Kidney, liver, spleen, adrenals |
| 8. <i>Stains to distinguish</i> | Congophilia persists after permanganate treatment of section; specific immunostains anti- λ , anti- κ | Congophilia disappears after permanganate treatment of section; specific immunostain anti-AA |

β_2 -microglobulin which is normal component of MHC. The amyloid deposits are preferentially found in the vessel walls at the synovium, joints, tendon sheaths and subchondral bones. Carpal tunnel syndrome is common presentation. However, systemic distribution has also been observed in these cases showing bulky visceral deposits of amyloid. Cessation of dialysis after renal transplant causes symptomatic improvement.

4. Heredofamilial Amyloidosis

A few rare examples of genetically-determined amyloidosis having familial occurrence and seen in certain geographic regions have been described. These are as under:

i) Hereditary polyneuropathic (ATTR) amyloidosis This is an autosomal dominant disorder in which amyloid is deposited in the peripheral and autonomic nerves resulting in muscular weakness, pain and paraesthesia, or may have cardiomyopathy. This type of amyloid is derived from transthyretin (ATTR) with single amino acid substitution in the structure of TTR; about 60 types of such mutations have been described. Though hereditary, the condition appears well past middle life.

ii) Amyloid in familial Mediterranean fever (AA) This is an autosomal recessive disease and is seen in the Mediterranean region (i.e. people residing in the countries surrounding the Mediterranean sea e.g. Sephardic Jews, Armenians, Arabs and Turks). The condition is characterised by periodic attacks of fever and polyserositis i.e. inflammatory involvement of the pleura, peritoneum, and synovium causing pain in the chest, abdomen and joints respectively. Amyloidosis occurring in these cases is AA type, suggesting relationship to secondary amyloidosis due to chronic inflammation. The distribution of this form of heredofamilial amyloidosis is similar to that of secondary amyloidosis.

iii) Rare hereditary forms Heredofamilial mutations of several normal proteins have been reported e.g. apolipoprotein I (AApoAI), gelsolin (AGel), lysozyme (ALys), fibrinogen α -chain (AFib), cystatin C (ACys) and amyloid of familial dementia etc. These types may also result in systemic amyloidosis.

B. LOCALISED AMYLOIDOSIS

1. Senile cardiac amyloidosis (ATTR) Senile cardiac amyloidosis is seen in 50% of people above the age of 70 years. The deposits are seen in the heart and aorta. The type of amyloid in these cases is ATTR but without any change in the protein structure of TTR.

2. Senile cerebral amyloidosis (A β , APrP) Senile cerebral amyloidosis is heterogeneous group of amyloid deposition of varying etiologies that includes sporadic, familial, hereditary and infectious. Some of the important diseases associated with cerebral amyloidosis and the corresponding amyloid proteins are: Alzheimer's disease (A β), Down's syndrome (A β) and transmissible spongiform encephalopathies (APrP) such as in Creutzfeldt-Jakob disease, fatal familial insomnia, mad cow disease, kuru.

In Alzheimer's disease, deposit of amyloid is seen as Congoophilic angiopathy (amyloid material in the walls of cerebral blood vessels), neurofibrillary tangles and in senile plaques.

3. Endocrine amyloidosis (Hormone precursors) Some endocrine lesions are associated with microscopic deposits of amyloid. The examples are as follows:

- i) Medullary carcinoma of the thyroid (from procalcitonin i.e. ACal).
- ii) Islet cell tumour of the pancreas (from islet amyloid polypeptide i.e. AIAPP or amylin).
- iii) Type 2 diabetes mellitus (from pro-insulin, i.e. AIns).
- iv) Pituitary amyloid (from prolactin i.e. APro).
- v) Isolated atrial amyloid deposits (from atrial natriuretic factor i.e. AANF).
- vi) Familial corneal amyloidosis (from lactoferrin i.e. ALac).

4. Localised tumour forming amyloid (AL) Sometimes, isolated tumour like formation of amyloid deposits are seen e.g. in lungs, larynx, skin, urinary bladder, tongue, eye, isolated atrial amyloid. In most of these cases, the amyloid type is AL.

STAINING CHARACTERISTICS OF AMYLOID

1. STAIN ON GROSS The oldest method since the time of Virchow for demonstrating amyloid on cut surface of a gross specimen, or on the frozen/paraffin section is iodine stain. Lugol's iodine imparts *mahogany brown* colour to the amyloid-containing area which on addition of dilute sulfuric acid turns blue. This starch-like property of amyloid is due to AP component, a glycoprotein, present in all forms of amyloid.

Various stains and techniques employed to distinguish and confirm amyloid deposits in sections are given in **Table 3.13**.

2. H & E Amyloid by light microscopy with haematoxylin and eosin staining appears as extracellular, homogeneous, structureless and eosinophilic hyaline material, especially in relation to blood vessels. However, if the deposits are small, they are difficult to detect by routine H and E stains. Besides, a few other hyaline deposits may also take pink colour (page 17).

3. METACHROMATIC STAINS (ROSANILINE DYES) Amyloid has the property of metachromasia i.e. the dye reacts with amyloid and undergoes a colour change. Metachromatic stains employed are rosaniline dyes such as methyl violet and crystal violet which impart *rose-pink* colouration to amyloid deposits. However, small amounts of amyloid are missed, mucins also have metachromasia; moreover, aqueous mountants are required for seeing the preparation. Therefore, this method has low sensitivity and lacks specificity.

4. CONGO RED AND POLARISED LIGHT All types of amyloid have affinity for Congo red stain; therefore this method is used for confirmation of amyloid of all types. The stain may be used on both gross specimens and microscopic sections; amyloid of all types stains *pink red colour*. If the stained section is viewed in polarised light, the amyloid characteristically shows *apple-green birefringence* due to cross- β -pleated sheet configuration of amyloid fibrils. The stain can also be used to distinguish between AL and AA amyloid (primary and secondary amyloid respectively). After prior treatment with permanganate or trypsin on the section, Congo red stain is repeated—in the case of primary amyloid (AL amyloid), the Congo red positivity (congophilia) persists,* while it turns negative for Congo red in secondary amyloid (AA amyloid). Congo red dye can also be used as an *in vivo* test (described below).

5. FLUORESCENT STAINS Fluorescent stain thioflavin-T binds to amyloid and fluoresces *yellow* under ultraviolet light

*Easy way to remember: Three *ps* i.e. there is *p*ersistence of congophilia after *p*ermanganate treatment in *p*rimary amyloid

Table 3.13 Staining characteristics of amyloid.

| STAIN | APPEARANCE |
|--|---|
| 1. H & E | Pink, hyaline, homogeneous |
| 2. Methyl violet/Crystal violet | Metachromasia: rose-pink |
| 3. Congo red | Light microscopy: pink-red Polarising light: red-green birefringence |
| 4. Thioflavin-T/Thioflavin-S | Ultraviolet light: fluorescence |
| 5. Immunohistochemistry (antibody against fibril protein) | Immunoreactivity: Positive |

i.e. amyloid emits secondary fluorescence. Thioflavin-S is less specific.

6. IMMUNOHISTOCHEMISTRY Type of amyloid can be classified by immunohistochemical stains in which corresponding antibody stain is used against the specific amyloid protein acting as antigen. However, for mere confirmation of any type of amyloid, most useful stain is *anti-AP stain* since P component is present in all forms of amyloid. But for determining the biochemical type of amyloid, various antibody stains against the specific antigenic protein types of amyloid are commercially available such as *anti-AA*, *anti-lambda* (λ), *anti-kappa* (κ), *transthyretin* antibody stains etc.

DIAGNOSIS OF AMYLOIDOSIS

Amyloidosis may be detected as an unsuspected morphologic finding in a case, or the changes may be severe so as to produce symptoms and may even cause death. The diagnosis of amyloid disease can be made from the following investigations:

1. TISSUE DIAGNOSIS Routine examination of biopsy or fine needle aspiration, followed by Congo red staining and examination under polarizing microscopy, are the two confirmatory methods of tissue diagnosis of amyloidosis:

◆ **Histologic examination** of biopsy material is the commonest and confirmatory method for diagnosis in a suspected case of amyloidosis. Biopsy of an obviously *affected organ* is likely to offer the best results e.g. *kidney biopsy* in a case on dialysis, *sural nerve biopsy* in familial polyneuropathy. In systemic amyloidosis, renal biopsy provides the best detection rate, but *rectal biopsy* also has a good pick up rate. However, *gingiva* and *skin biopsy* have poor result.

◆ **Fine needle aspiration** of abdominal *subcutaneous fat* followed by Congo red staining and polarising microscopic examination for confirmation has become an acceptable simple and useful technique with excellent result (Fig. 3.13).

2. IN VIVO CONGO RED TEST A known quantity of Congo red dye may be injected intravenously in living patient. If amyloidosis is present, the dye gets bound to amyloid deposits and its levels in blood rapidly decline. The test is, however, not popular due to the risk of anaphylaxis to the injected dye.

3. OTHER TESTS Besides tissue diagnosis, a few other tests which are supportive but not confirmatory of amyloidosis include protein electrophoresis, immunoelectrophoresis of urine and serum, and bone marrow aspiration.

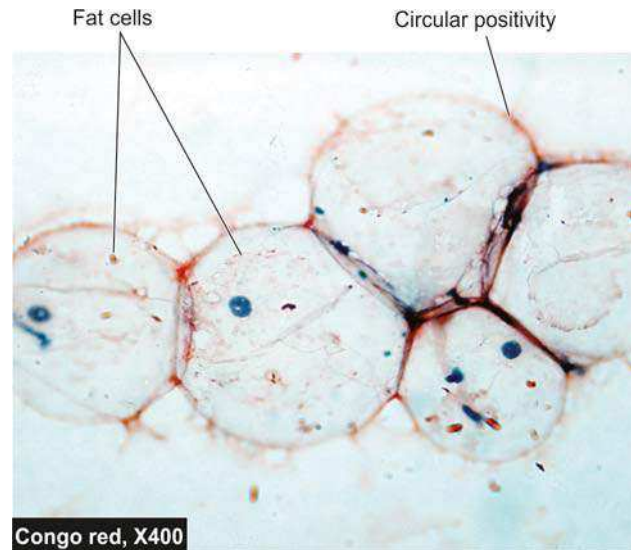

Figure 3.13 Abdominal fat aspirate smear stained with Congo red.

MORPHOLOGIC FEATURES OF AMYLOIDOSIS OF ORGANS

Although amyloidosis of different organs shows variation in morphologic pattern, some features are applicable in general to most of the involved organs.

Locations of amyloid deposit In general, amyloid proteins get filtered from blood across the basement membrane of vascular capillaries into extravascular spaces. Thus, most commonly amyloid deposits appear at the contacts between the vascular spaces and parenchymal cells, in the extracellular matrix and within the basement membranes of blood vessels.

Grossly, the affected organ is usually enlarged, pale and rubbery. Cut surface shows firm, waxy and translucent parenchyma which takes positive staining with the iodine test.

Microscopically, the deposits of amyloid are found in the extracellular locations, initially in the walls of small blood vessels producing microscopic changes and effects, while later the deposits are in large amounts causing pressure atrophy of parenchymal cells.

Based on these general features of amyloidosis, the salient pathologic findings of major organ involvements are described here.

AMYLOIDOSIS OF KIDNEYS

Amyloidosis of the kidneys is most common and most serious because of ill-effects on renal function. The deposits in the kidneys are found in most cases of secondary amyloidosis and in about one-third cases of primary amyloidosis. Amyloidosis of the kidney accounts for about 20% of deaths from amyloidosis. Even small quantities of amyloid deposits in the glomeruli can cause proteinuria and nephrotic syndrome.

Grossly, the kidneys may be normal-sized, enlarged or terminally contracted due to ischaemic effect of narrowing of vascular lumina. Cut surface is pale, waxy and translucent (Fig. 3.14).

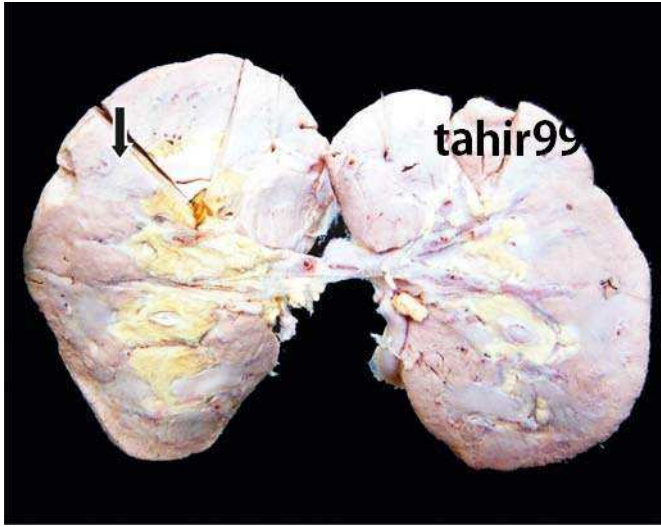

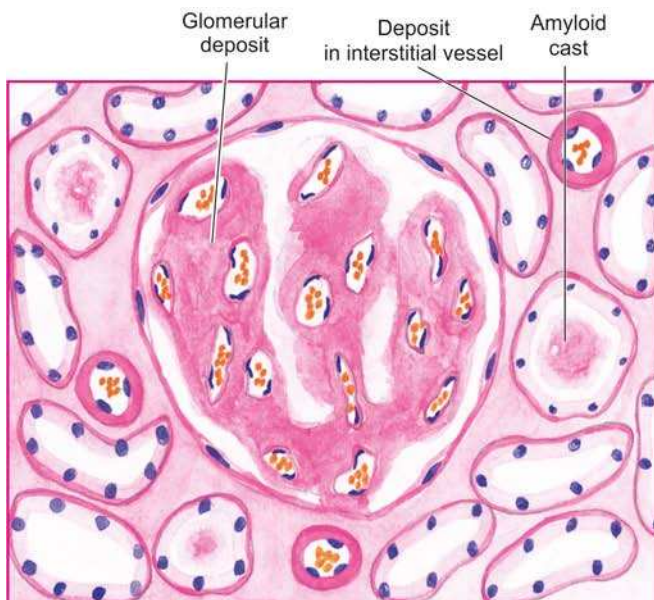

Figure 3.14 Amyloidosis of kidney. The kidney is small and pale in colour. Sectioned surface shows loss of cortico-medullary distinction (arrow) and pale, waxy translucency.

Microscopically, amyloid deposition occurs primarily in the glomeruli, though it may involve peritubular interstitial tissue and the walls of arterioles as well (**Fig. 3.15**):

- ◆ *In the glomeruli*, the deposits initially appear on the basement membrane of the glomerular capillaries, but later extend to produce luminal narrowing and distortion of the glomerular capillary tuft. This results in abnormal increase in permeability of the glomerular capillaries to macromolecules with consequent proteinuria and nephrotic syndrome.

- ◆ *In the tubules*, the amyloid deposits likewise begin close to the tubular epithelial basement membrane. Subsequently, the deposits may extend further outwards into the intertubular connective tissue, and inwards to produce degenerative changes in the tubular epithelial cells and amyloid casts in the tubular lumina.

- ◆ *Vascular involvement* affects chiefly the walls of small arterioles and venules, producing narrowing of their lumina and consequent ischaemic effects.

- ◆ *Congo red staining* imparts red pink colour and polarising microscopy shows apple-green birefringence which confirms the presence of amyloid (**Fig. 3.16**).

AMYLOIDOSIS OF SPLEEN

Amyloid deposition in the spleen, for some unknown reasons, may have one of the following two patterns (**Fig. 3.17**):

1. SAGO SPLEEN *Grossly*, splenic enlargement is not marked and cut surface shows characteristic translucent pale and waxy nodules resembling sago grains and hence the name.

Microscopically, the amyloid deposits begin in the walls of the arterioles of the white pulp and may subsequently extend out and replace the follicles.

2. LARDACEOUS SPLEEN *Grossly*, there is generally moderate to marked splenomegaly (weight up to 1 kg). Cut surface of the spleen shows map-like areas of amyloid (lardaceous-lard-like; *lard* means fat of pigs) (**Fig. 3.18**).

Microscopically, the deposits involve the red pulp in the walls of splenic sinuses and the small arteries and in the connective tissue (**Fig. 3.19**). Confirmation is by observing Congo red staining and demonstration of apple-green birefringence under polarising microscopy in the corresponding positive areas.

AMYLOIDOSIS OF LIVER

In about half the cases of systemic amyloidosis, liver is involved by amyloidosis.

Grossly, the liver is often enlarged, pale, waxy and firm.

Histologically, the features are as under (**Fig. 3.20**):

- ◆ The amyloid initially appears in the space of Disse (the space between the hepatocytes and sinusoidal endothelial cells).

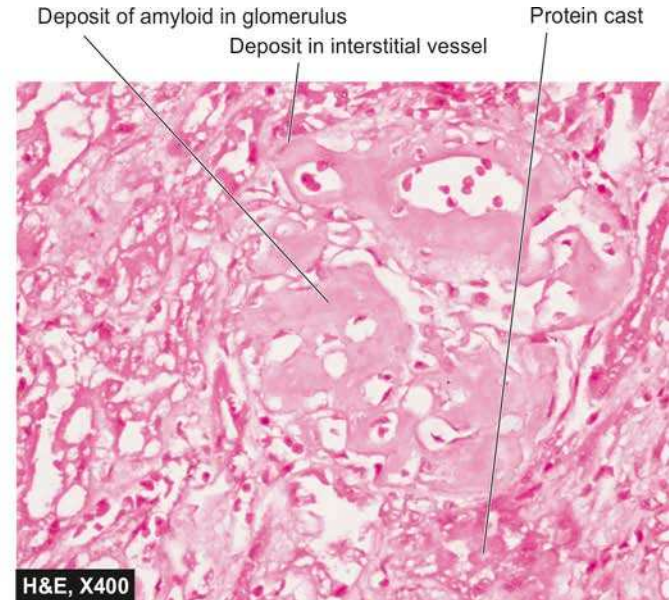

Figure 3.15 Amyloidosis of kidney. The amyloid deposits are seen mainly in the glomerular capillary tuft. The deposits are also present in peritubular connective tissue producing atrophic tubules and amyloid casts in the tubular lumina, and in the arterial wall producing luminal narrowing.

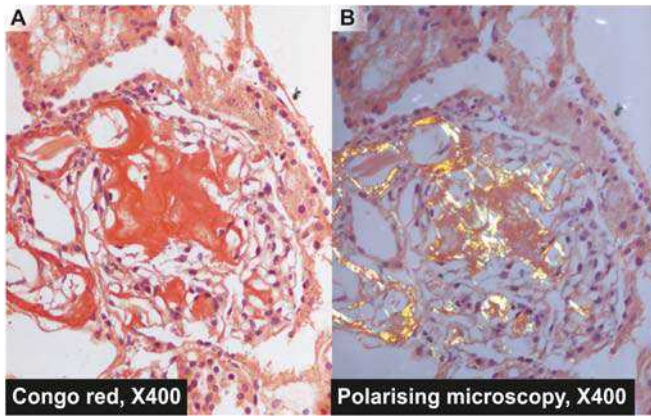

Figure 3.16 Amyloidosis kidney, Congo red stain. A, The amyloid deposits are seen mainly in the glomerular capillary tuft stained red-pink (Congophilia). B, Viewing the same under polarising microscopy, the congophilic areas show apple-green birefringence.

- ◆ Later, as the deposits increase, they compress the cords of hepatocytes so that eventually the liver cells are shrunken and atrophic and replaced by amyloid. However, hepatic function remains normal even at an advanced stage of the disease.
- ◆ To a lesser extent, portal tracts and Kupffer cells are involved in amyloidosis.

AMYLOIDOSIS OF HEART

Heart is involved in systemic amyloidosis quite commonly, more so in the primary than in secondary systemic amyloidosis. It may also be involved in localised form of amyloidosis (senile cardiac). In advanced cases, there may be a pressure atrophy of the myocardial fibres and impaired ventricular function which may produce restrictive cardiomyopathy. Amyloidosis of the heart may produce arrhythmias due to deposition in the conduction system.

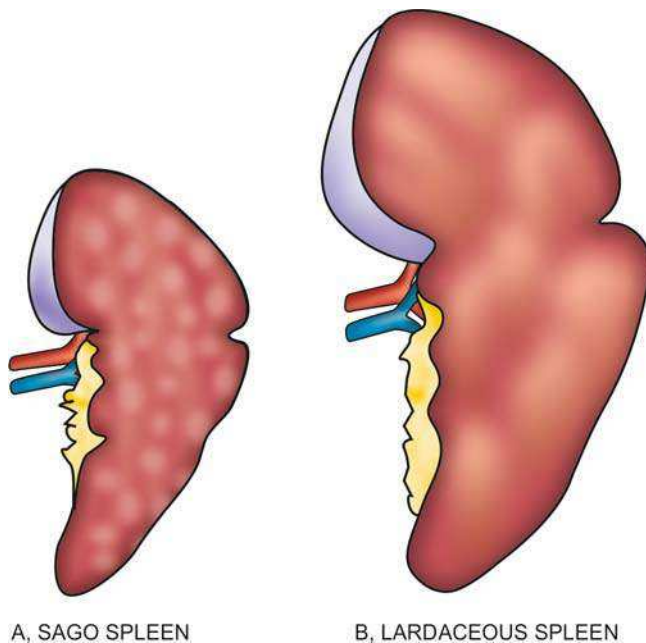

Figure 3.17 Gross patterns of amyloidosis of the spleen.

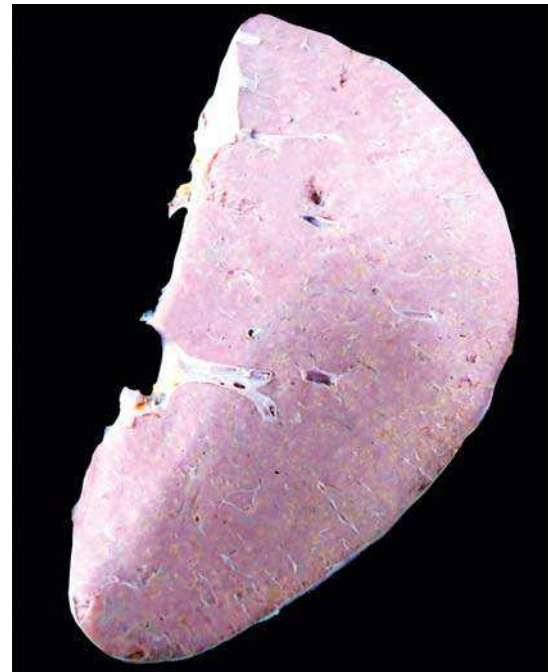

Figure 3.18 Lardaceous amyloidosis of the spleen. The sectioned surface shows presence of plaques waxy translucency in a map-like pattern.

Grossly, the heart may be enlarged. The external surface is pale, translucent and waxy. The epicardium, endocardium and valves show tiny nodular deposits or raised plaques of amyloid.

Microscopically, the changes are as under:

- ◆ Amyloid deposits are seen in and around the coronaries and their small branches.
- ◆ In cases of primary amyloidosis of the heart, the deposits of AL amyloid are seen around the myocardial fibres in ring-like formations (ring fibres).
- ◆ In localised form of amyloid of the heart, the deposits are seen in the left atrium and in the interatrial septum.

AMYLOIDOSIS OF ALIMENTARY TRACT

Involvement of the gastrointestinal tract by amyloidosis may occur at any level from the oral cavity to the anus. Rectal and gingival biopsies are the common sites for diagnosis of systemic amyloidosis. The deposits are initially located around the small blood vessels but later may involve adjacent layers of the bowel wall. Tongue may be the site for tumour-forming amyloid, producing macroglossia.

OTHER ORGANS

The deposits of amyloid may also occur in various other tissues such as pituitary, thyroid, adrenals, skin, lymph nodes, respiratory tract and peripheral and autonomic nerves.

PROGNOSIS OF AMYLOIDOSIS

Amyloidosis may be an incidental finding at autopsy, or in symptomatic cases diagnosis can be made from the methods given above, biopsy examination being the most important method. The prognosis of patients with generalised amyloidosis is generally poor. Primary amyloidosis, if left untreated, is rapidly progressive and fatal. Therapy in these cases is directed at reducing the clonal marrow plasma cells

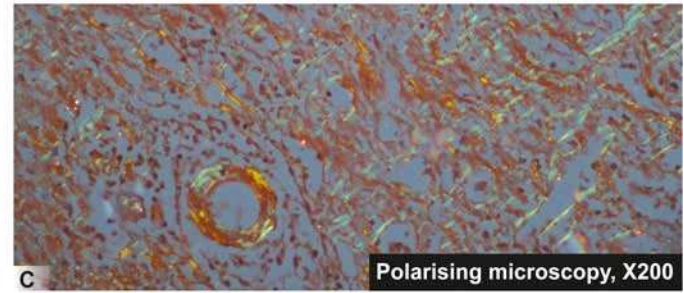

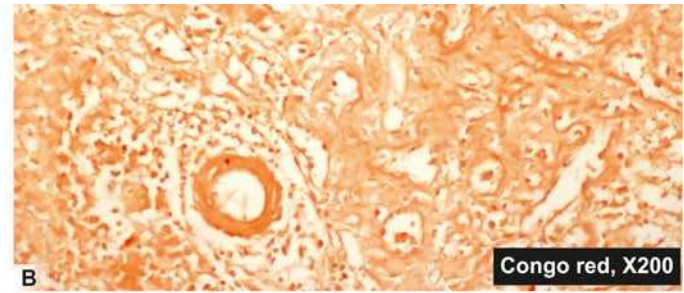

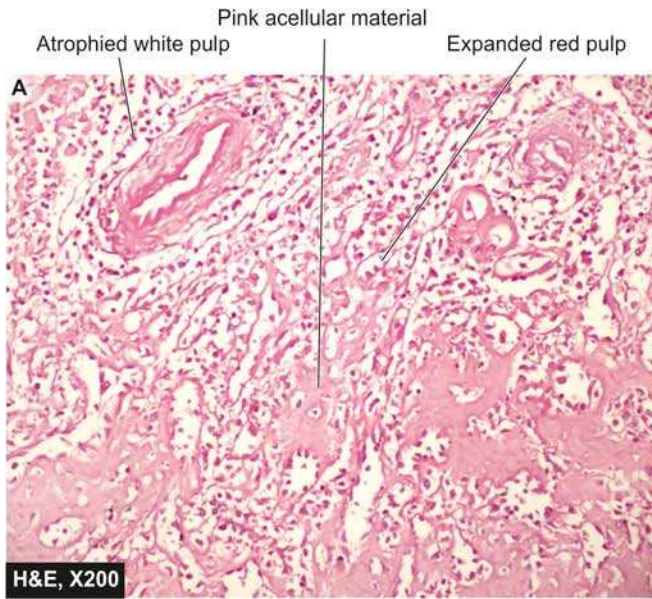

Figure 3.19 Amyloidosis spleen. A, The pink acellular amyloid material is seen in the red pulp causing atrophy of white pulp. B, Congo red staining shows Congo-philia as seen by red-pink colour. C, When viewed under polarising microscopy the corresponding area shows apple-green birefringence.

as is done for treatment of multiple myeloma. For secondary reactive amyloidosis, control of inflammation or infection is the mainstay of treatment. Secondary amyloidosis has somewhat better outcome due to controllable underlying condition.

Renal failure and cardiac arrhythmias are the most common causes of death in most cases of systemic amyloidosis.

GIST BOX 3.7 Amyloidosis

By H&E staining under *light microscopy*, all forms of amyloid appear as extracellular, homogeneous, structureless and eosinophilic hyaline material; it stains *positive with Congo red* staining and shows apple-green birefringence on *polarising microscopy*.

Biochemically, *fibril proteins* comprise about 95% of amyloid while *non-fibrillar components* constitute the remaining 5% of amyloid.

Fibrils proteins are predominantly are of two types: AL (primary amyloid in association with plasma cell and B cell proliferative disorders) and AA (secondary amyloid seen in chronic infections and chronic inflammatory diseases); others are transthyretin or ATTR (in hereditary forms), A β 2-microglobulin or A β 2M (seen in patients on long-term haemodialysis), amyloid β -peptide or A β (seen in Alzheimer's disease), endocrine amyloid from hormone precursor proteins (seen in type 2 diabetes, medullary carcinoma thyroid etc) and amyloid of prion protein or APrP.

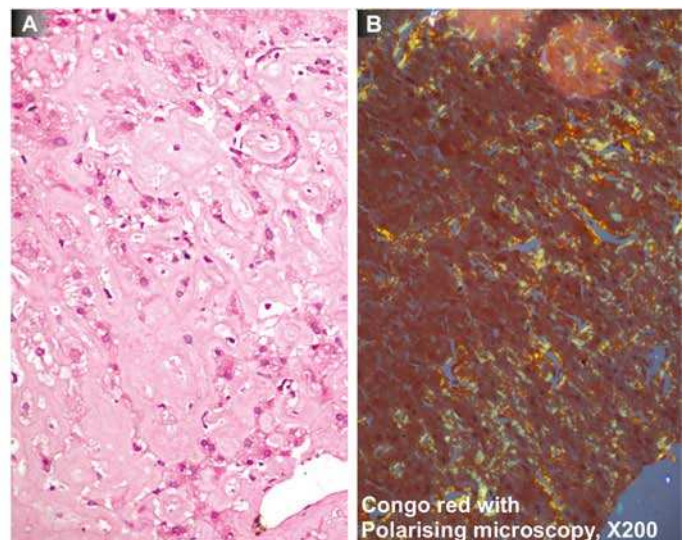

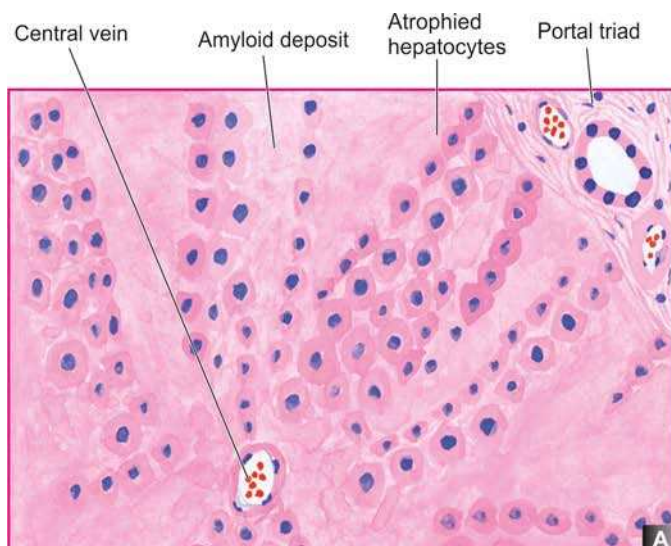

Figure 3.20 Amyloidosis of the liver. A, The deposition is extensive in the space of Disse causing compression and pressure atrophy of hepatocytes. B, Congo red staining shows congo-philia which under polarising microscopy shows apple-green birefringence.

- ▣ *Non-fibrillar components* consist mainly of P component seen in all forms of amyloid; others are apolipoprotein-E, sulfated glycosaminoglycans etc.
- ▣ *Pathogenesis* of amyloid includes rise in level of precursor of fibrillary protein (AL in primary and SAA in secondary form) followed by its partial degradation by reticuloendothelial cells. Non-fibrillary components facilitate protein aggregation and protection against solubilisation.
- ▣ Amyloid deposition causes morphologic and functional disturbance of the affected organ. The affected organ is enlarged, waxy and translucent.
- ▣ Primary amyloidosis is rapidly progressive with poor prognosis. Secondary form can occur at any age including children and has better outlook by control of the underlying chronic infection or autoimmune disease.

CLINICAL CASE 1

A 46 years old male is admitted to medical ward with history of shortness of breath, loss of weight and appetite, and low-grade fever, all for the last one month. He has been smoking *bidis* for 25 years, and gives history of having productive cough with foul smelling expectoration for 15 years, interspersed with haemoptysis off and on. During these years, he had two episodes of bronchopneumonia.

On examination, he is poorly built and poorly nourished. His pulse rate is 90 per minute, respiratory rate 45 per minute, and blood pressure 130/90 mmHg. He has pallor ++, icterus +, pedal oedema +, and grade II clubbing of fingers. On auscultation of chest, rhonchi and crepts are heard.

1. **Discuss the clinical correlation with pathogenesis of the features.**
2. **What is the probable diagnosis?**
3. **How will you investigate and confirm the diagnosis?**

Derangements of Homeostasis and Haemodynamics

HOMEOSTASIS

Many workers have pointed out that life on earth probably arose in the sea, and that the body water which is the environment of the cells, consisting of “salt water” is similar to the ancient ocean. The sea within us flows through blood and lymph vessels, bathes the cells as well as lies within the cells. However, water within body contains several salts that include sodium, chloride, potassium, calcium, magnesium, phosphate, and other electrolytes. Although it appears quite tempting to draw comparison between environment of the cell and the ancient oceans, it would be rather an oversimplification in considering the cellular environment to be wholly fluid ignoring the presence of cells, fibres and ground substance.

Claude Bernarde (1949) first coined the term *internal environment or milieu interieur* for the state in the body in which the interstitial fluid that bathes the cells and the plasma, together maintain the normal morphology and function of the cells and tissues of the body. The mechanism by which the constancy of the internal environment is maintained and ensured is called the *homeostasis*. For this purpose, living membranes with varying permeabilities such as vascular endothelium and the cell wall play important role in exchange of fluids, electrolytes, nutrients and metabolites across the compartments of body fluids.

The normal composition of internal environment consists of the following components (Fig. 4.1):

1. WATER Water is the principal and essential constituent of the body. The total body water in a normal adult male comprises 50-70% (average 60%) of the body weight and about 10% less in a normal adult female (average 50%). Thus, the body of a normal male weighing 65 kg contains approximately 40 litres of water. The total body water (assuming average of 60%) is distributed into 2 main compartments of body fluids separated from each other by membranes freely permeable to water. These are as under (Fig. 4.2):

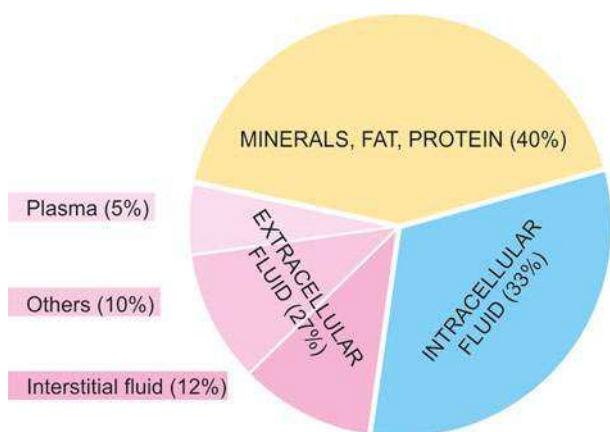

Figure 4.1 Distribution of body fluid compartments.

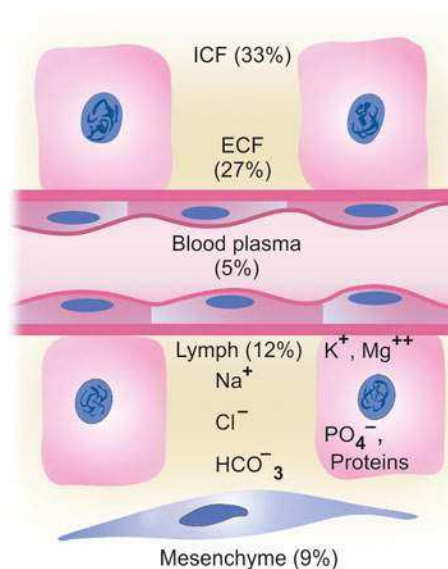

Figure 4.2 Body fluid compartments (ICF = intracellular fluid compartment; ECF = extracellular fluid compartment).

i) Intracellular fluid compartment This comprises about 33% of the body weight, the bulk of which is contained in the muscles.

ii) Extracellular fluid compartment This constitutes the remaining 27% of body weight containing water. Included in this are the following 4 subdivisions of extracellular fluid (ECF):

a) Interstitial fluid including lymph fluid constitutes the major proportion of ECF (12% of body weight).

b) Intravascular fluid or blood plasma comprises about 5% of the body weight. Plasma content is about 3 litres of fluid out of 5 litres of total blood volume.

c) Mesenchymal tissues such as dense connective tissue, cartilage and bone contain body water that comprises about 9% of the body weight.

d) Transcellular fluid constitutes 1% of body weight. This is the fluid contained in the secretions of secretory cells of the body e.g. skin, salivary glands, mucous membranes of alimentary and respiratory tracts, pancreas, liver and biliary tract, kidneys, gonads, thyroid, lacrimal gland and CSF.

2. ELECTROLYTES The concentration of cations (positively charged) and anions (negatively charged) is different in intracellular and extracellular fluids:

◆ *In the intracellular fluid*, the main cations are potassium and magnesium and the main anions are phosphates and proteins. It has low concentration of sodium and chloride.

◆ *In the extracellular fluid*, the predominant cation is sodium and the principal anions are chloride and bicarbonate. Besides these, a small proportion of non-diffusible proteins and some

diffusible nutrients and metabolites such as glucose and urea are present in the ECF.

The essential difference between the two main subdivisions of ECF is the higher protein content in the plasma than in the interstitial fluid which plays an important role in maintaining fluid balance.

The **major functions** of electrolytes are as follows:

- i) Electrolytes are the main solutes in the body fluids for maintenance of acid-base equilibrium.
- ii) Electrolytes maintain the proper osmolality and volume of body fluids (*Osmolality* is the solute concentration per kg water, compared from *osmolarity* which is the solute concentration per litre solution).
- iii) The concentration of certain electrolytes determines their specific physiologic functions e.g. the effect of calcium ions on neuromuscular excitability. The concentration of the major electrolytes is expressed in milliequivalent (mEq) per litre so as to compare the values directly with each other. In order to convert mg per dl into mEq per litre the following formula is used:

$$\text{mEq/L} = \frac{\text{mg/dl}}{\text{Eq weight of element}} \times 10$$

NORMAL WATER AND ELECTROLYTE BALANCE (GIBBS-DONNAN EQUILIBRIUM)

Normally, a state of balance exists between the amount of water absorbed into the body and the amount eliminated from the body. The water and electrolytes are distributed nearly constantly in different body fluid compartments:

1. Water is normally *absorbed* into the body from the bowel or is introduced parenterally; average intake being 2800 ml per day.
2. Water is *eliminated* from the body via:
 - i) kidneys in the urine (average 1500 ml per day);
 - ii) via the skin as insensible loss in perspiration or as sweat (average 800 ml per day), though there is wide variation in loss via sweat depending upon weather, temperature, fever and exercise;
 - iii) via the lungs in exhaled air (average 400 ml per day); and
 - iv) minor losses via the faeces (average 100 ml per day) and lacrimal, nasal, oral, sexual and mammary (milk) secretions.

The cell wall as well as capillary endothelium are entirely permeable to water but they differ in their permeability to electrolytes. Capillary wall is completely permeable to electrolytes while the cell membrane is somewhat impermeable. As mentioned earlier, concentration of potassium and phosphate are high in the intracellular fluid whereas concentration of sodium and chloride are high in the ECF. The osmotic equilibrium between the two major body fluid compartments is maintained by the passage of water from or into the intracellular compartment. The 2 main subdivisions of ECF—blood plasma and interstitial fluid, are separated from each other by capillary wall which is freely permeable to water but does not allow free passage of macro-molecules of plasma proteins resulting in higher protein content in the plasma.

ACID-BASE BALANCE

Besides changes in the volume of fluids in the compartments, changes in ionic equilibrium affecting the acid-base balance of fluids occur. In terms of body fluids,

- ◆ an *acid* is a molecule or ion which is capable of giving off a hydrogen ion (H⁺ ion donor); and
- ◆ a *base* is a molecule or ion which is capable of taking up hydrogen ion (H⁺ ion acceptor).

A number of acids such as carbonic, phosphoric, sulfuric, lactic, hydrochloric and ketoacids are formed during normal metabolic activity. However, carbonic acid is produced in largest amount as it is the end-product of aerobic tissue activity. In spite of these acids, the pH of the blood is kept constant at 7.4 ± 0.05 in health.

The pH of blood and acid-base balance are regulated in the body as follows:

1. BUFFER SYSTEM Buffers are substances which have weak acids and strong bases and limit the change in H⁺ ion concentration to the normal range. They are the first line of defense for maintaining acid-base balance and do so by taking up H⁺ ions when the pH rises. The most important buffer which regulates the pH of blood is *bicarbonate-carbonic acid system* followed by *intracellular buffering action of haemoglobin and carbonic anhydrase* in the red cells.

2. PULMONARY MECHANISM During respiration, CO₂ is removed by the lungs depending upon the partial pressure of CO₂ in the arterial blood. With ingestion of high quantity of acid-forming salts, ventilation is increased as seen in acidosis in diabetic ketosis and uraemia.

3. RENAL MECHANISM The other route by which H⁺ ions can be excreted from the body is in the urine. Here, H⁺ ions secreted by the renal tubular cells are buffered in the glomerular filtrate by:

- i) *combining with phosphates* to form phosphoric acid;
- ii) *combining with ammonia* to form ammonium ions; and
- iii) *combining with filtered bicarbonate ions* to form carbonic acid.

However, carbonic acid formed is dissociated to form CO₂ which diffuses back into the blood to reform bicarbonate ions.

PRESSURE GRADIENTS AND FLUID EXCHANGES

Besides water and electrolytes (or crystalloids), both of which are freely interchanged between the interstitial fluid and plasma, the ECF contains colloids (i.e. proteins) which minimally cross the capillary wall. These substances exert pressures responsible for exchange between the interstitial fluid and plasma.

Normal Fluid Pressures

1. OSMOTIC PRESSURE This is the pressure exerted by the chemical constituents of the body fluids. Accordingly, osmotic pressure may be of the following types (**Fig. 4.3,A**):

◆ **Crystalloid osmotic pressure** exerted by electrolytes present in the ECF and comprises the major portion of the total osmotic pressure.

◆ **Colloid osmotic pressure (Oncotic pressure)** exerted by proteins present in the ECF and constitutes a small part of the total osmotic pressure but is more significant physiologically. Since the protein content of the plasma is higher than that of interstitial fluid, oncotic pressure of plasma is higher (average 25 mmHg) than that of interstitial fluid (average 8 mmHg).

◆ **Effective oncotic pressure** is the difference between the higher oncotic pressure of plasma and the lower oncotic

pressure of interstitial fluid and is *the force that tends to draw fluid into the vessels*.

2. HYDROSTATIC PRESSURE This is the capillary blood pressure.

There is considerable *pressure gradient* at the two ends of capillary loop—being higher at the arteriolar end (average 32 mmHg) than at the venular end (average 12 mmHg).

◆ **Tissue tension** is the hydrostatic pressure of interstitial fluid and is lower than the hydrostatic pressure in the capillary at either end (average 4 mmHg).

◆ **Effective hydrostatic pressure** is the difference between the higher hydrostatic pressure in the capillary and the lower tissue tension; it is *the force that drives fluid through the capillary wall into the interstitial space*.

Normal Fluid Exchanges

Normally, the fluid exchanges between the body compartments take place as under:

◆ *At the arteriolar end of the capillary*, the balance between the hydrostatic pressure (32 mmHg) and plasma oncotic pressure (25 mmHg) is the hydrostatic pressure of 7 mmHg which is the outward-driving force so that a small quantity of fluid and solutes leave the vessel to enter the interstitial space.

◆ *At the venular end of the capillary*, the balance between the hydrostatic pressure (12 mmHg) and plasma oncotic pressure (25 mmHg) is the oncotic pressure of 13 mmHg which is the inward-driving force so that the fluid and solutes re-enter the plasma.

◆ *Tissue fluid* left after exchanges across the capillary wall escapes into the lymphatics from where it is finally drained into venous circulation.

◆ *Tissue factors* (i.e. oncotic pressure of interstitial fluid and tissue tension) are normally small and insignificant forces opposing the plasma hydrostatic pressure and capillary hydrostatic pressure, respectively.

GIST BOX 4.1

Homeostasis

□ The mechanism by which constancy of the internal environment is maintained and ensured is called the *homeostasis*. Living membranes such as cell wall and vascular endothelium play important role in exchanges of fluid, electrolytes, nutrients and metabolites.

□ Total body water is about 60% of the body weight and is divided into intracellular (33%) and extracellular compartments (27%). Intracellular fluid has low concentration of sodium and chloride while extracellular compartment has high sodium, chloride and bicarbonate; plasma has high protein content compared from interstitial fluid.

□ Effective oncotic pressure is the difference between the higher oncotic pressure of plasma and the lower oncotic pressure of interstitial fluid and is *the force that tends to draw fluid into the vessels*.

□ Effective hydrostatic pressure is the difference between the higher hydrostatic pressure in the capillary and the lower tissue tension; it is *the force that drives fluid through the capillary wall into the interstitial space*.

DISTURBANCES OF BODY WATER

The common derangements of body water are as follows:

1. Oedema
 2. Dehydration
 3. Overhydration
- These are discussed below.

OEDEMA

DEFINITION AND TYPES

The Greek word *oidema* means swelling. *Oedema is defined as abnormal and excessive accumulation of "free fluid" in the interstitial tissue spaces and serous cavities*. The presence of abnormal collection of fluid within the cell is sometimes called intracellular oedema but should more appropriately be called hydropic degeneration (page 17).

◆ *Free fluid in body cavities*: Commonly called as effusion, it is named according to the body cavity in which the fluid accumulates. For example, ascites (if in the peritoneal cavity), hydrothorax or pleural effusion (if in the pleural cavity), and hydropericardium or pericardial effusion (if in the pericardial cavity).

◆ *Free fluid in interstitial space*: Commonly termed as oedema, the fluid lies free in the interstitial space between the cells and can be displaced from one place to another. In the case of oedema in the subcutaneous tissues, momentary pressure of finger produces a depression known as *pitting oedema*. The other variety is *non-pitting* or *solid oedema* in which no pitting is produced on pressure e.g. in myxoedema, elephantiasis.

Oedema may be of 2 main types:

1. *Localised* when limited to an organ or limb e.g. lymphatic oedema, inflammatory oedema, allergic oedema, pulmonary oedema, cerebral oedema etc.
2. *Generalised (anasarca or dropsy)* when it is systemic in distribution, particularly noticeable in the subcutaneous tissues e.g. renal oedema, cardiac oedema, nutritional oedema.

Depending upon fluid composition, oedema fluid may be:

- ◆ *transudate* which is more often the case, such as in oedema of cardiac and renal disease; or
- ◆ *exudate* such as in inflammatory oedema.

The differences between transudate and exudate are tabulated in **Table 4.1**.

PATHOGENESIS OF OEDEMA

Oedema is caused by mechanisms that interfere with normal fluid balance of plasma, interstitial fluid and lymph flow. The following mechanisms may be operating singly or in combination to produce oedema:

1. Decreased plasma oncotic pressure
2. Increased capillary hydrostatic pressure
3. Lymphatic obstruction
4. Tissue factors (increased oncotic pressure of interstitial fluid, and decreased tissue tension)
5. Increased capillary permeability
6. Sodium and water retention.

These mechanisms are discussed below and illustrated in

Fig. 4.3:

1. **DECREASED PLASMA ONCOTIC PRESSURE** The plasma oncotic pressure exerted by the total amount of plasma

Table 4.1 Differences between transudate and exudate.

| FEATURE | TRANSUDATE | EXUDATE |
|-------------------------------------|---|--|
| 1. Definition | Filtrate of blood plasma without changes in endothelial permeability | Oedema of inflamed tissue associated with increased vascular permeability |
| 2. Character | Non-inflammatory oedema | Inflammatory oedema |
| 3. Protein content | Low (less than 1 gm/dl); mainly albumin, low fibrinogen; hence no tendency to coagulate | High (2.5-3.5 gm/dl), readily coagulates due to high content of fibrinogen and other coagulation factors |
| 4. Glucose content | Same as in plasma | Low (less than 60 mg/dl) |
| 5. Specific gravity | Low (less than 1.015) | High (more than 1.018) |
| 6. pH | > 7.3 | < 7.3 |
| 7. LDH | Low | High |
| 8. Effusion LDH/ Serum LDH ratio | < 0.6 | > 0.6 |
| 9. Cells | Few cells, mainly mesothelial cells and cellular debris | Many cells, inflammatory as well as parenchymal |
| 10. Examples | Oedema in congestive cardiac failure | Purulent exudate such as pus |

proteins tends to draw fluid into the vessels normally. A fall in the total plasma protein level (hypoproteinaemia of less than 5 g/dl, mainly hypoalbuminaemia), results in lowering of plasma oncotic pressure in a way that it can no longer counteract the effect of hydrostatic pressure of blood. This results in increased outward movement of fluid from the capillary wall and decreased inward movement of fluid from the interstitial space causing oedema (Fig. 4.3,B). Hypoproteinaemia usually produces generalised oedema (anasarca). Out of the various plasma proteins, albumin has four times higher plasma oncotic pressure than globulin; thus it is mainly hypoalbuminaemia (albumin below 2.5 g/dl) that generally results in oedema.

The examples of oedema by this mechanism are seen in the following conditions:

- i) *Oedema of renal disease* e.g. in nephrotic and nephritic syndrome.
- ii) *Ascites of liver disease* e.g. in cirrhosis of the liver.
- iii) *Oedema due to other causes* of hypoproteinaemia e.g. in protein-losing enteropathy.

2. INCREASED CAPILLARY HYDROSTATIC PRESSURE

The hydrostatic pressure of the capillary is the force that normally tends to drive fluid through the capillary wall into the interstitial space by counteracting the force of plasma oncotic pressure. A rise in the hydrostatic pressure at the venular end of the capillary which is normally low (average 12 mmHg) to a level more than the plasma oncotic pressure results in minimal or no reabsorption of fluid at the venular end, consequently leading to oedema (Fig. 4.3,C).

The examples of oedema by this mechanism are seen in the following disorders:

- i) *Oedema of cardiac disease* e.g. in congestive cardiac failure, constrictive pericarditis.
- ii) *Ascites of liver disease* e.g. in cirrhosis of the liver.
- iii) *Passive congestion* e.g. in mechanical obstruction due to thrombosis of veins of the lower legs, varicosities, pressure by pregnant uterus, tumours etc.
- iv) *Postural oedema* e.g. transient oedema of feet and ankles due to increased venous pressure seen in individuals whose

job involves standing for long hours such as traffic constables and nurses.

3. LYMPHATIC OBSTRUCTION Normally, the interstitial fluid in the tissue spaces escapes by way of lymphatics. Obstruction to outflow of these channels causes localised oedema, known as lymphoedema (Fig. 4.3,D).

The examples of lymphoedema include the following:

- i) *Removal of axillary lymph nodes* in radical mastectomy for carcinoma of the breast causing lymphoedema of the affected arm.
- ii) *Pressure from outside* on the main abdominal or thoracic duct such as due to tumours, effusions in serous cavities etc may produce lymphoedema. At times, the main lymphatic channel may rupture and discharge chyle into the pleural cavity (chylothorax) or into peritoneal cavity (chylous ascites).
- iii) *Inflammation of the lymphatics* as seen in filariasis (infection with *Wuchereria bancrofti*) results in chronic lymphoedema of scrotum and legs known as elephantiasis, a form of non-pitting oedema.
- iv) *Occlusion of lymphatic channels* by malignant cells may result in lymphoedema.
- v) *Milroy's disease or hereditary lymphoedema* is due to abnormal development of lymphatic channels. It is seen in families and the oedema is mainly confined to one or both the lower limbs (page 391).

4. TISSUE FACTORS The two forces acting in the interstitial space—oncotic pressure of the interstitial space and tissue tension, are normally quite small and insignificant to counteract the effects of plasma oncotic pressure and capillary hydrostatic pressure respectively. However, in some situations, the tissue factors in combination with other mechanisms play a role in causation of oedema (Fig. 4.3,E). These are as under:

- i) *Elevation of oncotic pressure of interstitial fluid* as occurs due to increased vascular permeability and inadequate removal of proteins by lymphatics.
- ii) *Lowered tissue tension* as seen in *loose subcutaneous tissues* of eyelids and external genitalia.

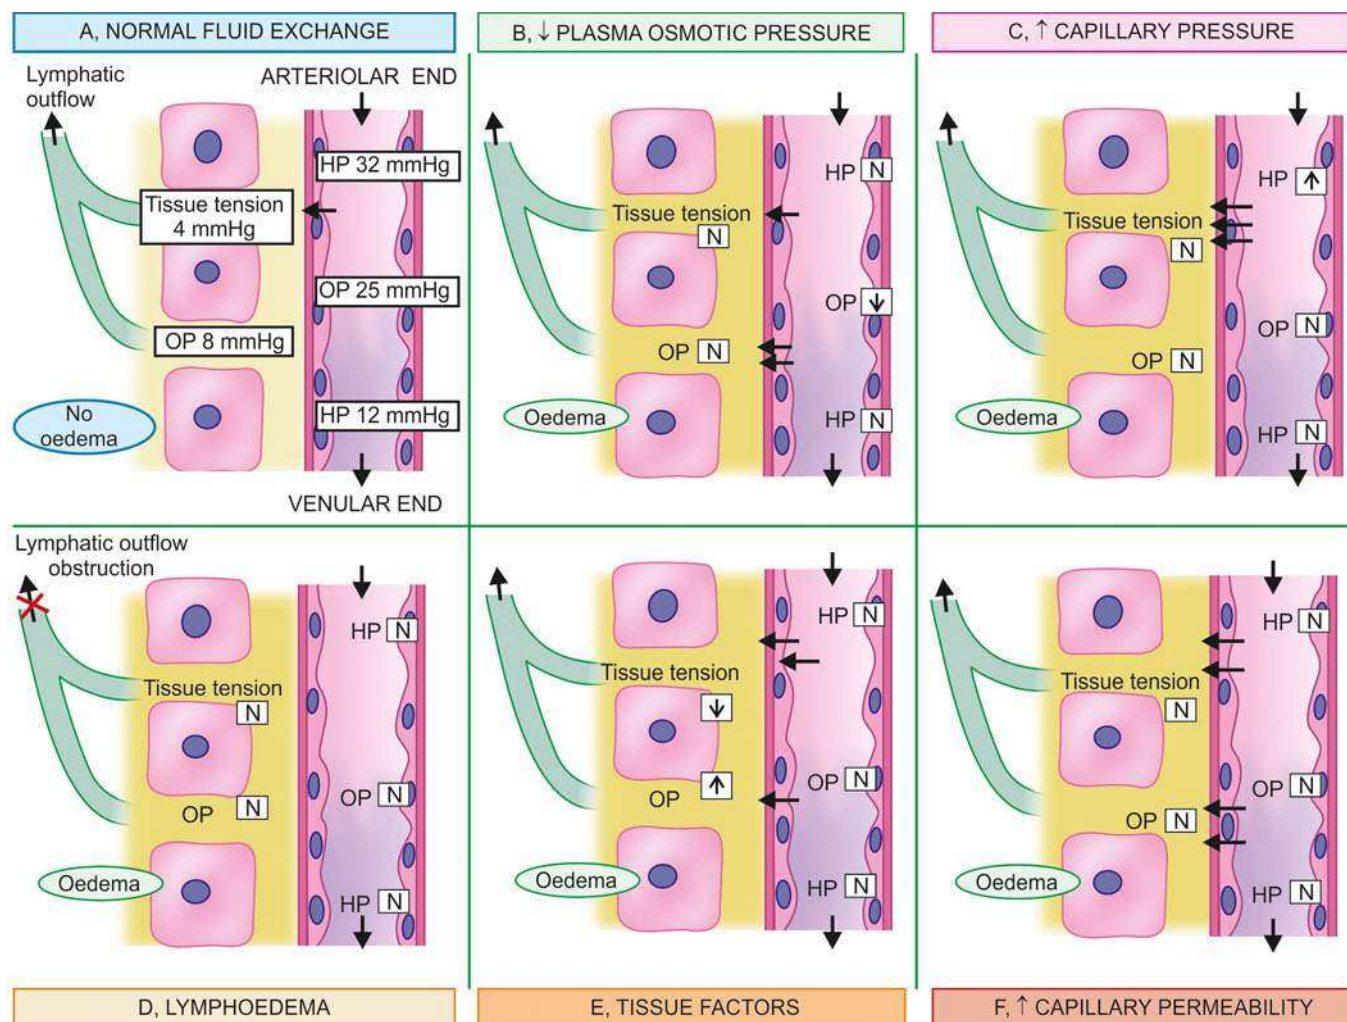

Figure 4.3 Diagrammatic representation of pathogenesis of oedema (OP = oncotic pressure; HP = hydrostatic pressure). A, Normal pressure gradients and fluid exchanges between plasma, interstitial space and lymphatics. B, Mechanism of oedema by decreased plasma oncotic pressure and hypoproteinaemia. C, Mechanism of oedema by increased hydrostatic pressure in the capillary. D, Mechanism of lymphoedema. E, Mechanism by tissue factors (increased oncotic pressure of interstitial fluid and lowered tissue tension). F, Mechanism of oedema by increased capillary permeability.

5. INCREASED CAPILLARY PERMEABILITY An intact capillary endothelium is a semipermeable membrane which permits the free flow of water and crystalloids but allows minimal passage of plasma proteins normally. However, when the capillary endothelium is injured by various 'capillary poisons' such as toxins and their products (e.g. histamine, anoxia, venoms, certain drugs and chemicals), the capillary permeability to plasma proteins is enhanced due to development of gaps between the endothelial cells, causing leakage of plasma proteins into interstitial fluid. This, in turn, causes reduced plasma oncotic pressure and elevated oncotic pressure of interstitial fluid, consequently producing oedema (**Fig. 4.3,F**).

The **examples** of oedema due to increased vascular permeability are seen in the following conditions:

i) *Generalised oedema* occurring in systemic infections, poisonings, certain drugs and chemicals, anaphylactic reactions and anoxia.

ii) *Localised oedema* A few examples are as under:

◆ *Inflammatory oedema* as seen in infections, allergic reactions, insect-bite, irritant drugs and chemicals. It is generally exudate in nature.

◆ *Angioneurotic oedema* is an acute attack of localised oedema occurring on the skin of face and trunk and may involve lips, larynx, pharynx and lungs. It is possibly neurogenic or allergic in origin.

6. SODIUM AND WATER RETENTION The mechanism of oedema by sodium and water retention in extravascular compartment is best described in relation to derangement in normal regulatory mechanism of sodium and water balance.

Natrium (Na) is the Latin term for sodium. Normally, about 80% of sodium is reabsorbed by the proximal convoluted tubule under the influence of either intrinsic renal mechanism or extra-renal mechanism while retention of water is affected by release of antidiuretic hormone (**Fig. 4.4**):

◆ **Intrinsic renal mechanism** is activated in response to sudden reduction in the effective arterial blood volume (hypovolaemia) e.g. in severe haemorrhage. Hypovolaemia stimulates the arterial baroreceptors present in the carotid sinus and aortic arch which, in turn, send the sympathetic outflow via the vasomotor centre in the brain. As a result of this, renal ischaemia occurs which causes reduction in the glomerular filtration rate, decreased excretion of sodium in the urine and consequent retention of sodium.

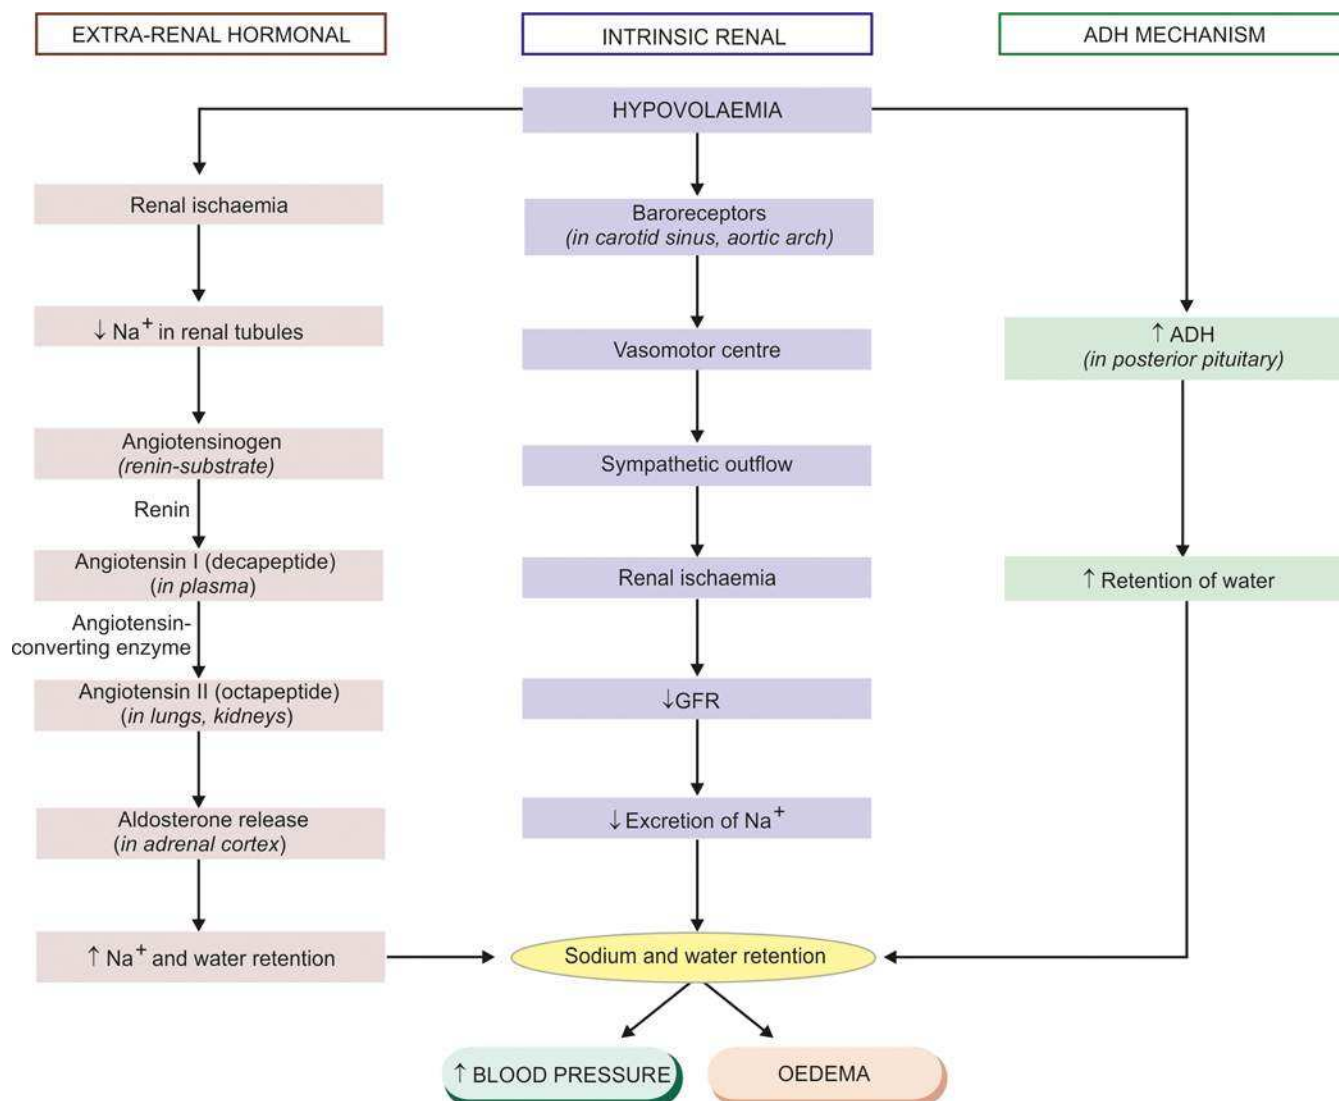

Figure 4.4 Mechanisms involved in oedema by sodium and water retention.

◆ **Extra-renal mechanism** involves the secretion of aldosterone, a sodium-retaining hormone, by the *renin-angiotensin-aldosterone system*. Renin is an enzyme secreted by the granular cells in the juxta-glomerular apparatus. Its release is stimulated in response to low concentration of sodium in the tubules. Its main action is stimulation of the angiotensinogen which is α_2 -globulin or renin substrate present in the plasma. On stimulation, angiotensin I, a decapeptide, is formed in the plasma which is subsequently converted into angiotensin II, an octapeptide, in the lungs and kidneys by angiotensin converting enzyme (ACE). Angiotensin II stimulates the adrenal cortex to secrete aldosterone hormone. Aldosterone increases sodium reabsorption in the renal tubules and sometimes causes a rise in the blood pressure.

◆ **ADH mechanism** Retention of sodium leads to retention of water secondarily under the influence of anti-diuretic hormone (ADH) or vasopressin. This hormone is secreted by the cells of the supraoptic and paraventricular nuclei in the hypothalamus and is stored in the neurohypophysis (posterior pituitary). The release of ADH is stimulated by increased concentration of sodium in the plasma and hypovolaemia. Large amounts of ADH produce highly concentrated urine.

Thus, the possible factors responsible for causing oedema by excessive retention of sodium and water in the extravascular compartment via stimulation of intrinsic renal and extra-renal mechanisms as well as via release of ADH are as under:

- Reduced glomerular filtration rate in response to hypovolaemia.
- Enhanced tubular reabsorption of sodium and consequently its decreased renal excretion.
- Increased filtration factor i.e. increased filtration of plasma from the glomerulus.
- Decreased capillary hydrostatic pressure associated with increased renal vascular resistance.

The **examples** of oedema by these mechanisms are as under:

- Oedema of cardiac disease* e.g. in congestive cardiac failure.
- Ascites of liver disease* e.g. in cirrhosis of liver.
- Oedema of renal disease* e.g. in nephrotic and nephritic syndrome.

IMPORTANT TYPES OF OEDEMA

As observed from the pathogenesis of oedema just described, more than one mechanism may be involved in many examples

of localised and generalised oedema. Some of the important examples are described below.

Renal Oedema

Generalised oedema occurs in certain diseases of renal origin such as in nephrotic syndrome, nephritic syndrome, and in renal failure due to acute tubular injury.

1. Oedema in nephrotic syndrome Since there is persistent and heavy proteinuria (albuminuria) in nephrotic syndrome, there is hypoalbuminaemia causing decreased plasma oncotic pressure resulting in severe generalised oedema (*nephrotic oedema*). The hypoalbuminaemia also causes fall in the plasma volume activating renin-angiotensin-aldosterone mechanism which results in retention of sodium and water, thus setting in a vicious cycle which persists till the albuminuria continues. Similar type of mechanism operates in the pathogenesis of oedema in protein-losing enteropathy, adding further support to the role of protein loss in the causation of oedema.

The *nephrotic oedema* is classically more severe, generalised and marked and is present in the subcutaneous tissues as well as in the visceral organs.

Grossly, the affected organ is enlarged and heavy with tense capsule.

Microscopically, the oedema fluid separates the connective tissue fibres of subcutaneous tissues. Depending upon the protein content, the oedema fluid may appear homogeneous, pale, eosinophilic, or may be deeply eosinophilic and granular.

2. Oedema in nephritic syndrome Oedema occurring in conditions with diffuse glomerular disease such as in acute diffuse glomerulonephritis and rapidly progressive glomerulonephritis is termed *nephritic oedema*. In contrast to nephrotic oedema, nephritic oedema is primarily not due to hypoproteinaemia because of low albuminuria but is largely due to excessive reabsorption of sodium and water in the renal tubules via renin-angiotensin-aldosterone mechanism. The protein content of oedema fluid in glomerulonephritis is quite low (less than 0.5 g/dl).

The *nephritic oedema* is usually mild as compared to nephrotic oedema and begins in the loose tissues such as on the face around eyes, ankles and genitalia. Oedema in these conditions is usually not affected by gravity (unlike cardiac oedema).

The salient differences between the nephrotic and nephritic oedema are outlined in **Table 4.2**.

3. Oedema in acute tubular injury Acute tubular injury following shock or toxic chemicals results in gross oedema of

the body. The damaged tubules lose their capacity for selective reabsorption and concentration of the glomerular filtrate, resulting in excessive retention of water and electrolytes, and consequent oliguria. Besides, there is rise in blood urea.

Cardiac Oedema

Generalised oedema develops in right-sided and congestive cardiac failure. Pathogenesis of cardiac oedema is explained on the basis of the following mechanisms (**Fig. 4.5**):

1. Reduced cardiac output causes hypovolaemia which stimulates intrinsic-renal and extra-renal hormonal (renin-angiotensin-aldosterone) mechanisms as well as ADH secretion resulting in *sodium and water retention* (as discussed above) and consequent oedema.

2. Due to heart failure, there is elevated central venous pressure which is transmitted backward to the venous end of the capillaries, raising the capillary hydrostatic pressure and consequent transudation; this is known as *back pressure hypothesis*.

3. Chronic hypoxia may injure the capillary endothelium causing increased capillary permeability and result in oedema; this is called *forward pressure hypothesis*. However, this theory lacks support since the oedema by this mechanism is exudate whereas the cardiac oedema is typically transudate.

In left heart failure, the changes are, however, different. There is venous congestion, particularly in the lungs, causing pulmonary oedema rather than generalised oedema.

Cardiac oedema is influenced by gravity and is thus characteristically *dependent oedema* i.e. in an ambulatory patient it is on the lower extremities, while in a bed-ridden patient oedema appears on the sacral and genital areas. The accumulation of fluid may also occur in serous cavities.

Pulmonary Oedema

Acute pulmonary oedema is the most important form of local oedema as it causes serious functional impairment. However, it has special features and differs from oedema elsewhere in that the fluid accumulation is not only in the tissue space but also in the pulmonary alveoli.

ETIOPATHOGENESIS The hydrostatic pressure in the pulmonary capillaries is much lower (average 10 mmHg). Normally the plasma oncotic pressure is adequate to prevent the escape of fluid into the interstitial space and hence lungs are normally free of oedema. Pulmonary oedema can result from either the elevation of pulmonary hydrostatic pressure or the increased capillary permeability (**Fig. 4.6**).

1. Elevation in pulmonary hydrostatic pressure (Haemodynamic oedema) In heart failure, there is increase in the

Table 4.2 Differences between nephrotic and nephritic oedema.

| FEATURE | NEPHROTIC OEDEMA | NEPHRITIC OEDEMA |
|---------------------|--|--|
| 1. Cause | Nephrotic syndrome | Glomerulonephritis (acute, rapidly progressive) |
| 2. Proteinuria | Heavy | Moderate |
| 3. Protein content | High (>1 g/dl) | Low (<0.5 g/dl) |
| 4. Mechanism | ↓ Plasma oncotic pressure, Na ⁺ and water retention | Na ⁺ and water retention |
| 5. Degree of oedema | Severe, generalised | Mild |
| 6. Distribution | Subcutaneous tissues as well as visceral organs | Loose tissues mainly (face, eyes, ankles, genitalia) |

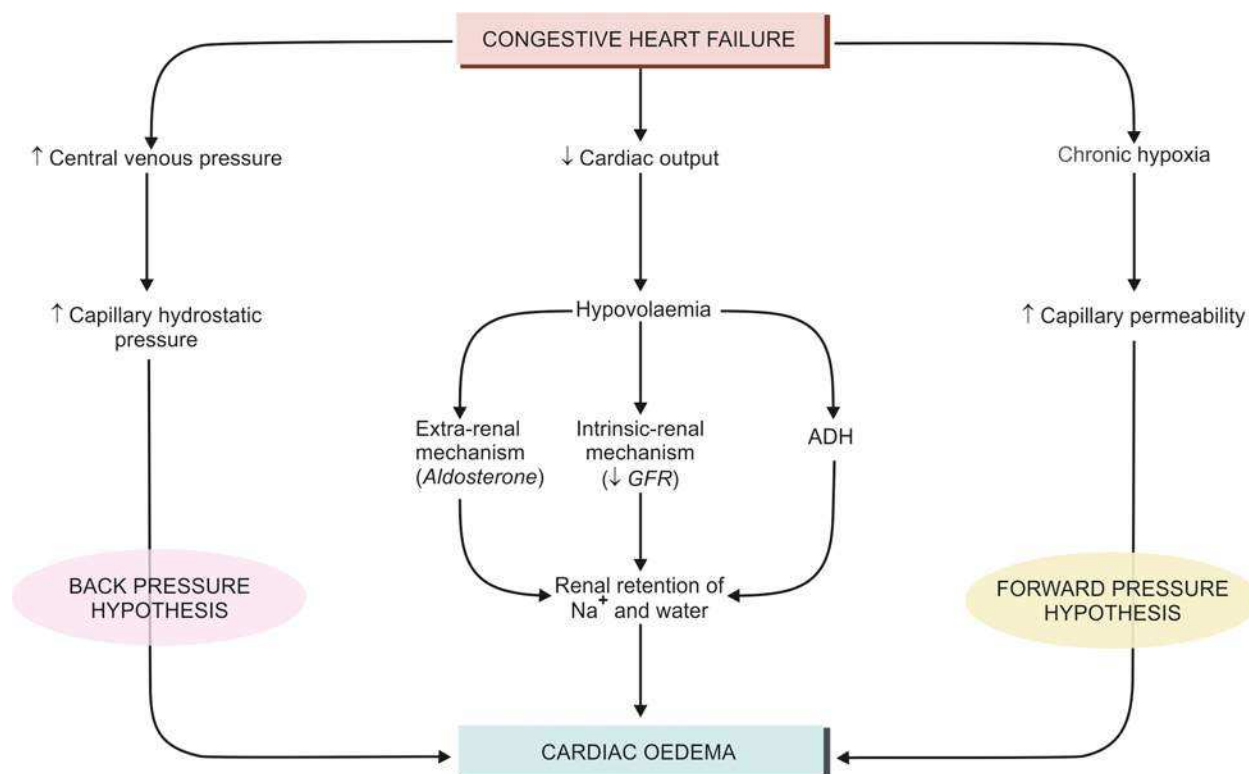

Figure 4.5 Mechanisms involved in the pathogenesis of cardiac oedema.

pressure in pulmonary veins which is transmitted to pulmonary capillaries. This results in imbalance between pulmonary hydrostatic pressure and the plasma oncotic pressure so that excessive fluid moves out of pulmonary capillaries into the interstitium of the lungs. Simultaneously, the endothelium of the pulmonary capillaries develops fenestrations permitting passage of plasma proteins and fluid into the interstitium. The interstitial fluid so collected is cleared by the lymphatics present around the bronchioles, small muscular arteries and veins. As the capacity of the lymphatics to drain the fluid is exceeded (about ten-fold increase in fluid), the excess fluid

starts accumulating in the interstitium (*interstitial oedema*) i.e. in the loose tissues around bronchioles, arteries and in the lobular septa. This causes thickening of the alveolar walls. Up to this stage, no significant impairment of gaseous exchange occurs. However, prolonged elevation of hydrostatic pressure and due to high pressure of interstitial oedema, the alveolar lining cells break and the alveolar air spaces are flooded with fluid (*alveolar oedema*) driving the air out of alveoli, thus seriously hampering the lung function.

Examples of pulmonary oedema by this mechanism are seen in left heart failure, mitral stenosis, pulmonary

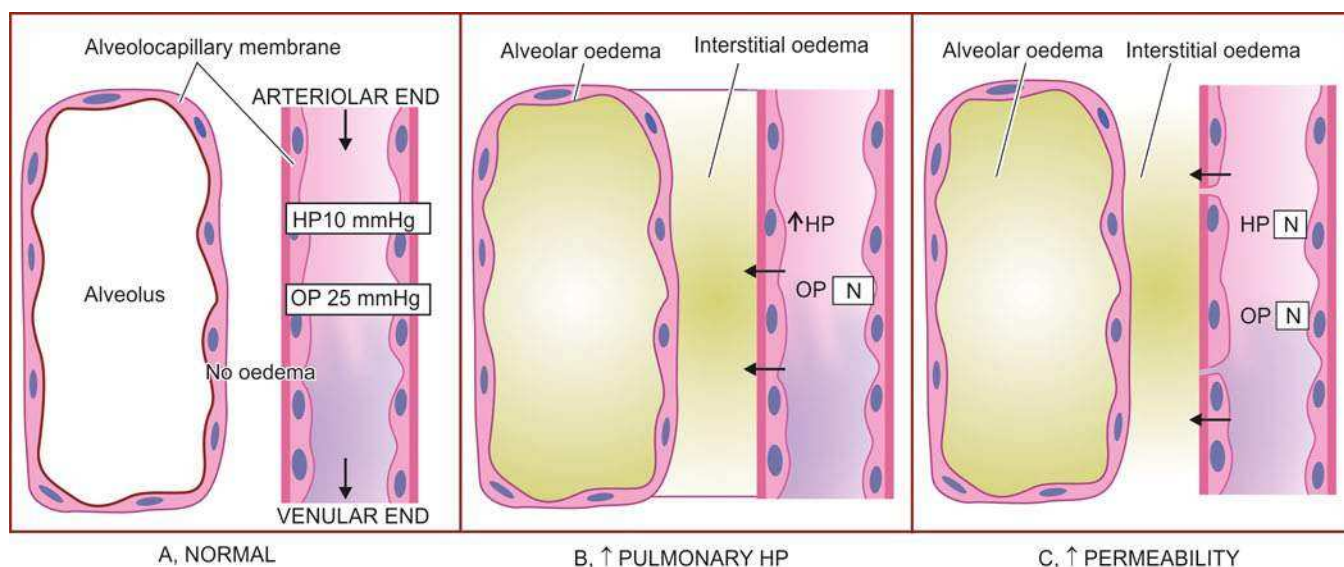

Figure 4.6 Mechanisms involved in the pathogenesis of pulmonary oedema. A, Normal fluid exchange at the alveolocapillary membrane (capillary endothelium and alveolar epithelium). B, Pulmonary oedema via elevated pulmonary hydrostatic pressure. C, Pulmonary oedema via increased vascular permeability.

vein obstruction, thyrotoxicosis, cardiac surgery, nephrotic syndrome and obstruction to the lymphatic outflow by tumour or inflammation.

2. Increased vascular permeability (Irritant oedema) The vascular endothelium as well as the alveolar epithelial cells (alveolo-capillary membrane) may be damaged causing increased vascular permeability so that excessive fluid and plasma proteins leak out, initially into the interstitium and subsequently into the alveoli.

This mechanism explains pulmonary oedema in conditions such as in fulminant pulmonary and extrapulmonary infections, inhalation of toxic substances, aspiration, shock, radiation injury, hypersensitivity to drugs or antisera, uraemia and adult respiratory distress syndrome (ARDS).

3. Acute high altitude oedema Individuals climbing to high altitude suddenly without halts and without waiting for acclimatisation to set in, suffer from serious circulatory and respiratory ill-effects. Commonly, the deleterious effects begin to appear after an altitude of 2500 metres is reached. These changes include appearance of oedema fluid in the lungs, congestion and widespread minute haemorrhages. These changes can cause death within a few days. The underlying mechanism is due to anoxic damage to the pulmonary vessels. However, if acclimatisation to high altitude is allowed to take place, the individual develops polycythaemia, raised pulmonary arterial pressure, increased pulmonary ventilation and a rise in heart rate and increased cardiac output, and thus the ill-effects do not appear.

MORPHOLOGIC FEATURES Irrespective of the underlying mechanism in the pathogenesis of pulmonary oedema, the fluid accumulates more in the basal regions of lungs. The thickened interlobular septa along with their dilated lymphatics may be seen in chest X-ray as linear lines perpendicular to the pleura and are known as *Kerley's lines*.

Grossly, the lungs in pulmonary oedema are heavy, moist and subcrepitant. Cut surface exudes frothy fluid (mixture of air and fluid).

Microscopically, the alveolar capillaries are congested. Initially, the excess fluid collects in the interstitial lung

spaces in the septal walls (interstitial oedema). Later, the fluid fills the alveolar spaces (alveolar oedema). Oedema fluid in the interstitium as well as the alveolar spaces appears as eosinophilic, granular and pink proteinaceous material, often admixed with some RBCs and alveolar macrophages, also called heart failure cells (**Fig. 4.7**). Organisation of alveolar oedema may be seen as brightly eosinophilic pink lines along the alveolar margin called *hyaline membrane*.

Long-standing pulmonary oedema is prone to get infected by bacteria producing hypostatic pneumonia which may be fatal.

Cerebral Oedema

Cerebral oedema or swelling of the brain is the most life-threatening example of oedema. The mechanism of fluid exchange in the brain differs from elsewhere in the body since there are no draining lymphatics in the brain but instead, the function of fluid-electrolyte exchange is performed by the blood-brain barrier located at the endothelial cells of the capillaries.

Cerebral oedema can be of 3 types: vasogenic, cytotoxic and interstitial.

1. VASOGENIC OEDEMA This is the most common type and its mechanism is similar to oedema in other body sites from increased filtration pressure or increased capillary permeability. Vasogenic oedema is prominent around cerebral contusions, infarcts, brain abscess and some tumours.

Grossly, the white matter is swollen, soft, with flattened gyri and narrowed sulci. Sectioned surface is soft and gelatinous.

Microscopically, there is separation of tissue elements by the oedema fluid and swelling of astrocytes. The perivascular (Virchow-Robin) space is widened and clear halos are seen around the small blood vessels.

2. CYTOTOXIC OEDEMA In this type, the blood-brain barrier is intact and the fluid accumulation is intracellular. The underlying mechanism is disturbance in the cellular osmoregulation as occurs in some metabolic derangements, acute hypoxia and with some toxic chemicals.

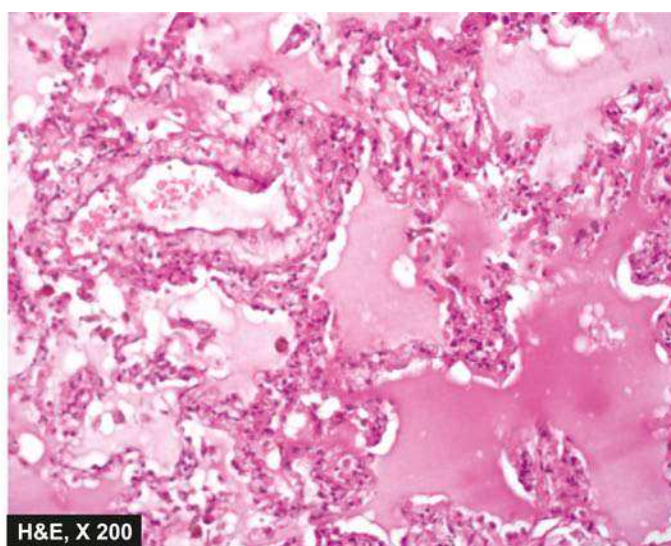

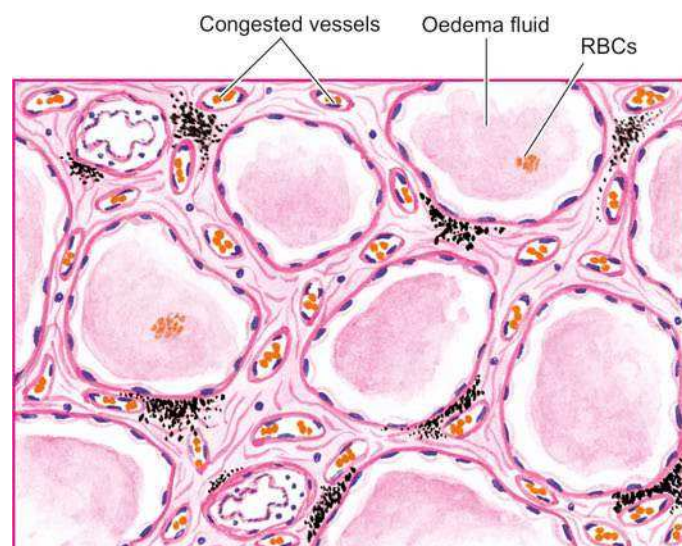

Figure 4.7 Pulmonary oedema. The alveolar capillaries are congested. The alveolar spaces as well as interstitium contain eosinophilic, granular, homogeneous and pink proteinaceous oedema fluid along with some RBCs and inflammatory cells.

Microscopically, the cells are swollen and vacuolated. In some situations, both vasogenic as well as cytotoxic cerebral oedema results e.g. in purulent meningitis.

3. INTERSTITIAL OEDEMA This type of cerebral oedema occurs when the excessive fluid crosses the ependymal lining of the ventricles and accumulates in the periventricular white matter. This mechanism is responsible for oedema in non-communicating hydrocephalus.

Hepatic Oedema

While oedema in chronic liver disease is discussed in detail in Chapter 19 (page 616), briefly the mechanisms involved in causation of oedema of the legs and ascites in cirrhosis of the liver is as under:

- i) There is *hypoproteinaemia* due to impaired synthesis of proteins by the diseased liver.
- ii) Due to portal hypertension, there is increased venous pressure in the abdomen, and hence *raised hydrostatic pressure*.
- iii) Failure of inactivation of aldosterone in the diseased liver and hence *hyperaldosteronism*.
- iv) Secondary stimulation of renin-angiotensin mechanism promoting *sodium and water retention*.

Nutritional Oedema

Oedema due to nutritional deficiency of proteins (kwashiorkor, prolonged starvation, famine, fasting), vitamins (beri-beri due to vitamin B₁ deficiency) and chronic alcoholism occurs on legs but sometimes may be more generalised. The main contributing factors are hypoproteinaemia and sodium-water retention related to metabolic abnormalities. In kwashiorkor occurring in children in economically deprived communities in Africa and Asia, oedema is associated with characteristic mucocutaneous ulceration and depigmentation of the hair, all of which reverts back to normal on adequate nutrition.

Myxoedema

Myxoedema from hypothyroidism (page 794) is a form of non-pitting oedema occurring on skin of face and other parts of the body as also in the internal organs due to excessive deposition of glycosaminoglycans in the interstitium. Microscopically, it appears as basophilic mucopolysaccharides.

DEHYDRATION

Dehydration is a state of pure deprivation of water leading to sodium retention and hence a state of hypernatraemia. In other words, there is only loss of water without loss of sodium. Clinically, the patients present with intense thirst, mental confusion, fever, and oliguria.

ETIOLOGY Pure water deficiency is less common than salt depletion but can occur in the following conditions:

1. GI excretion:

- i) Severe vomitings
- ii) Diarrhoea
- iii) Cholera

2. Renal excretion:

- i) Acute renal failure in diuretic phase
- ii) Extensive use of diuretics
- iii) Endocrine diseases e.g. diabetes insipidus, Addison's disease

3. Loss of blood and plasma:

- i) Severe injuries, severe burns
- ii) During childbirth

4. Loss through skin:

- i) Excessive perspiration
- ii) Hyperthermia

5. Accumulation in third space:

- i) Sudden development of ascites
- ii) Acute intestinal obstruction with accumulation of fluid in the bowel.

MORPHOLOGICAL FEATURES There are no particular pathological changes in organs, except in advanced cases when the organs are dark and shrunken. However, there are haematological and biochemical changes.

- ◆ There is haemoconcentration as seen by increased PCV and raised haemoglobin.
- ◆ In late stage, there is rise in blood urea and serum sodium.
- ◆ Renal shutdown and a state of shock may develop.

OVERHYDRATION

Overhydration is increased extracellular fluid volume due to pure water excess or water intoxication. Clinically, the patients present with disordered cerebral function e.g. nausea, vomiting, headache, confusion and in severe cases convulsions, coma, and even death.

ETIOLOGY Overhydration is generally an induced condition and is encountered in the following situations:

1. Excessive unmonitored intravascular infusion:

- i) Normal saline (0.9% sodium chloride)
- ii) Ringer lactate

2. Renal retention of sodium and water:

- i) Congestive heart failure
- ii) Acute glomerulonephritis
- iii) Cirrhosis
- iv) Cushing's syndrome
- v) Chronic renal failure

MORPHOLOGICAL FEATURES Sudden weight gain is a significant parameter of excess of fluid accumulation. Haematological and biochemical changes include the following:

- ◆ Reduced PCV.
- ◆ Reduced plasma electrolytes and lowered plasma proteins.

GIST BOX 4.2

Disturbances of Body Water

- ▣ Oedema is abnormal and excessive accumulation of "free fluid" in the interstitial tissue spaces and serous cavities.
- ▣ Oedema may be localised when limited to an organ or limb, and generalised (anasarca or dropsy) when it is systemic in distribution, particularly noticeable in the subcutaneous tissues.
- ▣ Depending upon fluid composition, oedema fluid may be transudate which is more often the case, such as in oedema of cardiac and renal disease; or exudate such as in inflammatory oedema.

- ▣ Various mechanisms operating singly or in combination to produce oedema are: decreased plasma oncotic pressure, increased capillary hydrostatic pressure, lymphatic obstruction, tissue factors (increased oncotic pressure of interstitial fluid, and decreased tissue tension), increased capillary permeability, and sodium and water retention.
- ▣ Generalised oedema of renal origin occurs in nephrotic syndrome, nephritic syndrome, and in renal failure due to acute tubular injury.
- ▣ Cardiac oedema is generalised and dependent type and develops in right-sided and congestive cardiac failure.
- ▣ Acute pulmonary oedema results from either the elevation of pulmonary hydrostatic pressure or the increased capillary permeability from various causes.
- ▣ In cerebral oedema, fluid-electrolyte exchange occurs at the blood-brain barrier because there are no lymphatics. Cerebral oedema can be vasogenic, cytotoxic and interstitial.
- ▣ Dehydration is pure deprivation of water leading to sodium retention and a state of hypernatraemia.
- ▣ Overhydration is increased extracellular fluid volume due to pure water excess or water intoxication.

DISTURBANCES OF ELECTROLYTES AND pH OF BLOOD

ELECTROLYTE IMBALANCE

It may be recalled here that normally the concentration of electrolytes within the cell and in the plasma is different. Intracellular compartment has higher concentration of potassium, calcium, magnesium and phosphate ions than the blood, while extracellular fluid (including serum) has higher concentration of sodium, chloride, and bicarbonate ions. In health, for *electrolyte homeostasis*, the concentration of electrolytes in both these compartments should be within normal limits. Normal serum levels of electrolytes are maintained in the body by a careful balance of 4 processes: their intake, absorption, distribution and excretion. Disturbance in any of these processes in diverse pathophysiological states may cause *electrolyte imbalance*.

Among the important components in electrolyte imbalance, abnormalities in serum levels of sodium (hypo- and hypernatraemia), potassium (hypo- and hyperkalaemia), calcium (hypo- and hypercalcaemia) and magnesium (hypo- and hypermagnesaemia) are clinically more important. A list of important clinical conditions producing abnormalities in sodium and potassium are given in **Table 4.3**, while calcium and phosphate imbalances are discussed in Chapter 26.

While it is beyond the scope of this book to delve into the subject of electrolyte imbalances in detail, a few general principles are as under:

- i) Electrolyte imbalance in a given case may result from one or more conditions.
- ii) Resultant abnormal serum level of more than one electrolyte may be linked to each other e.g. abnormality in serum levels of sodium and potassium; calcium and phosphate.
- iii) Generally, the reflection of biochemical serum electrolyte levels is in the form of metabolic syndrome and clinical features rather than morphological findings in organs.

Table 4.3 Electrolyte imbalances of sodium and potassium.

HYPONATRAEMIA

- A. *Gain of Relatively More Water Than Loss of Sodium*
 - i. Excessive use of diuretics
 - ii. Hypotonic irrigating fluid administration
 - iii. Excessive IV infusion of 5% dextrose
 - iv. Psychogenic polydipsia
 - v. Large volume of beer consumption
 - vi. Addison's disease
- B. *Loss of Relatively More Salt Than Water*
 - i. Excessive use of diuretics
 - ii. Renal failure (ARF, CRF)
 - iii. Replacement of water without simultaneous salt replacement in conditions causing combined salt and water deficiency

HYPERNATRAEMIA

- A. *Gain of Relatively More Salt Than Loss Of Water*
 - i. IV infusion of hypertonic solution
 - ii. Survivors from sea-drowning
 - iii. Difficulty in swallowing e.g. oesophageal obstruction
 - iv. Excessive sweating (in deserts, heat stroke)
- B. *Loss of Relatively More Water Than Salt*
 - i. Diabetes insipidus
 - ii. Induced water deprivation (non-availability of water, total fasting)
 - iii. Replacement of salt without simultaneous water replacement in conditions causing combined salt and water deficiency

HYPOKALAEMIA

- A. *Decreased Potassium Intake*
 - i. Anorexia
 - ii. IV infusions without potassium
 - iii. Fasting
 - iv. Diet low in potassium
- B. *Excessive Potassium Excretion*
 - i. Loss from GI tract (e.g. vomitings, diarrhoea, laxatives)
 - ii. Loss from kidneys (e.g. excessive use of diuretics, corticosteroid therapy, hyperaldosteronism, Cushing's syndrome)
 - iii. Loss through skin (e.g. profuse perspiration)
 - iv. Loss from abnormal routes (e.g. mucinous tumours, drainage of fistula, gastric suction)
- C. *Excessive Mobilisation from Extracellular into Intracellular Compartment*
 - i. Excess insulin therapy
 - ii. Alkalosis

HYPERKALAEMIA

- A. *Excessive Potassium Intake*
 - i. Excessive or rapid infusion containing potassium
 - ii. Large volume of transfusion of stored blood
- B. *Decreased Potassium Excretion*
 - i. Oliguric phase of acute renal failure
 - ii. Adrenal cortical insufficiency (e.g. Addison's disease)
 - iii. Drugs such as ACE (angiotensin-converting enzyme) inhibitors
 - iv. Renal tubular disorders
- C. *Excessive Mobilisation from Intracellular into Extracellular Compartment*
 - i. Muscle necrosis (e.g. in crush injuries, haemolysis)
 - ii. Diabetic acidosis
 - iii. Use of drugs such as beta-blockers, cytotoxic drugs
 - iv. Insufficient insulin

iv) Clinical manifestations of a particular electrolyte imbalance are related to its pathophysiologic role in that organ or tissue.

pH OF BLOOD

During metabolism of cells, carbon dioxide and metabolic acids are produced. CO_2 combines with water to form carbonic acid. The role of bicarbonate buffering system in the extracellular compartment has already been stated above. In order to have acid-base homeostasis to maintain blood pH of 7.4, both carbonic acid and metabolic acids must be excreted from the body via lungs (for CO_2) and kidneys (for metabolic acids). Thus, the pH of blood depends upon 2 principal factors:

- ◆ serum concentration of bicarbonate; and
- ◆ partial pressure of CO_2 that determines the concentration of carbonic acid.

Accordingly, the disorders of the pH of the blood, termed as acidosis (blood pH below 7.4) and alkalosis (blood pH above 7.4), can be of 2 types:

1. *Alterations in the blood bicarbonate levels:* These are metabolic acidosis and alkalosis.
2. *Alteration in Pco_2* (which depends upon the ventilatory function of the lungs): These are respiratory acidosis and alkalosis.

ACID BASE IMBALANCE

Abnormalities in acid-base homeostasis produce following 4 principal metabolic states which have diverse clinical manifestations due to pathophysiologic derangements:

Metabolic Acidosis

A fall in the blood pH due to metabolic component is brought about by fall of bicarbonate level and excess of H^+ ions in the blood. This occurs in the following situations:

- i) Production of large amounts of lactic acid (lactic acidosis) e.g. in vigorous exercise, shock.
- ii) Uncontrolled diabetes mellitus (diabetic ketoacidosis).
- iii) Starvation.
- iv) Chronic renal failure.
- v) Therapeutic administration of ammonium chloride or acetazolamide (diamox).

High blood levels of H^+ ions in metabolic acidosis stimulate the respiratory centre so that the breathing is deep and rapid (*air hunger or Kussmaul's respiration*). There is fall in the plasma bicarbonate levels.

Metabolic Alkalosis

A rise in the blood pH due to rise in the bicarbonate levels of plasma and loss of H^+ ions is called metabolic alkalosis. This is seen in the following conditions:

- i) Severe and prolonged vomitings.
- ii) Administration of alkaline salts like sodium bicarbonate.
- iii) Hypokalaemia such as in Cushing's syndrome, increased secretion of aldosterone.

Clinically, metabolic alkalosis is characterised by depression of respiration, depressed renal function with uraemia and increased bicarbonate excretion in the urine. The blood level of bicarbonate is elevated.

Respiratory Acidosis

A fall in the blood pH occurring due to raised Pco_2 consequent to hypoventilation of lungs (CO_2 retention) causes respiratory acidosis. This can occur in the following circumstances:

- i) Air obstruction as occurs in chronic bronchitis, emphysema, asthma.
- ii) Restricted thoracic movement e.g. in pleural effusion, ascites, pregnancy, kyphoscoliosis.
- iii) Impaired neuromuscular function e.g. in poliomyelitis, polyneuritis.

Clinically, there is peripheral vasodilatation and raised intracranial pressure. If there is severe CO_2 retention, patients may develop confusion, drowsiness and coma. The arterial Pco_2 level is raised.

Respiratory Alkalosis

A rise in the blood pH occurring due to lowered Pco_2 consequent to hyperventilation of the lungs (excess removal of CO_2) is called respiratory alkalosis. This occurs in the following conditions:

- i) Hysterical overbreathing.
- ii) Working at high temperature.
- iii) At high altitude.
- iv) Meningitis, encephalitis.
- v) Salicylate intoxication.

Clinically, the patients with respiratory alkalosis are characterised by peripheral vasoconstriction and consequent pallor, lightheadedness and tetany. The arterial Pco_2 is lowered.

GIST BOX 4.3

Disturbances of Electrolytes and pH of Blood

- ▣ Normal serum levels of electrolytes are maintained in the body by a careful balance of 4 processes: their intake, absorption, distribution and excretion.
- ▣ The pH of blood depends upon serum concentration of bicarbonate and partial pressure of CO_2 .
- ▣ *Metabolic acidosis* is a fall in the blood pH due to fall of bicarbonate level and excess of H^+ ions in the blood, while a rise in the blood pH due to rise in bicarbonate levels of plasma and loss of H^+ ions is called *metabolic alkalosis*.
- ▣ Raised Pco_2 consequent to hypoventilation of lungs (CO_2 retention) causes *respiratory acidosis*, while a lowered Pco_2 consequent to hyperventilation of the lungs (excess removal of CO_2) is called *respiratory alkalosis*.

HAEMODYNAMIC DERANGEMENTS

The principles of blood flow are called haemodynamics. Normal circulatory function requires uninterrupted flow of blood from the left ventricle to the farthest capillaries in the body; return of blood from systemic capillary network into the right ventricle; and from the right ventricle to the farthest pulmonary capillaries and back to the left atrium (**Fig. 4.8**). There are three essential requirements to maintain normal blood flow and perfusion of tissues: normal anatomic features, normal physiologic controls for blood flow, and normal biochemical composition of the blood.

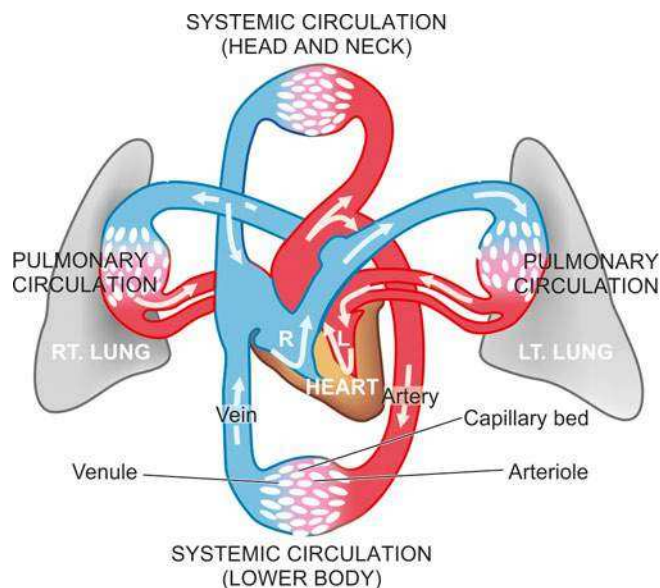

Figure 4.8 Normal haemodynamic flow of blood in the body.

Derangements of blood flow or haemodynamic disturbances are considered under 2 broad headings:

- I. *Disturbances in the volume of the circulating blood* These include: hyperaemia and congestion, haemorrhage and shock.
- II. *Circulatory disturbances of obstructive nature* These are: thrombosis, embolism, ischaemia and infarction.

DISTURBANCES IN THE VOLUME OF CIRCULATING BLOOD

HYPERAEMIA AND CONGESTION

Hyperaemia and congestion are the terms used for localised increase in the volume of blood within dilated vessels of an organ or tissue.

◆ Increased volume of blood from arterial and arteriolar dilatation (i.e. increased inflow) is referred to as *hyperaemia* or *active hyperaemia*.

◆ Impaired venous drainage (i.e. diminished outflow) is called *venous congestion* or *passive hyperaemia* (**Fig. 4.9**).

If the condition develops rapidly it is called *acute*, while more prolonged and gradual response is known as *chronic*.

Active Hyperaemia

The dilatation of arteries, arterioles and capillaries is effected either through sympathetic neurogenic mechanism or via the release of vasoactive substances. The affected tissue or organ is pink or red in appearance (erythema).

The *examples* of active hyperaemia are seen in the following conditions:

- i) Inflammation e.g. congested vessels in the walls of alveoli in pneumonia
- ii) Blushing i.e. flushing of the skin of face in response to emotions
- iii) Menopausal flush
- iv) Muscular exercise

- v) High grade fever
- vi) Goitre
- vii) Arteriovenous malformations

Clinically, hyperaemia is characterised by redness and raised temperature in the affected part.

Passive Hyperaemia (Venous Congestion)

The dilatation of veins and capillaries due to impaired venous drainage results in passive hyperaemia or venous congestion, commonly referred to as *passive congestion*. Congestion may be acute or chronic, the latter being more common and is called *chronic venous congestion* (CVC). The affected tissue or organ is bluish in colour due to accumulation of venous blood (cyanosis). Obstruction to the venous outflow may be local or systemic. Accordingly, venous congestion is of 2 types:

◆ *Local venous congestion* results from obstruction to the venous outflow from an organ or part of the body e.g. portal venous obstruction in cirrhosis of the liver, outside pressure on the vessel wall as occurs in tight bandage, plasters, tumours, pregnancy, hernia etc, or intraluminal occlusion by thrombosis.

◆ *Systemic (General) venous congestion* is engorgement of veins e.g. in left-sided and right-sided heart failure and diseases of the lungs which interfere with pulmonary blood flow like pulmonary fibrosis, emphysema etc. Usually the fluid accumulates upstream to the specific chamber of the heart which is initially affected (page 399). For example, in *left-sided heart failure* (such as due to mechanical overload in aortic stenosis, or due to weakened left ventricular wall

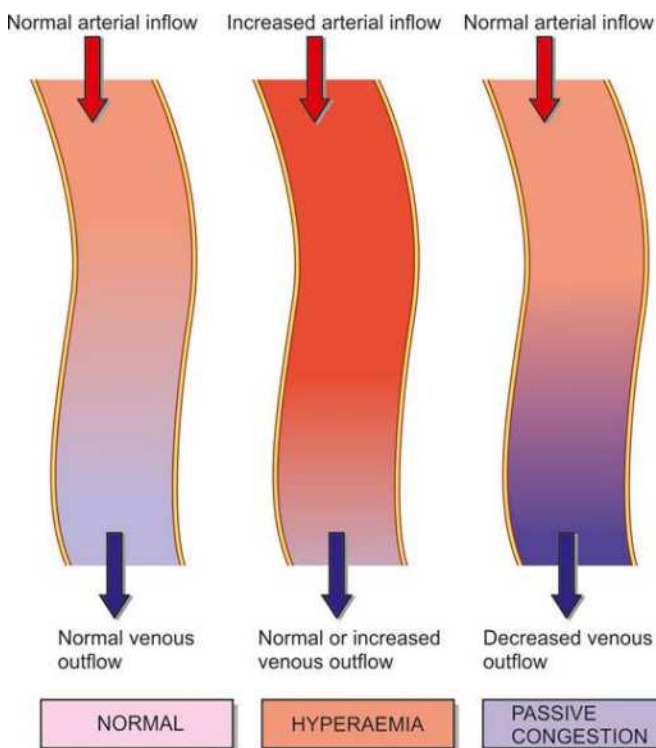

Figure 4.9 Schematic representation of abnormal accumulation of blood in the arteriovenous capillary bed causing hyperaemia and passive congestion.

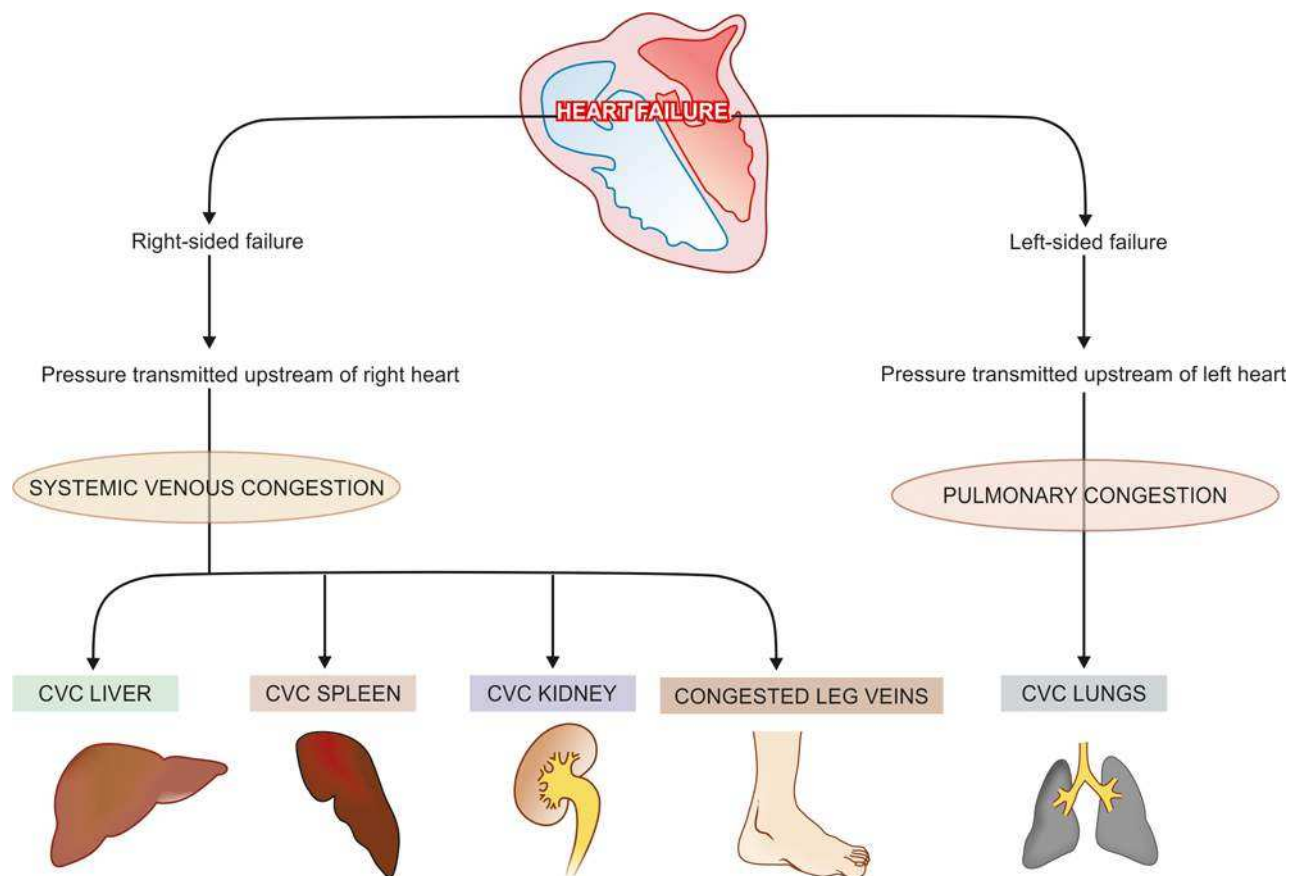

Figure 4.10 Schematic representation of mechanisms involved in chronic venous congestion (CVC) of different organs.

as in myocardial infarction) pulmonary congestion (or CVC lungs) results, whereas in *right-sided heart failure* (such as due to pulmonary stenosis or pulmonary hypertension) systemic venous congestion (i.e. CVC of systemic organs) results. **Fig. 4.10** illustrates the mechanisms involved in passive or venous congestion of different organs.

MORPHOLOGY OF CVC OF ORGANS

CVC Lung

Chronic venous congestion of the lung occurs in left heart failure (Chapter 14) (e.g. in rheumatic mitral stenosis) resulting in rise in pulmonary venous pressure.

Grossly, the lungs are heavy and firm in consistency. The sectioned surface is dark and rusty brown in colour, referred to as *brown induration* of the lungs.

Histologically, the features are as under:

- i) The alveolar septa are widened due to presence of interstitial oedema and dilated and congested capillaries in the septal wall. There is also slight increase in fibrous connective tissue in the alveolar septa.
- ii) Rupture of dilated and congested capillaries may result in minute intra-alveolar haemorrhages. The breakdown of erythrocytes liberates haemosiderin pigment which is taken

up by alveolar macrophages, called as *heart failure cells*, seen in the alveolar lumina. The brown induration observed on the cut surface of the lungs is due to the pigmentation and fibrosis (**Fig. 4.11**).

CVC Liver

Chronic venous congestion of the liver occurs in right heart failure and sometimes due to occlusion of inferior vena cava and hepatic vein.

Grossly, the liver is enlarged and tender and the capsule is tense. Cut surface shows characteristic *nutmeg** appearance due to red and yellow mottled appearance corresponding to congested centre of lobules and fatty peripheral zone respectively (**Fig. 4.12**).

Microscopically, the changes of passive congestion are more marked in the centrilobular zone (zone 3) which is farthest from blood supply (periportal zone, zone 1) and thus bears the brunt of hypoxia the most.

*Nutmeg (vernacular name *jaiphal*) is the seed of a spice tree that grows in India, and is used in cooking as spice for giving flavours.

Thickened alveolar septa Heart failure cells Intra-alveolar RBCs

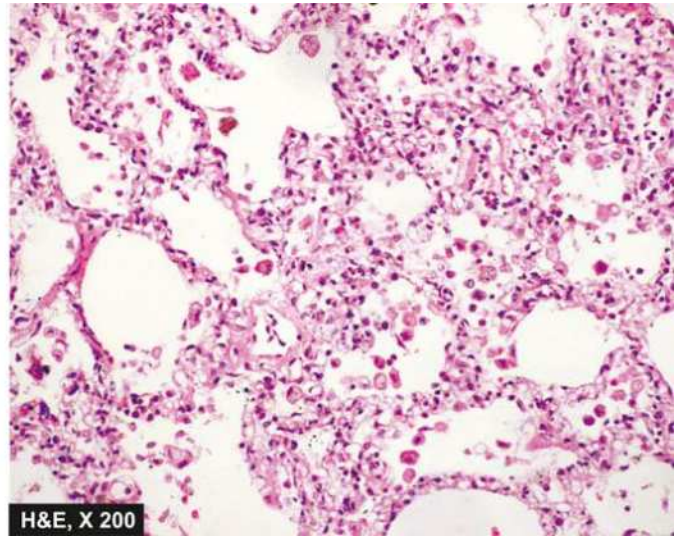

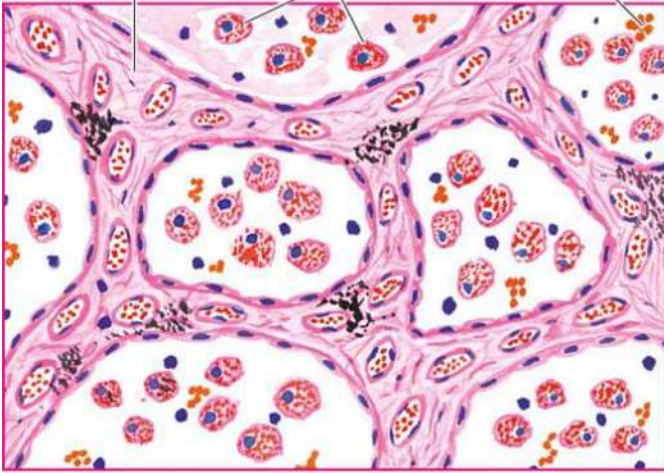

Figure 4.11 CVC lung. The alveolar septa are widened and thickened due to congestion, oedema and mild fibrosis. The alveolar lumina contain heart failure cells (alveolar macrophages containing haemosiderin pigment).

- i) The central veins as well as the adjacent sinusoids are distended and filled with blood. The centrilobular hepatocytes undergo degenerative changes, and eventually *centrilobular haemorrhagic necrosis* occurs.
- ii) Long-standing cases may show fine centrilobular fibrosis and regeneration of hepatocytes, resulting in cardiac cirrhosis (Chapter 19).
- iii) The peripheral zone of the lobule is less severely affected by chronic hypoxia and shows some *fatty change* in the hepatocytes (**Fig. 4.13**).

CVC Spleen

Chronic venous congestion of the spleen occurs in right heart failure and in portal hypertension from cirrhosis of liver.

Grossly, the spleen in early stage is slightly to moderately enlarged (up to 250 g as compared to normal 150 g), while in long-standing cases there is progressive enlargement and may weigh up to 500 to 1000 g. The organ is deeply congested, tense and cyanotic. Sectioned surface is gray tan (**Fig. 4.14**).

Microscopically, the features are as under (**Fig. 4.15**):

- i) *Red pulp* is enlarged due to congestion and marked sinusoidal dilatation and there are areas of recent and old haemorrhages. Sinusoids may get converted into capillaries (capillarisation of sinusoids).
- ii) There is *hyperplasia* of *reticuloendothelial cells* in the red pulp of the spleen (splenic macrophages).
- iii) There is *fibrous thickening* of the capsule and of the trabeculae.

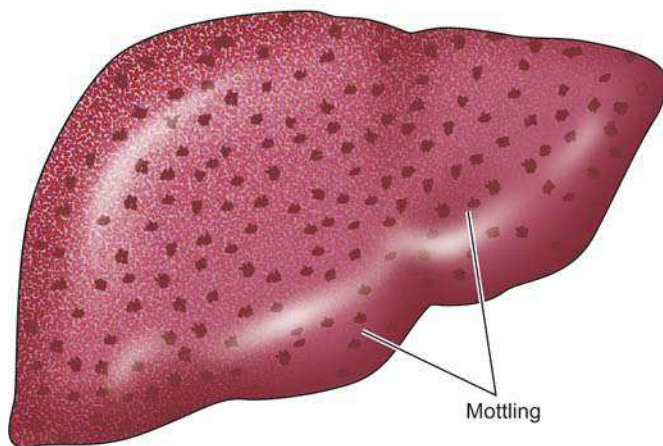

Figure 4.12 Nutmeg liver. The cut surface shows mottled appearance—alternate pattern of dark congestion and pale fatty change.

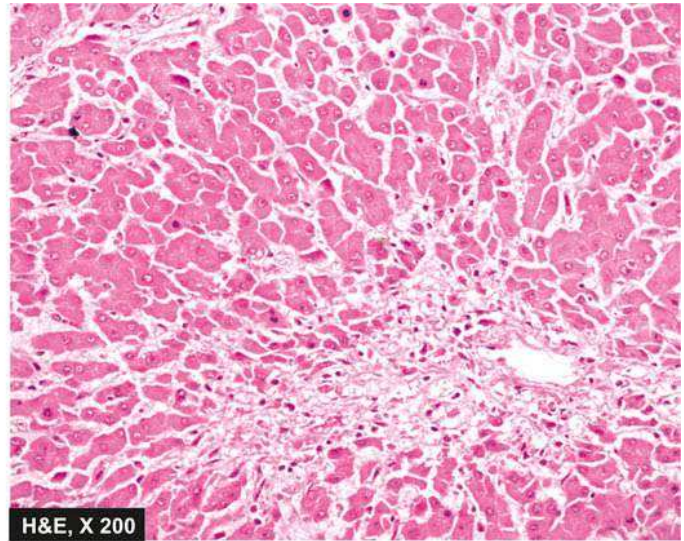

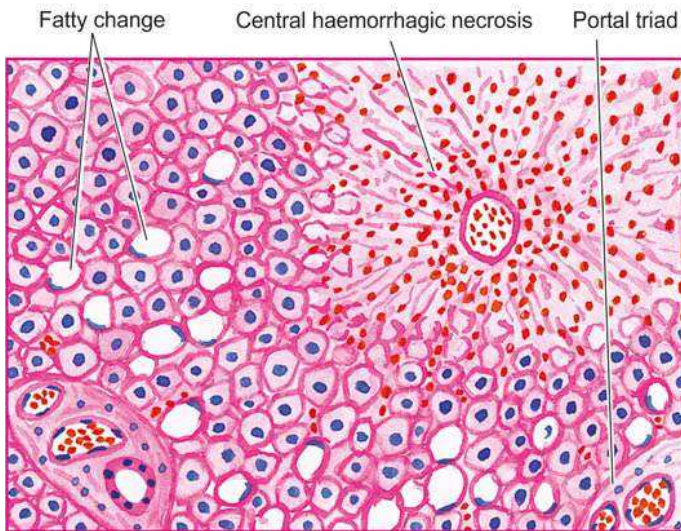

Figure 4.13 CVC liver. The centrilobular zone shows marked degeneration and necrosis of hepatocytes accompanied by haemorrhage while the peripheral zone shows mild fatty change of liver cells.

- iv) Some of haemorrhages overlying fibrous tissue get deposits of haemosiderin pigment and calcium salts; these organised structures are termed as *Gamna-Gandy bodies* or siderofibrotic nodules.
- v) Firmness of the spleen in advanced stage is seen more commonly in hepatic cirrhosis (*congestive splenomegaly*) and is the commonest cause of hypersplenism (Chapter 12).

CVC Kidney

Grossly, the kidneys are slightly enlarged and the medulla is congested.

Microscopically, the changes are rather mild. The tubules may show degenerative changes like cloudy swelling and fatty change. The glomeruli may show mesangial proliferation.

HAEMORRHAGE

Haemorrhage is the escape of blood from a blood vessel. The bleeding may occur *externally*, or *internally* into the serous cavities (e.g. haemothorax, haemoperitoneum, haemopericardium), or into a hollow viscus. Extravasation of blood into the tissues with resultant swelling is known as *haematoma*. Large extravasations of blood into the skin and mucous membranes are called *ecchymoses*. *Purpuras* are small areas of haemorrhages (upto 1 cm) into the skin and mucous membrane, whereas *petechiae* are minute pinhead-sized haemorrhages. Microscopic escape of erythrocytes into loose tissues may occur following marked congestion and is known as *diapedesis*.

ETIOLOGY The blood loss may be large and sudden (*acute*), or small repeated bleeds may occur over a period of time (*chronic*). The various causes of haemorrhage are as under:

1. *Trauma* to the vessel wall e.g. penetrating wound in the heart or great vessels, during labour etc.
2. *Spontaneous haemorrhage* e.g. rupture of an aneurysm, septicaemia, bleeding diathesis (such as purpura), acute leukaemias, pernicious anaemia, scurvy.

3. *Inflammatory lesions of the vessel wall* e.g. bleeding from chronic peptic ulcer, typhoid ulcers, blood vessels traversing a tuberculous cavity in the lung, syphilitic involvement of the aorta, polyarteritis nodosa.
4. *Neoplastic invasion* e.g. haemorrhage following vascular invasion in carcinoma of the tongue.
5. *Vascular diseases* e.g. atherosclerosis.
6. *Elevated pressure within the vessels* e.g. cerebral and retinal haemorrhage in systemic hypertension, severe haemorrhage from varicose veins due to high pressure in the veins of legs or oesophagus.

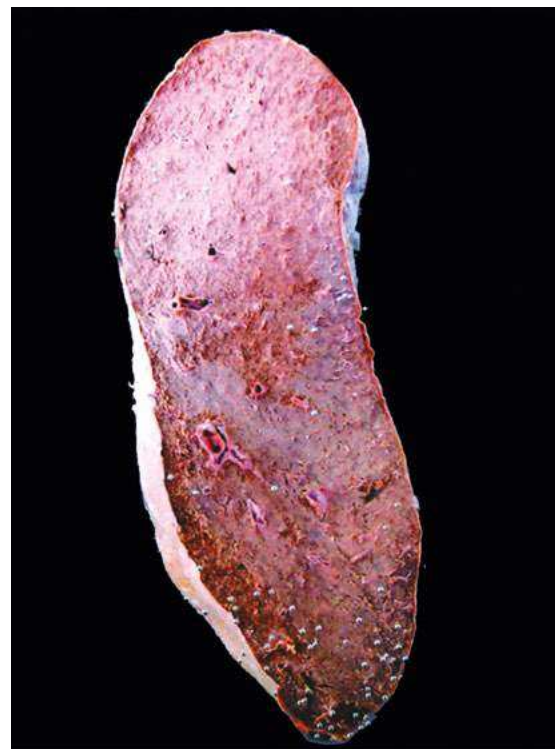

Figure 4.14 CVC spleen (Congestive splenomegaly). Sectioned surface shows that the spleen is heavy and enlarged in size. The colour of sectioned surface is grey-tan.

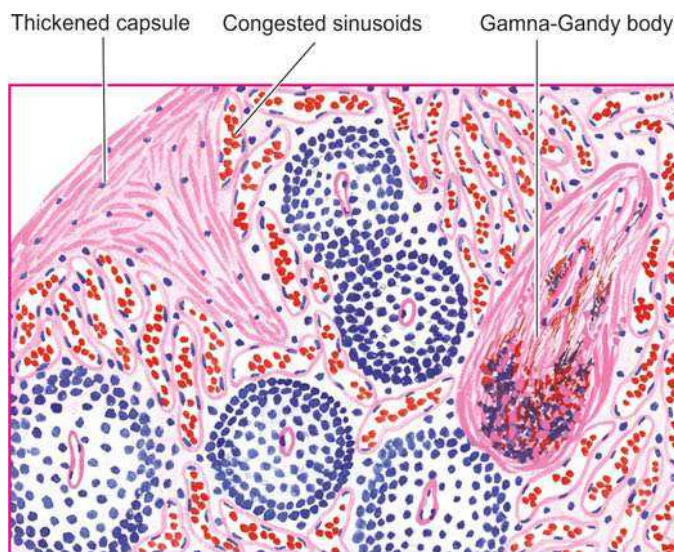

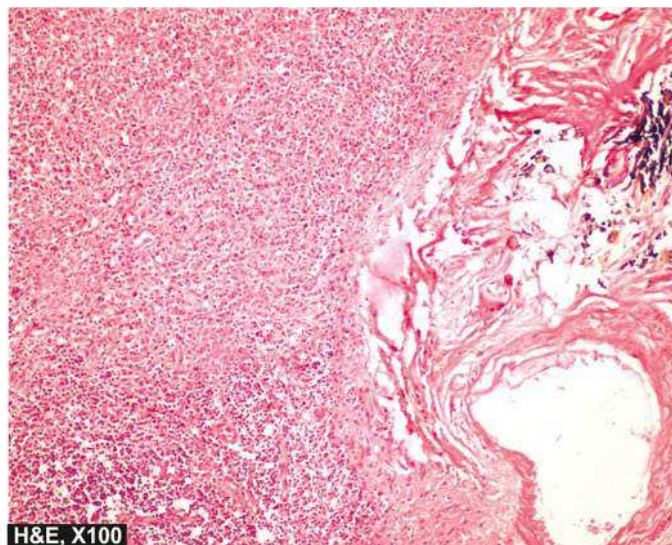

Figure 4.15 CVC spleen. The sinusoids are dilated and congested. There is increased fibrosis in the red pulp, capsule and the trabeculae. A Gamna-Gandy body is also seen.

EFFECTS The effects of blood loss depend upon 3 main factors:

- i) the amount of blood loss;
- ii) the speed of blood loss; and
- iii) the site of haemorrhage.

The loss up to 20% of blood volume suddenly or slowly generally has little clinical effects because of compensatory mechanisms. A sudden loss of 33% of blood volume may cause death, while loss of up to 50% of blood volume gradually over a period of 24 hours may not be necessarily fatal. However, chronic blood loss generally produces iron deficiency anaemia, whereas acute haemorrhage may lead to serious immediate consequences such as hypovolaemic shock.

GIST BOX 4.4

Hyperaemia, Congestion and Haemorrhage

- ▣ Increased volume of blood from arterial and arteriolar dilatation (i.e. increased inflow) is referred to as hyperaemia or active hyperaemia, while impaired venous drainage (i.e. diminished outflow) is called venous congestion or passive hyperaemia.
- ▣ Congestion may be acute or chronic, the latter being more common and is called chronic venous congestion (CVC).
- ▣ Systemic venous congestion is engorgement of veins e.g. in left-sided heart failure (CVC lungs), right-sided heart failure (CVC liver, spleen, kidneys, other sites).
- ▣ Haemorrhage is the escape of blood from a blood vessel. The bleeding may occur externally, or internally into the serous cavities, into a hollow viscus, or in to skin and mucous membranes.
- ▣ Rapid loss of above 33% of blood volume is more serious than gradual blood loss of 50% in 24 hours.

SHOCK

Definition

Shock is a life-threatening clinical syndrome of cardiovascular collapse characterised by:

- ◆ an acute reduction of effective circulating blood volume (hypotension); and
- ◆ an inadequate perfusion of cells and tissues (hypoperfusion).

If uncompensated, these mechanisms may lead to impaired cellular metabolism and death.

Thus, by definition “*true (or secondary) shock*” is a circulatory imbalance between oxygen supply and oxygen requirements at the cellular level, and is also called as circulatory shock and is the type which is commonly referred to as ‘shock’ if not specified.

The term “*initial (or primary) shock*” is used for transient and usually a benign vasovagal attack resulting from sudden reduction of venous return to the heart caused by neurogenic vasodilatation and consequent peripheral pooling of blood e.g. immediately following trauma, severe pain or emotional overreaction such as due to fear, sorrow or surprise. Clinically, patients of primary shock suffer from the attack lasting for a few seconds or minutes and develop brief unconsciousness, weakness, sinking sensation, pale and clammy limbs, weak and rapid pulse, and low blood pressure. Another type of shock which is not due to circulatory derangement is *anaphylactic shock* from type 1 immunologic (amaphylactic) reaction (page 60).

Classification and Etiology

Although in a given clinical case, two or more factors may be involved in causation of true shock, a simple etiologic classification of shock syndrome divides it into following 3 major types and a few other variants (**Table 4.4**):

1. Hypovolaemic shock This form of shock results from inadequate circulatory blood volume by various etiologic factors that may be *either* from the loss of red cell mass and plasma due to haemorrhage, *or* from the loss of plasma volume alone.

2. Cardiogenic shock Acute circulatory failure with sudden fall in cardiac output from acute diseases of the heart without

| | ii) <i>Gram-positive septicaemia (exotoxic shock) e.g.</i> Infection with streptococci, pneumococci |
| 4. | OTHER TYPES |
| | i) <i>Traumatic shock</i> |
| | a) Severe injuries |
| | b) Surgery with marked blood loss |
| | c) Obstetrical trauma |
| | ii) <i>Neurogenic shock</i> |
| | a) High cervical spinal cord injury |
| | b) Accidental high spinal anaesthesia |
| | c) Severe head injury |
| | iii) <i>Hypoadrenal shock</i> |
| | a) Administration of high doses of glucocorticoids |
| | b) Secondary adrenal insufficiency (e.g. in tuberculosis, metastatic disease, bilateral adrenal haemorrhage, idiopathic adrenal atrophy) |

actual reduction of blood volume (normovolaemia) results in cardiogenic shock.

3. Septic (Toxaemic) shock Severe bacterial infections or septicaemia induce septic shock. It may be the result of Gram-negative septicaemia (endotoxic shock) which is more common, or less often from Gram-positive septicaemia (exotoxic shock).

4. Other types These include following types:

i) *Traumatic shock* Shock resulting from trauma is initially due to hypovolaemia, but even after haemorrhage has been controlled, these patients continue to suffer loss of plasma volume into the interstitium of injured tissue and hence is considered separately in some descriptions.

ii) *Neurogenic shock* Neurogenic shock results from causes of interruption of sympathetic vasomotor supply.

iii) *Hypoadrenal shock* Hypoadrenal shock occurs from unknown adrenal insufficiency in which the patient fails to respond normally to the stress of trauma, surgery or illness.

Pathogenesis

In general, all forms of shock involve following 3 derangements:

- Reduced effective circulating blood volume.
- Reduced supply of oxygen to the cells and tissues with resultant anoxia.
- Inflammatory mediators and toxins released from shock-induced cellular injury.

These derangements initially set in compensatory mechanisms (discussed below) but eventually a vicious cycle of cell injury and severe cellular dysfunction lead to breakdown of organ function (Fig. 4.16).

1. Reduced effective circulating blood volume It may result by either of the following mechanisms:

- by actual loss of blood volume as occurs in hypovolaemic shock; or
- by decreased cardiac output without actual loss of blood (normovolaemia) as occurs in cardiogenic shock and septic shock.

2. Impaired tissue oxygenation Following reduction in the effective circulating blood volume from either of the above two mechanisms and from any of the etiologic agents, there is decreased venous return to the heart resulting in decreased cardiac output. This consequently causes reduced supply of oxygen to the organs and tissues and hence tissue anoxia occurs, which sets in cellular injury.

3. Release of inflammatory mediators In response to cellular injury, innate immunity of the body gets activated as a body defense mechanism and causes release of inflammatory mediators but eventually these agents themselves become the cause of cell injury. Endotoxins in bacterial wall in septic shock stimulate massive release of pro-inflammatory mediators (cytokines) but a similar process of release of these agents takes place in late stages of shock from other causes. Several pro-inflammatory mediators are released from monocytes-macrophages, other leucocytes and other body cells, the most important being the tumour necrosis factor-(TNF)- α and interleukin-1 (IL-1) cytokines (Fig. 4.17).

After these general comments on mechanisms in shock, features specific to pathogenesis of three major forms of shock are given below:

PATHOGENESIS OF HYPOVOLAEMIC SHOCK Hypovolaemic shock occurs from inadequate circulating blood volume due to various causes, most often from loss of red cell mass due to haemorrhage and, therefore, also called as haemorrhagic shock. The major effects in this are due to decreased cardiac output and low intracardiac pressure. The severity of clinical features depends upon degree of blood volume lost; accordingly haemorrhagic shock is divided into 4 types:

- ≤ 1000 ml: Compensated
- 1000-1500 ml: Mild
- 1500-2000 ml: Moderate
- >2000 ml: Severe

Major clinical features are increased heart rate (tachycardia), low blood pressure (hypotension), low urinary output (oliguria to anuria) and alteration in mental state (agitated to confused to lethargic).

PATHOGENESIS OF CARDIOGENIC SHOCK Cardiogenic shock results from a severe left ventricular dysfunction from various causes such as acute myocardial infarction. The

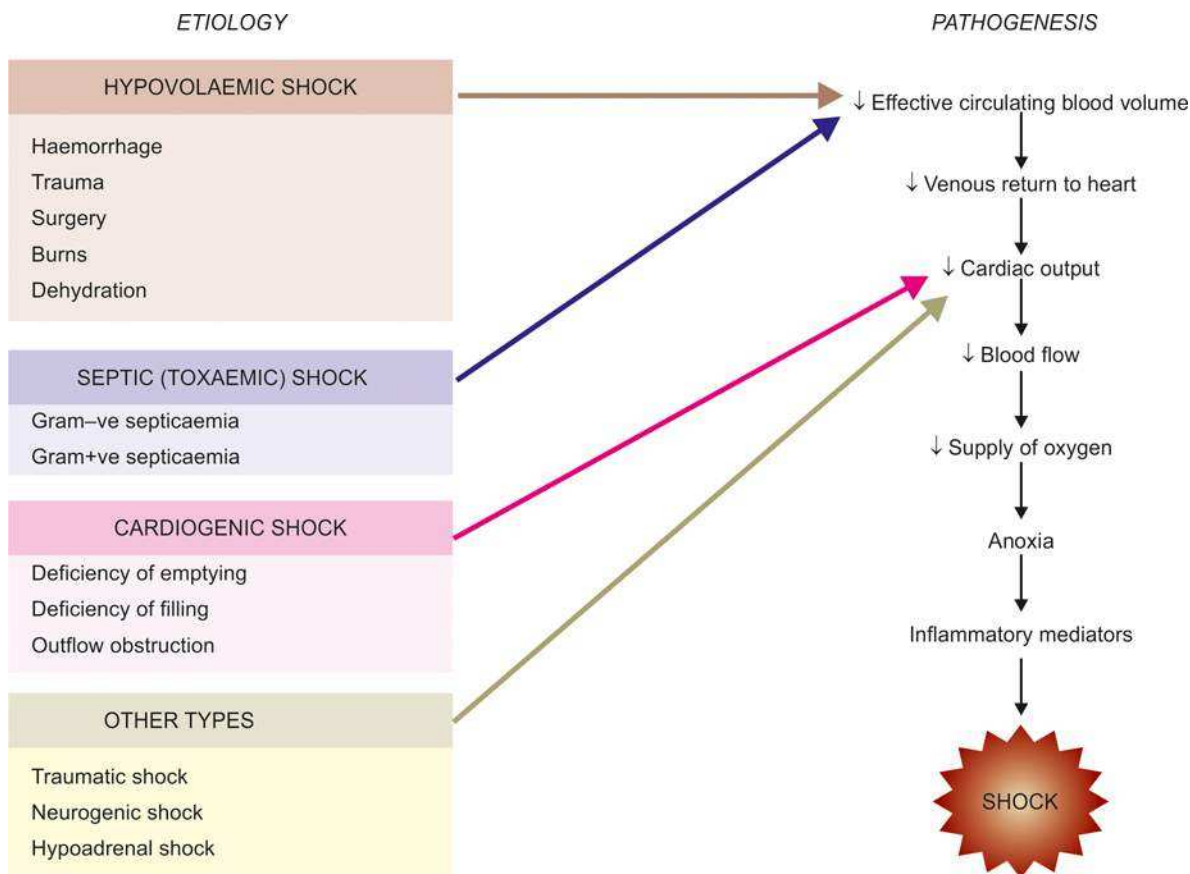

Figure 4.16 Pathogenesis of circulatory shock.

resultant decreased cardiac output has its effects in the form of decreased tissue perfusion and movement of fluid from pulmonary vascular bed into pulmonary interstitial space initially (*interstitial pulmonary oedema*) and later into alveolar spaces (*alveolar pulmonary oedema*).

PATHOGENESIS OF SEPTIC SHOCK Septic shock results most often from Gram-negative bacteria entering the body from genitourinary tract, alimentary tract, respiratory tract or skin, and less often from Gram-positive bacteria. In septic shock, there is immune system activation and severe systemic inflammatory response to infection as follows:

i) Activation of macrophage-monocytes Lysis of Gram-negative bacteria releases endotoxin, a lipopolysaccharide (LPS), into circulation where it binds to lipopolysaccharide-binding protein (LBP). The complex of LPS-LBP binds to CD14 molecule on the surface of the monocyte/macrophages which are stimulated to elaborate proinflammatory cytokines, the most important ones being $\text{TNF-}\alpha$ and IL-1. The effects of these cytokines are as under:

a) *By altering endothelial cell adhesiveness*: This results in recruitment of more neutrophils which liberate free radicals that cause vascular injury.

b) *Promoting nitric oxide synthase*: This stimulates increased synthesis of nitric oxide which is responsible for vasodilatation and hypotension.

ii) Activation of other inflammatory responses Microbial infection activates other inflammatory cascades which have profound effects in triggering septic shock. These are as under:

a) *Activation of complement pathway*: End-products C5a and C3a induce microemboli and endothelial damage.

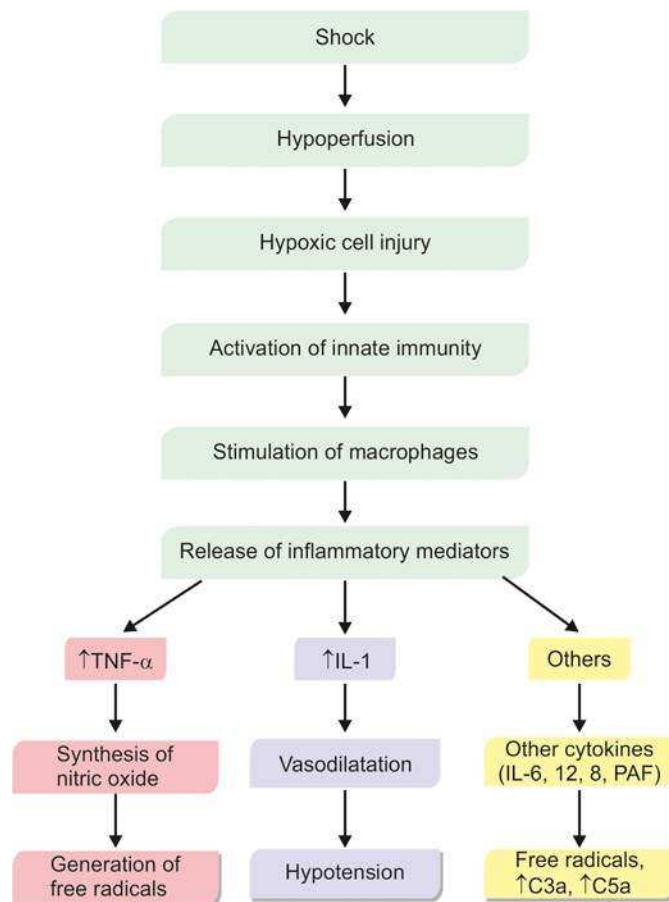

Figure 4.17 Response of inflammatory mediators in shock.

b) *Activation of mast cells*: Histamine is released which increases capillary permeability.

c) *Activation of coagulation system*: Enhances development of thrombi.

d) *Activation of kinin system*: Released bradykinin causes vasodilatation and increased capillary permeability.

The net result of above mechanisms is vasodilatation and increased vascular permeability in septic shock. Profound peripheral vasodilatation and pooling of blood causes hyperdynamic circulation in septic shock, in contrast to hypovolaemic and cardiogenic shock. Increased vascular permeability causes development of inflammatory oedema. Disseminated intravascular coagulation (DIC) is prone to develop in septic shock due to endothelial cell injury by toxins. Reduced blood flow produces hypotension, inadequate perfusion of cells and tissues, finally leading to organ dysfunction.

Pathophysiology (Stages of Shock)

Although deterioration of the circulation in shock is a progressive and continuous phenomenon and compensatory mechanisms become progressively less effective, historically shock has been divided arbitrarily into 3 stages (Fig. 4.18):

1. Compensated (non-progressive, initial, reversible) shock
2. Progressive decompensated shock
3. Irreversible decompensated shock

COMPENSATED (NON-PROGRESSIVE, INITIAL, REVERSIBLE) SHOCK In the early stage of shock, an attempt is made to maintain adequate cerebral and coronary blood supply by redistribution of blood so that the vital organs (brain and heart) are adequately perfused and oxygenated. This is achieved by activation of various neurohormonal mechanisms causing *widespread vasoconstriction* and by *fluid conservation by the kidney*. If the condition that caused the shock is adequately treated, the compensatory mechanism may be able to bring about recovery and re-establish the normal circulation; this is called compensated or reversible shock. These compensatory mechanisms are as under:

i) Widespread vasoconstriction In response to reduced blood flow (hypotension) and tissue anoxia, the neural

and humoral factors (e.g. baroreceptors, chemoreceptors, catecholamines, renin, and angiotensin-II) are activated. All these bring about vasoconstriction, particularly in the vessels of the skin and abdominal viscera. Widespread vasoconstriction is a protective mechanism as it causes increased peripheral resistance, increased heart rate (tachycardia) and increased blood pressure. However, in septic shock, there is initial vasodilatation followed by vasoconstriction. Besides, in severe septic shock there is elevated level of thromboxane A₂ which is a potent vasoconstrictor and may augment the cardiac output along with other sympathetic mechanisms. Clinically, cutaneous vasoconstriction is responsible for cool and pale skin in initial stage of shock.

ii) Fluid conservation by the kidney In order to compensate the actual loss of blood volume in hypovolaemic shock, the following factors may assist in restoring the blood volume and improve venous return to the heart:

- a) Release of aldosterone from hypoxic kidney by activation of renin-angiotensin-aldosterone mechanism.
- b) Release of ADH due to decreased effective circulating blood volume.
- c) Reduced glomerular filtration rate (GFR) due to arteriolar constriction.
- d) Shifting of tissue fluids into the plasma due to lowered capillary hydrostatic pressure (hypotension).

iii) Stimulation of adrenal medulla In response to low cardiac output, adrenal medulla is stimulated to release excess of catecholamines (epinephrine and non-epinephrine) which increase heart rate and try to increase cardiac output.

PROGRESSIVE DECOMPENSATED SHOCK This is a stage when the patient suffers from some other stress or risk factors (e.g. pre-existing cardiovascular and lung disease) besides persistence of the shock condition; this causes progressive deterioration. The effects of resultant tissue hypoperfusion in progressive decompensated shock are as under:

i) Pulmonary hypoperfusion Decompensated shock worsens pulmonary perfusion and increases vascular permeability resulting in tachypnoea and adult respiratory distress syndrome (ARDS).

| STAGE | PATHOGENESIS | EFFECTS |
|----------------------------------|--|---|
| COMPENSATED (INITIAL) SHOCK | <ol style="list-style-type: none"> i) Widespread vasoconstriction ii) Fluid conservation by kidney iii) Stimulation of adrenal medulla | <ul style="list-style-type: none"> • Tachycardia • Cool clammy skin |
| PROGRESSIVE DECOMPENSATED SHOCK | <ol style="list-style-type: none"> i) Pulmonary hypoperfusion ii) Tissue ischaemia | <ul style="list-style-type: none"> • ↓ Cardiac output • Mental confusion • ↓ Urinary output • Tachypnoea |
| IRREVERSIBLE DECOMPENSATED SHOCK | <ol style="list-style-type: none"> i) Progressive vasodilatation ii) ↑ Vascular permeability iii) Myocardial depressant factor (MDF) iv) Pulmonary hypoperfusion v) Anoxic damage vi) Hypercoagulability | <ul style="list-style-type: none"> • Brain: Hypoxic encephalopathy • Heart: Focal myocardial necrosis • Lungs: ARDS • Kidney: ATN • Adrenals: Necrosis • GI: Haemorrhagic gastroenteropathy • Liver: Necrosis • Blood : DIC |

Figure 4.18 Mechanisms and effects of three stages of shock.

ii) Tissue ischaemia Impaired tissue perfusion causes switch from aerobic to anaerobic glycolysis resulting in *metabolic lactic acidosis*. Lactic acidosis lowers the tissue pH which in turn makes the vasomotor response ineffective. This results in vasodilatation and peripheral pooling of blood.

Clinically, at this stage the patient develops confusion and worsening of renal function.

IRREVERSIBLE DECOMPENSATED SHOCK When the shock is so severe that in spite of compensatory mechanisms and despite therapy and control of etiologic agent which caused the shock, no recovery takes place, it is called decompensated or irreversible shock. Its effects due to widespread cell injury are as follows:

i) Progressive vasodilatation During later stages of shock, anoxia damages the capillary and venular wall while arterioles become unresponsive to vasoconstrictors listed above and begin to dilate. Vasodilatation results in peripheral pooling of blood which further deteriorates the effective circulating blood volume.

ii) Increased vascular permeability Anoxic damage to tissues releases proinflammatory mediators which cause increased vascular permeability. This results in escape of fluid from circulation into the interstitial tissues thus deteriorating effective circulating blood volume.

iii) Myocardial depressant factor (MDF) Progressive fall in the blood pressure and persistently reduced blood flow to myocardium causes coronary insufficiency and myocardial ischaemia due to release of myocardial depressant factor (MDF). This results in further depression of cardiac function, reduced cardiac output and decreased blood flow.

iv) Worsening pulmonary hypoperfusion Further pulmonary hypoperfusion causes respiratory distress due to pulmonary oedema, tachypnoea and adult respiratory distress syndrome (ARDS).

v) Anoxic damage to heart, kidney and brain Progressive tissue anoxia causes severe metabolic acidosis due to anaerobic glycolysis. There is release of proinflammatory cytokines and other inflammatory mediators and generation of free radicals. Since highly specialised cells of the myocardium, proximal tubular cells of the kidney, and neurons of the CNS are dependent solely on aerobic respiration for ATP generation, there is ischaemic cell death in these tissues.

vi) Hypercoagulability of blood Tissue damage in shock activates coagulation cascade with release of clot promoting factor, thromboplastin and release of platelet aggregator, ADP, which contributes to slowing of blood-stream and vascular thrombosis. In this way, hypercoagulability of blood with consequent microthrombi impair the blood flow and cause further tissue necrosis.

Clinically, at this stage the patient has features of coma, worsened heart function and progressive renal failure due to acute tubular necrosis.

MORPHOLOGIC FEATURES

Eventually, shock is characterised by multisystem failure. The morphologic changes in shock are due to hypoxia resulting in degeneration and necrosis in various organs. The major organs affected are the brain, heart, lungs

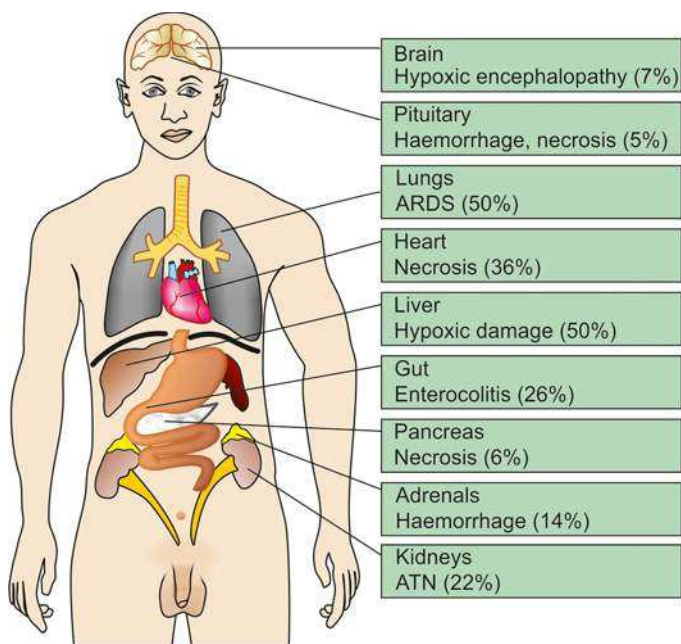

Figure 4.19 Morphologic features of shock.

and kidneys. Morphologic changes are also noted in the adrenals, gastrointestinal tract, liver and other organs. The predominant morphologic changes and their incidence are shown in **Fig. 4.19** and described below.

1. HYPOXIC ENCEPHALOPATHY Cerebral ischaemia in compensated shock may produce altered state of consciousness. However, if the blood pressure falls below 50 mmHg as occurs in systemic hypotension in prolonged shock and cardiac arrest, brain suffers from serious ischaemic damage with loss of cortical functions, coma, and a vegetative state.

Grossly, the area supplied by the most distal branches of the cerebral arteries suffers from severe ischaemic necrosis which is usually the border zone between the anterior and middle cerebral arteries (page 874).

Microscopically, the changes are noticeable if ischaemia is prolonged for 12 to 24 hours. Neurons, particularly Purkinje cells, are more prone to develop the effects of ischaemia. The cytoplasm of the affected neurons is intensely eosinophilic and the nucleus is small pyknotic. Dead and dying nerve cells are replaced by gliosis.

2. HEART IN SHOCK The heart is more vulnerable to the effects of hypoxia than any other organ. Heart is affected in cardiogenic as well as in other forms of shock. There are 2 types of morphologic changes in heart in all types of shock:

i) **Haemorrhages and necrosis** There may be small or large ischaemic areas or infarcts, particularly located in the subepicardial and subendocardial region.

ii) **Zonal lesions** These are opaque transverse contraction bands in the myocytes near the intercalated disc.

3. SHOCK LUNG Lungs due to dual blood supply are generally not affected by hypovolaemic shock but in septic shock the morphologic changes in lungs are quite prominent termed 'shock lung'.

Grossly, the lungs are heavy and wet.

Microscopically, changes of adult respiratory distress syndrome (ARDS) are seen (page 444). Briefly, the changes include congestion, interstitial and alveolar oedema, interstitial lymphocytic infiltrate, alveolar hyaline membranes, thickening and fibrosis of alveolar septa, and fibrin and platelet thrombi in the pulmonary microvasculature.

4. SHOCK KIDNEY One of the important complications of shock is irreversible renal injury, first noted in persons who sustained crush injuries in building collapses in air raids in World War II. Renal ischaemia following systemic hypotension is considered responsible for renal changes in shock. The end-result is generally anuria and death.

Grossly, the kidneys are soft and swollen. Sectioned surface shows blurred architectural markings.

Microscopically, tubular lesions are seen at all levels of nephron and are referred to as acute tubular necrosis (ATN) which can occur following other causes besides shock (page 661). If extensive muscle injury or intravascular haemolysis is also associated, peculiar brown tubular casts are seen.

5. ADRENALS IN SHOCK The adrenals show stress response in shock. This includes release of aldosterone in response to hypoxic kidney, release of glucocorticoids from adrenal cortex and catecholamines like adrenaline from adrenal medulla. In severe shock, acute adrenal haemorrhagic necrosis may occur.

6. HAEMORRHAGIC GASTROENTEROPATHY The hypoperfusion of the alimentary tract in conditions such as shock and cardiac failure may result in mucosal and mural infarction called haemorrhagic gastroenteropathy (page 547). This type of non-occlusive ischaemic injury of bowel must be distinguished from full-fledged infarction in which deeper layers of the gut (muscularis and serosa) are also damaged. In shock due to burns, acute stress ulcers of the stomach or duodenum may occur and are known as Curling's ulcers.

Grossly, the lesions are multifocal and widely distributed throughout the bowel. The lesions are superficial ulcers, reddish purple in colour. The adjoining bowel mucosa is oedematous and haemorrhagic.

Microscopically, the involved surface of the bowel shows dilated and congested vessels and haemorrhagic necrosis of the mucosa and sometimes submucosa. Secondary infection may supervene and condition may progress into pseudomembranous enterocolitis.

7. LIVER IN SHOCK **Grossly**, faint nutmeg appearance is seen.

Microscopically, depending upon the time gap between injury and cell death, ischaemic shrinkage, hydropic change, focal necrosis, or fatty change may be seen. Liver function may be impaired.

8. OTHER ORGANS Other organs such as lymph nodes, spleen and pancreas may also show foci of necrosis in shock. In addition, patients who survive acute phase of shock succumb to overwhelming infections due to altered immune status and impaired host defense mechanism.

Clinical Features and Complications

The classical features of decompensated shock are characterised by *depression of 4 vital processes*:

- i) Very low blood pressure
- ii) Subnormal temperature
- iii) Feeble and irregular pulse
- iv) Shallow and sighing respiration

In addition, the patients in shock have pale face, sunken eyes, weakness, cold and clammy skin.

Life-threatening complications in shock are due to hypoxic cell injury resulting in immuno-inflammatory responses and activation of various cascades (clotting, complement, kinin). These include the following*:

1. Acute respiratory distress syndrome (ARDS)
2. Disseminated intravascular coagulation (DIC)
3. Acute renal failure (ARF)
4. Multiple organ dysfunction syndrome (MODS)

With progression of the condition, the patient may develop stupor, coma and death.

GIST BOX 4.5

Shock

- ☐ Shock is a clinical syndrome of cardiovascular collapse characterised by an acute reduction of effective circulating blood volume (hypotension) and an inadequate perfusion of cells and tissues (hypoperfusion).
- ☐ There are 3 major forms of shock: hypovolaemic, cardiogenic and septic.
- ☐ All forms of shock involve 3 mechanisms: reduced effective circulating blood volume, impaired tissue oxygenation and release of proinflammatory mediators.
- ☐ Shock is divided into 3 stages: initial reversible stage (compensated shock), progressive decompensated shock and finally the stage of irreversible decompensated shock.
- ☐ Shock causes morphologic changes in different organ systems, notably in the brain (hypoxic encephalopathy), heart (haemorrhage and necrosis), lungs (ARDS), kidneys (tubular necrosis), adrenals (haemorrhage and necrosis), liver (focal necrosis), gut (haemorrhagic gastroenteropathy) and other organs.
- ☐ Clinically, shock is characterised by low blood pressure, low body temperature, feeble pulse, shallow respiration, pale face and cold clammy skin.

CIRCULATORY DISTURBANCES OF OBSTRUCTIVE NATURE

THROMBOSIS

Definition and Effects

Thrombosis is the process of formation of solid mass in circulation from the constituents of flowing blood; the mass itself is called a *thrombus*. A term commonly used erroneously synonymous with thrombosis is blood clotting. While *thrombosis* is characterised by events that essentially involve activation of platelets, the process of *clotting* involves only

*Major complications of shock can be remembered from acronym ADAM: A = ARDS; D = DIC; A = ARF; M = MODS.

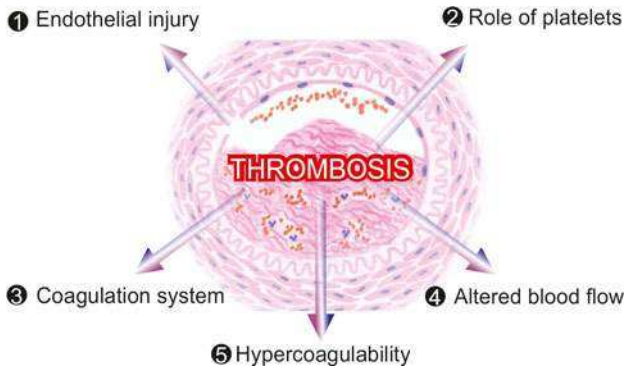

Figure 4.20 Major factors in pathophysiology of thrombus formation.

conversion of soluble fibrinogen to insoluble polymerised fibrin. Besides, clotting is also used to denote coagulation of blood *in vitro* e.g. in a test tube. *Haematoma* is the extravascular accumulation of blood e.g. into the tissues. *Haemostatic plugs* are the blood clots formed in healthy individuals at the site of bleeding e.g. in injury to the blood vessel. In other words, haemostatic plug at the cut end of a blood vessel may be considered the simplest form of thrombosis. Haemostatic plugs are useful as they stop escape of blood and plasma, whereas thrombi developing in the unruptured cardiovascular system may be life-threatening by causing one of the following harmful effects:

1. *Ischaemic injury* Thrombi may decrease or stop the blood supply to part of an organ or tissue and cause ischaemia which may subsequently result in infarction.
2. *Thromboembolism* Thrombus or its part may get dislodged and be carried along in the bloodstream as embolus to lodge in a distant vessel.

Pathophysiology

Since the protective haemostatic plug formed as a result of normal haemostasis is an example of thrombosis, it is essential to describe *thrombogenesis* in relation to the normal haemostatic mechanism.

Human beings possess inbuilt system by which the blood remains in fluid state normally and guards against the hazards of thrombosis and haemorrhage. However, injury to the blood vessel initiates haemostatic repair mechanism or thrombogenesis.

Virchow described three primary events which predispose to thrombus formation (*Virchow's triad*): endothelial injury, altered blood flow, and hypercoagulability of blood. To this are added the activation processes that follow these primary events: activation of platelets and of clotting system (**Fig. 4.20**). These events are discussed below:

1. ENDOTHELIAL INJURY The integrity of blood vessel wall is important for maintaining normal blood flow. An intact endothelium has the following functions:

- i) It *protects* the flowing blood from thrombogenic influence of subendothelium.
- ii) It elaborates a few *anti-thrombotic* factors (thrombosis inhibitory factors) as follows:
 - a) Heparin-like substance which accelerates the action of antithrombin III and inactivates some other clotting factors.

- b) Thrombomodulin which converts thrombin into activator of protein C, an anticoagulant.
- c) Inhibitors of platelet aggregation such as ADPase, PGI₂ (or prostacyclin).
- d) Tissue plasminogen activator which accelerates fibrinolytic activity.

iii) It releases a few *prothrombotic factors* which have procoagulant properties (thrombosis favouring factors) as under:

- a) Thromboplastin or tissue factor released from endothelial cells.
- b) von Willebrand factor that causes adherence of platelets to the subendothelium.
- c) Platelet activating factor which is activator and aggregator of platelets.
- d) Inhibitor of plasminogen activator that suppresses fibrinolysis.

Vascular injury exposes the subendothelial extracellular matrix or ECM (e.g. collagen, elastin, fibronectin, laminin and glycosaminoglycans) which is thrombogenic and thus plays an important role in initiating haemostasis as well as thrombosis (**Fig. 4.21**). Injury to vessel wall also causes vasoconstriction of small blood vessels briefly so as to reduce the blood loss. Endothelial injury is of major significance in the formation of arterial thrombi and thrombi of the heart, especially of the left ventricle. A number of factors and conditions may cause vascular injury and predispose to the formation of thrombi. These are as under:

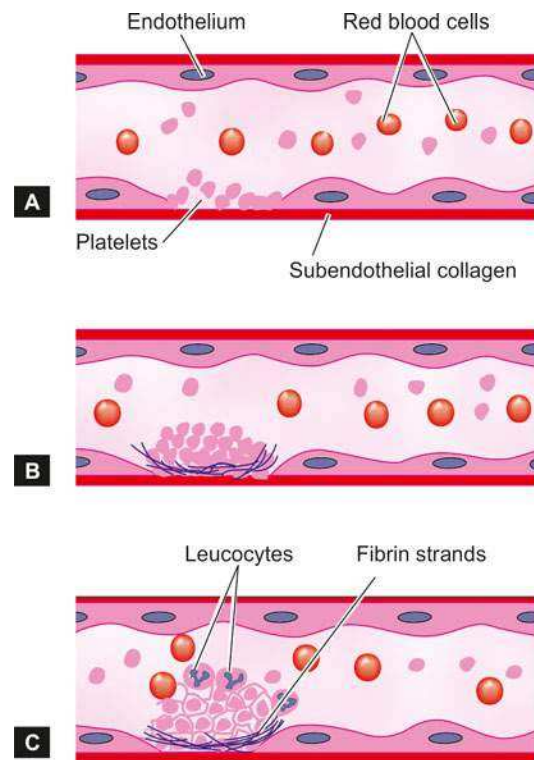

Figure 4.21 Role of endothelial injury and platelet activation in thrombosis. A, Endothelial injury exposes subendothelial matrix to circulating blood. B, This triggers three platelet steps involving platelet activation: adhesion, release and aggregation. Platelet release is associated with release of granules (alpha granules and dense bodies). C, Concurrent activation of coagulation cascade generates fibrin strands and thrombin forming a tight meshwork called thrombus.

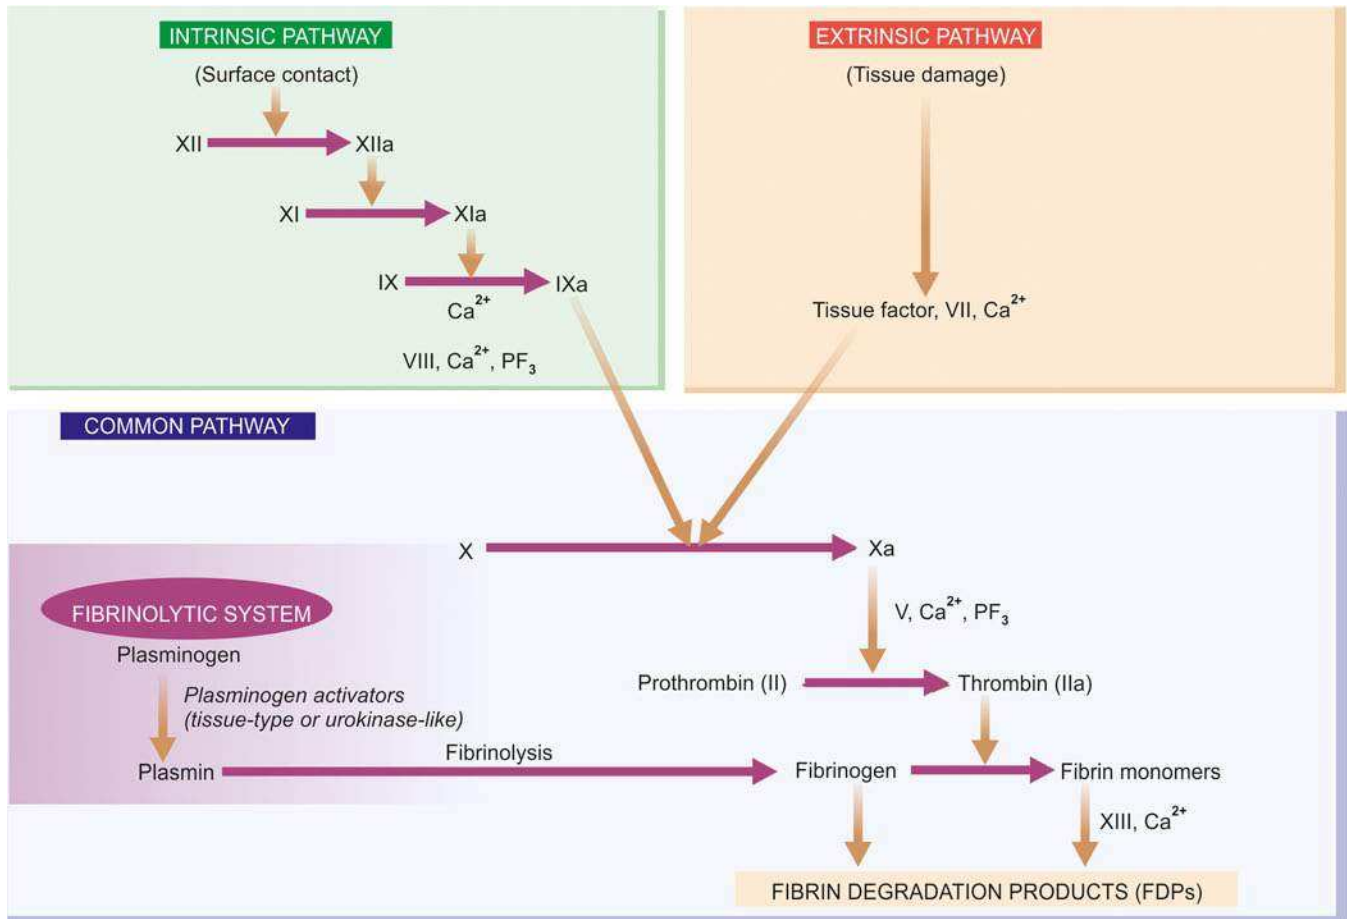

Figure 4.22 Schematic representation of pathways of coagulation mechanism and fibrinolytic system.

- i) Endocardial injury in myocardial infarction, myocarditis, cardiac surgery, prosthetic valves.
- ii) Ulcerated plaques in advanced atherosclerosis.
- iii) Haemodynamic stress in hypertension.
- iv) Arterial diseases.
- v) Diabetes mellitus.
- vi) Endogenous chemical agents such as hypercholesterolaemia, endotoxins.
- vii) Exogenous chemical agents such as cigarette smoke.

2. ROLE OF PLATELETS Following endothelial cell injury, platelets come to play a central role in normal haemostasis as well as in thrombosis. The sequence of events is as under (**Fig. 4.21**):

i) Platelet adhesion Glycoprotein Ib (GpIb) receptor on the platelets recognises the site of endothelial injury and the circulating platelets adhere to exposed subendothelial ECM (*primary aggregation*). von Willebrand's factor (vWF), synthesised by the endothelial cells binds to GpIb and forms a firm adhesion of platelets with ECM. Thus, deficiency of vWF (as happens in von Willebrand's disease) or absence of GpIb (as is seen in Bernard-Soulier disease) would result in defective platelet adhesion and cause abnormal bleeding.

ii) Platelet release reaction Activated platelets then undergo release reaction by which the platelet granules are released to the exterior. Two main types of platelet granules are released: *a) Dense bodies* Their release liberates ADP (adenosine diphosphate), ionic calcium, 5-HT (serotonin), histamine and

epinephrine. Release of contents of dense bodies are more important since ADP is further an activator of platelets, and calcium is required in the coagulation cascade.

b) Alpha granules Their release produces fibrinogen, fibronectin, platelet-derived growth factor (PDGF), platelet factor 4 (an antiheparin) and thrombospondin.

As a sequel to platelet activation and release reaction, the phospholipid complex-platelet factor 3 gets activated which plays important role in the intrinsic pathway of coagulation.

iii) Platelet aggregation Following release of ADP, a potent platelet aggregating agent, aggregation of additional platelets takes place (*secondary aggregation*). This results in formation of temporary haemostatic plug. However, stable haemostatic plug is formed by the action of fibrin, thrombin and thromboxane A_2 .

3. ROLE OF COAGULATION SYSTEM Coagulation mechanism is the conversion of the plasma fibrinogen into solid mass of fibrin. The coagulation system is involved in both haemostatic process and thrombus formation. **Fig. 4.22** shows schematic representation of the cascade of intrinsic (blood) pathway, the extrinsic (tissue) pathway, and the common pathway leading to formation of fibrin polymers.

i) In the intrinsic pathway, contact with abnormal surface (e.g. ECM in the subendothelium) leads to activation of factor XII and the sequential interactions of factors XI, IX, VIII and finally factor X, along with calcium ions (factor IV) and platelet factor 3.

ii) **In the extrinsic pathway**, tissue damage results in release of tissue factor or thromboplastin. Tissue factor on interaction with factor VII activates factor X.

iii) **The common pathway** begins where both intrinsic and extrinsic pathways converge to activate factor X which forms a complex with factor Va and platelet factor 3, in the presence of calcium ions. This complex activates prothrombin (factor II) to thrombin (factor IIa) which, in turn, converts fibrinogen to fibrin. Initial monomeric fibrin is polymerised to form insoluble fibrin by activation of factor XIII.

Regulation of coagulation system Normally, the blood is kept in fluid state and the coagulation system is kept in check by controlling mechanisms. These are as under:

- i) **Protease inhibitors** These act on coagulation factors so as to oppose the formation of thrombin e.g. antithrombin III, protein C, C1 inactivator, α 1-antitrypsin, α 2-macroglobulin.
- ii) **Fibrinolytic system** Plasmin, a potent fibrinolytic enzyme, is formed by the action of plasminogen activator on plasminogen present in the normal plasma. Two types of plasminogen activators (PA) are identified:
 - a) **Tissue-type PA** derived from endothelial cells and leucocytes.
 - b) **Urokinase-like PA** present in the plasma.

Plasmin so formed acts on fibrin to destroy the clot and produces fibrin split products (FSP).

4. ALTERATION OF BLOOD FLOW *Turbulence* means unequal flow while *stasis* means slowing.

i) **Normally**, there is axial flow of blood in which the most rapidly-moving central stream consists of leucocytes and red cells. The platelets are present in the slow-moving laminar stream adjacent to the central stream while the peripheral stream consists of most slow-moving cell-free plasma close to endothelial layer (**Fig. 4.23,A**).

ii) **Turbulence and stasis** occur in thrombosis in which the normal axial flow of blood is disturbed. When blood slows down, the blood cells including platelets marginate to the periphery and form a kind of pavement close to endothelium (margination and pavingmenting) (**Fig. 4.23,B**). While stasis allows a higher release of oxygen from the blood, turbulence

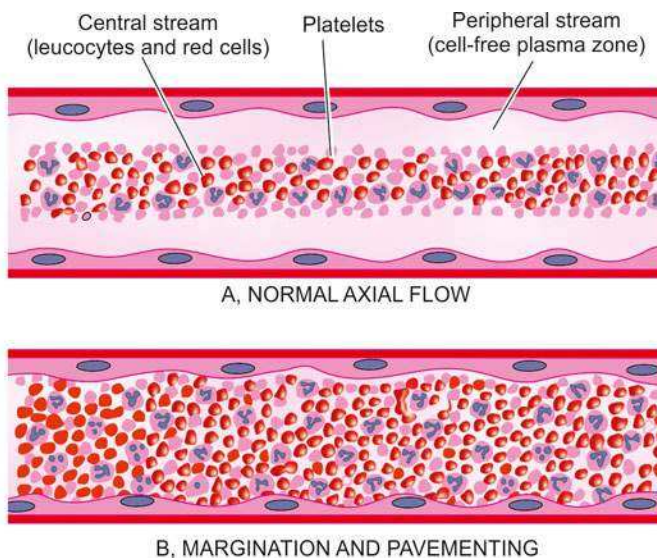

Figure 4.23 Alterations in flow of blood.

may actually injure the endothelium resulting in deposition of platelets and fibrin. Formation of arterial and cardiac thrombi is facilitated by *turbulence* in the blood flow, while *stasis* initiates the venous thrombi even without evidence of endothelial injury.

5. HYPERCOAGULABLE STATES (THROMBOPHILIA)

Thrombophilia or hypercoagulable states are a group of conditions having increased risk or predisposition to develop venous thrombosis. These conditions may be hereditary (or primary) or acquired (or secondary) causes (**Table 4.5**). However, in a given case of thrombosis, several factors are generally present simultaneously.

Hereditary (Primary) factors These include deficiency or mutation of some factors as under:

- i) **Deficiency of antithrombin III** It is inherited as autosomal dominant disorder having less than 50% antithrombin III. The condition is associated with recurrent episodes of venous thrombosis.
- ii) **Deficiency of protein C and S** Both these are autosomal dominant disorders having either reduced amount of protein C or S, or both, or their functional defect. Clinically, both the conditions are associated with lifelong risk of thrombosis of deep leg veins.
- iii) **Mutation in factor V Leiden** This is also a autosomal dominant disorder in which the mutation lies in replacement of arginine by glycine at position 506. It is the most common cause of thrombophilia.
- iv) **Defects in fibrinolysis** These include a few rare inherited disorders such as dysfibrinogenaemia and plasminogen disorders.

Table 4.5 Causes of thrombophilia (hypercoagulable states).

INHERITED (PRIMARY) FACTORS

- i) Deficiency of antithrombin III
- ii) Deficiency of protein C
- iii) Deficiency of protein S
- iv) Mutation in factor V Leiden
- v) Defects in fibrinolysis (dysfibrinogenaemia, plasminogen disorders)
- vi) Increased levels of coagulations factors (II and VIII)

ACQUIRED (SECONDARY) FACTORS

- a) **Risk factors:**
 - i) Advancing age, ii) prolonged bed-rest, iii) prolonged immobilisation (e.g. in plaster cast, long distance travel), iv) cigarette smoking, v) obesity
- b) **Predisposing clinical conditions:**
 - i) Heart diseases (e.g. myocardial infarction, CHF, rheumatic mitral stenosis, cardiomyopathy)
 - ii) Vascular diseases (e.g. atherosclerosis, aneurysms of the aorta and other vessels, varicosities of leg veins)
 - iii) Hypercoagulable conditions (e.g. polycythaemia, myeloproliferative disorders, dehydration, nephrotic syndrome, disseminated cancers)
 - iv) Shock
 - v) Tissue damage e.g. trauma, fractures, burns, major surgery on bones, abdomen or brain.
 - vi) Late pregnancy and puerperium
 - vii) Certain drugs (e.g. anaesthetic agents, oral contraceptives, hormonal replacement therapy).
- c) **Antiphospholipid antibody (APLA) syndrome:**
 - i) Lupus anticoagulant antibody
 - ii) Anti-cardiolipin antibody

v) *Increased levels of coagulations factors (II and VIII).* Elevated level of prothrombin and factor VIII due to genetic mutation may predispose to thrombosis.

Secondary (acquired) factors As listed in **Table 4.5**, thrombosis is favoured by certain risk factors, some predisposing clinical conditions and antiphospholipid antibody (APLA) syndrome. There are 2 types of APLA: lupus anticoagulant antibody and anti-cardiolipin antibody. Presence of either of the two APLA predisposes an individual to recurrent thrombosis: venous in the former and arterial in the latter type. Other features include spontaneous abortions, transient ischaemic attacks, thrombocytopenia, elevation of activated partial thromboplastin time and multi-organ involvement. Patients of SLE may often coexpress lupus anticoagulant.

Origin of Thrombi at Different Sites

Thrombi may arise from the heart, arteries, veins or in microcirculation by different mechanisms.

CARDIAC THROMBI Thrombi may form in any of the chambers of the heart and on the valve cusps. They are more common in the atrial appendages, especially of the right atrium, and on mitral and aortic valves such as vegetations seen in infective endocarditis and non-bacterial thrombotic endocarditis (page 425). Cardiac thrombi are mural (non-occlusive) as are the mural thrombi encountered in large vessels such as the aorta in atherosclerosis and in aneurysmal dilatations. Rarely, large round thrombus may form and obstruct the mitral valve and is called *ball-valve thrombus*. *Agonal thrombi* are formed shortly before death and may occur in either or both the ventricles. They are composed mainly of fibrin.

ARTERIAL THROMBI The examples of major forms of thrombi formed in the arteries are as under:

- i) *Aorta*: aneurysms, arteritis.
- ii) *Coronary arteries*: atherosclerosis.
- iii) *Mesenteric artery*: atherosclerosis, arteritis.
- iv) *Arteries of limbs*: atherosclerosis, diabetes mellitus, Buerger's disease, Raynaud's disease.
- v) *Renal artery*: atherosclerosis, arteritis.
- vi) *Cerebral artery*: atherosclerosis, vasculitis.

VENOUS THROMBI A few common examples of these are as under:

- i) *Veins of lower limbs*: deep veins of legs, varicose veins.
- ii) *Popliteal, femoral and iliac veins*: postoperative stage, postpartum.
- iii) *Pulmonary veins*: CHF, pulmonary hypertension.
- iv) *Hepatic and portal vein*: portal hypertension.
- v) *Superior vena cava*: infections in head and neck.
- vi) *Inferior vena cava*: extension of thrombus from hepatic vein.
- vii) *Mesenteric veins*: volvulus, intestinal obstruction.
- viii) *Renal vein*: renal amyloidosis.

Distinguishing features between thrombi formed in rapidly-flowing arterial circulation and slow-moving venous blood are given in **Table 4.6**.

CAPILLARY THROMBI Minute thrombi composed mainly of packed red cells are formed in the capillaries in acute inflammatory lesions, vasculitis and in disseminated intravascular coagulation (DIC).

Table 4.6 Distinguishing features of arterial and venous thrombi.

| FEATURE | ARTERIAL THROMBI | VENOUS THROMBI |
|--------------------------|---|--|
| 1. <i>Blood flow</i> | Formed in rapidly-flowing blood of arteries and heart | Formed in slow-moving blood in veins |
| 2. <i>Sites</i> | Common in aorta, coronary, cerebral, iliac, femoral, renal and mesenteric arteries | Common in superficial varicose veins, deep leg veins, popliteal, femoral and iliac veins |
| 3. <i>Thrombogenesis</i> | Formed following endothelial cell injury e.g. in atherosclerosis | Formed following venous stasis e.g. in abdominal operations, child-birth |
| 4. <i>Development</i> | Usually mural, not occluding the lumen completely, may propagate | Usually occlusive, take the cast of the vessel in which formed, may propagate in both directions |
| 5. <i>Macroscopy</i> | Grey-white, friable with lines of Zahn on surface | Red-blue with fibrin strands and lines of Zahn |
| 6. <i>Microscopy</i> | Distinct lines of Zahn composed of platelets, fibrin with entangled red and white blood cells | Lines of Zahn with more abundant red cells |
| 7. <i>Effects</i> | Ischaemia leading to infarcts e.g. in the heart, brain etc | Thromboembolism, oedema, skin ulcers, poor wound healing |

Morphologic Features

The general morphologic features of thrombi formed in various locations are as under:

Grossly, thrombi may be of various shapes, sizes and composition depending upon the site of origin. Arterial thrombi tend to be white and mural while the venous thrombi are red and occlusive. Mixed or laminated thrombi are also common and consist of alternate white and red layers called lines of Zahn. Red thrombi are soft, red and gelatinous whereas white thrombi are firm and pale.

Microscopically, the composition of thrombus is determined by the rate of flow of blood i.e. whether it is formed in the rapid arterial and cardiac circulation, or in the slow moving flow in veins. The lines of Zahn are formed by alternate layers of light-staining aggregated platelets admixed with fibrin meshwork and dark-staining layer of red cells. Red (venous) thrombi have more abundant red cells, leucocytes and platelets entrapped in fibrin meshwork. Thus, red thrombi closely resemble blood clots *in vitro* (**Fig. 4.24**).

Red thrombi (antemortem) have to be distinguished from postmortem clots (**Table 4.7**).

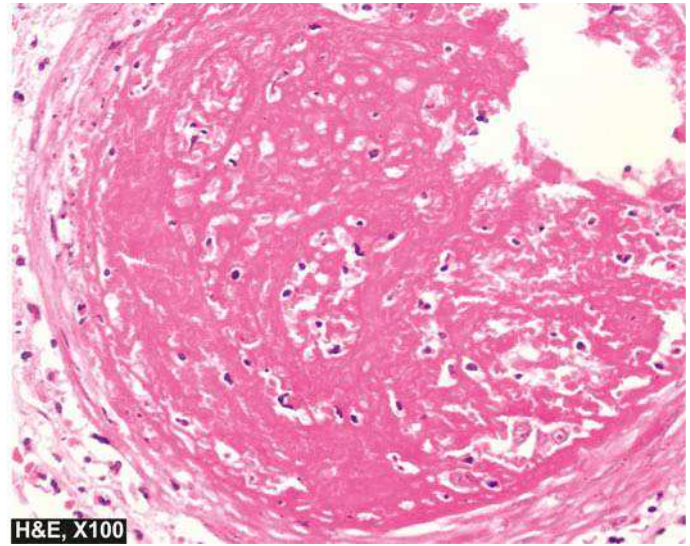

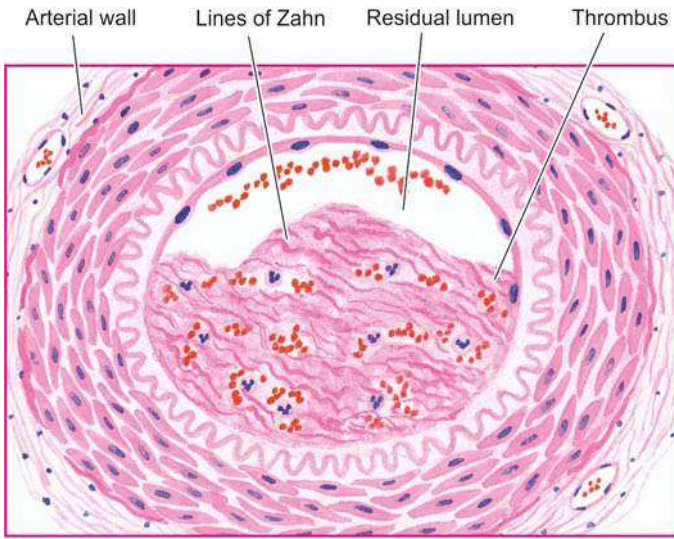

Figure 4.24 Thrombus in an artery. The thrombus is adherent to the arterial wall and is seen occluding most of the lumen. It shows lines of Zahn composed of granular-looking platelets and fibrin meshwork with entangled red cells and leucocytes.

Fate of Thrombus

The outcome of thrombi can be as under (Fig. 4.25):

1. RESOLUTION Thrombus activates the fibrinolytic system with consequent release of plasmin which may dissolve the thrombus completely resulting in resolution. Usually, lysis is complete in small venous thrombi while large thrombi may not be dissolved. Fibrinolytic activity can be accentuated by administration of thrombolytic substances (e.g. urokinase, streptokinase), especially in the early stage when fibrin is in monomeric form e.g. thrombolytic therapy in early stage acute myocardial infarction.

2. ORGANISATION If the thrombus is not removed, it starts getting organised. Phagocytic cells (neutrophils and macrophages) appear and begin to phagocytose fibrin and cell debris. The proteolytic enzymes liberated by leucocytes and endothelial cells start digesting coagulum. Capillaries grow into the thrombus from the site of its attachment and fibroblasts start invading the thrombus. Thus, fibrovascular granulation tissue is formed which subsequently becomes dense and less vascular and is covered over by endothelial cells. The thrombus in this way is excluded from the vascular lumen and becomes part of vessel wall. The new vascular channels in it may be

able to re-establish the blood flow, called recanalisation. The fibrosed thrombus may undergo hyalinisation and calcification e.g. phleboliths in the pelvic veins.

3. PROPAGATION The thrombus may enlarge in size due to more and more deposition from the constituents of flowing blood. In this way, it may ultimately cause obstruction of some important vessel.

4. THROMBOEMBOLISM The thrombi in early stage and infected thrombi are quite friable and may get detached from the vessel wall. These are released in part or completely in blood-stream as emboli which produce ill-effects at the site of their lodgement (page 105).

Clinical Effects

Besides differences in mechanism of thrombosis at different sites, clinical effects depend upon not only the site but also on rapidity of formation and nature of thrombi.

1. Cardiac thrombi Large thrombi in the heart may cause sudden death by mechanical obstruction of blood flow or through thromboembolism to vital organs.

2. Arterial thrombi These cause ischaemic necrosis of the deprived part (infarct) which may lead to gangrene. Sudden death may occur following thrombosis of coronary artery.

3. Venous thrombi (Phlebothrombosis) These may cause following effects:

- i) Thromboembolism
- ii) Oedema of area drained
- iii) Poor wound healing
- iv) Skin ulcer
- v) Painful thrombosed veins (thrombophlebitis)
- vi) Painful white leg (phlegmasia alba dolens) due to iliofemoral venous thrombosis in postpartum cases
- vii) Thrombophlebitis migrans in cancer.

4. Capillary thrombi Microthrombi in microcirculation may give rise to disseminated intravascular coagulation (DIC).

Table 4.7 Distinguishing features of antemortem thrombi and postmortem clots.

| FEATURE | ANTEMORTEM THROMBI | POSTMORTEM CLOTS |
|----------------------------|---|---|
| 1. Gross | Dry, granular, firm and friable | Gelatinous, soft and rubbery |
| 2. Relation to vessel wall | Adherent to the vessel wall | Weakly attached to the vessel wall |
| 3. Shape | May or may not fit their vascular contours | Take the shape of vessel or its bifurcation |
| 4. Microscopy | The surface contains apparent lines of Zahn | The surface is 'chicken fat' yellow covering the underlying red 'currant jelly' |

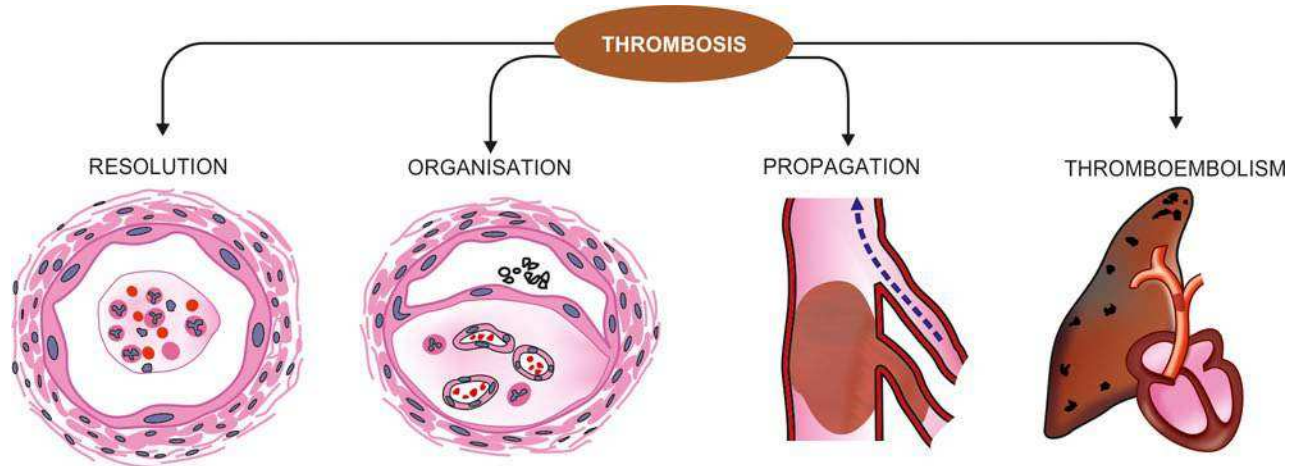

Figure 4.25 Fate of thrombus.

GIST BOX 4.6

Thrombosis

- ☐ Thrombosis is the process of formation of solid mass in circulation from the constituents of flowing blood; the mass itself is called a thrombus.
- ☐ Thrombogenesis involves interplay of 5 events: endothelial injury, platelets and their release reaction, coagulation system, alterations in the flow of blood and role of certain predisposing conditions and factors causing hypercoagulable states (or thrombophilia).
- ☐ Thrombi may originate in the chambers of the heart, lumina of arteries, veins and microcirculation.
- ☐ The effects of thrombi depend upon their anatomic location, rapidity of formation and nature of thrombi. In general, thrombi produce life-threatening harmful effects by ischaemia and by thromboembolism.
- ☐ Grossly, thrombi are of various shapes, size, consistency and colour. Microscopically, all types of thrombi show lines of Zahn formed by alternate layers of light-staining aggregated platelets and dark-staining red cells.
- ☐ The possible fates of thrombi are resolution, organisation, propagation and thromboembolism.

C. Depending upon the source of the emboli:

- i) *Cardiac emboli* from left side of the heart e.g. emboli originating in the atrium and atrial appendages, infarct in the left ventricle, vegetations of endocarditis.
- ii) *Arterial emboli* e.g. in systemic arteries in the brain, spleen, kidney, intestine.
- iii) *Venous emboli* e.g. in pulmonary arteries.
- iv) *Lymphatic emboli* can also sometimes occur.

D. Depending upon the flow of blood, two special types of emboli are mentioned:

- i) *Paradoxical embolus* An embolus which is carried from the venous side of circulation to the arterial side or vice versa, is called paradoxical or crossed embolus e.g. through arteriovenous communication such as in patent foramen ovale, septal defect of the heart, and arteriovenous shunts in the lungs.
- ii) *Retrograde embolus* An embolus which travels against the flow of blood is called retrograde embolus. For example, metastatic deposits in the spine from carcinoma prostate in which case the spread occurs by retrograde embolism through intraspinal veins (which normally do not carry the blood from the prostate) which carry tumour emboli from large thoracic and abdominal veins because of increased pressure in body cavities such as during coughing or straining.

Some of the important types of embolism are listed in **Table 4.8** and are described below:

Table 4.8 Important types of embolism.

| TYPE | COMMON ORIGIN |
|-----------------------------------|---|
| 1. <i>Pulmonary embolism</i> | Veins of lower legs |
| 2. <i>Systemic embolism</i> | Left ventricle (arterial) |
| 3. <i>Fat embolism</i> | Trauma to bones/soft tissues |
| 4. <i>Air embolism</i> | Venous: head and neck operations, obstetrical trauma Arterial: cardiothoracic surgery, angiography |
| 5. <i>Decompression sickness</i> | Descent: divers Ascent: unpressurised flight |
| 6. <i>Amniotic fluid embolism</i> | Components of amniotic fluid |
| 7. <i>Atheroembolism</i> | Atheromatous plaques |
| 8. <i>Tumour embolism</i> | Tumour fragments |

EMBOLISM

Definition and Types

Embolism is the process of partial or complete obstruction of some part of the cardiovascular system by any mass carried in the circulation; the transported intravascular mass detached from its site of origin is called an *embolus*. Most usual forms of emboli (90%) are thromboemboli i.e. originating from thrombi or their parts detached from the vessel wall.

Emboli may be of various types:

A. Depending upon the matter in the emboli:

- i) *Solid* e.g. detached thrombi (thromboemboli), atheromatous material, tumour cell clumps, tissue fragments, parasites, bacterial clumps, foreign bodies.
- ii) *Liquid* e.g. fat globules, amniotic fluid, bone marrow.
- iii) *Gaseous* e.g. air, other gases.

B. Depending upon whether infected or not:

- i) *Bland*, when sterile.
- ii) *Septic*, when infected.

Thromboembolism

A detached thrombus or part of thrombus constitutes the most common type of embolism. These may arise in the arterial or venous circulation (**Fig. 4.26**):

Arterial (systemic) thromboembolism Arterial emboli may be derived from the following sources:

A. *Causes within the heart* (80-85%): These are mural thrombi in the left atrium or left ventricle, vegetations on the mitral or aortic valves, prosthetic heart valves and cardiomyopathy.

B. *Causes within the arteries*: These include emboli developing in relation to atherosclerotic plaques, aortic aneurysms, pulmonary veins and paradoxical arterial emboli from the systemic venous circulation.

The *effects* of arterial emboli depend upon their size, site of lodgement, and adequacy of collateral circulation. If the vascular occlusion occurs, the following ill-effects may result:

i) *Infarction* of the organ or its affected part e.g. ischaemic necrosis in the lower limbs (70-75%), spleen, kidneys, brain, intestine.

ii) *Gangrene* following infarction in the lower limbs if the collateral circulation is inadequate.

iii) *Arteritis and mycotic aneurysm* formation from bacterial endocarditis.

iv) *Myocardial infarction* may occur following coronary embolism.

v) *Sudden death* may result from coronary embolism or embolism in the middle cerebral artery.

Venous thromboembolism Venous emboli may arise from the following sources:

i) Deep vein thrombosis (DVT) of the lower legs, the most common cause of venous thrombi.

ii) Thrombi in the pelvic veins.

iii) Thrombi in the veins of the upper limbs.

iv) Thrombosis in cavernous sinus of the brain.

v) Thrombi in the right side of heart.

The most significant *effect* of venous embolism is obstruction of pulmonary arterial circulation leading to pulmonary embolism described below.

Pulmonary Thromboembolism

DEFINITION Pulmonary embolism is the most common and fatal form of venous thromboembolism in which there is occlusion of pulmonary arterial tree by thromboemboli. In contrast, pulmonary thrombosis is uncommon and may occur in pulmonary atherosclerosis and pulmonary hypertension. Differentiation of pulmonary thrombosis from pulmonary thromboembolism is tabulated in **Table 4.9**.

ETIOLOGY Pulmonary emboli are more common in hospitalised or bed-ridden patients, though they can occur in ambulatory patients as well. The causes are as follows:

i) Thrombi originating from large veins of lower legs (such as popliteal, femoral and iliac) are the cause in 95% of pulmonary emboli.

ii) Less common sources include thrombi in varicosities of superficial veins of the legs, and pelvic veins such as periprostatic, periovarian, uterine and broad ligament veins.

PATHOGENESIS The risk factors for pulmonary thromboembolism are stasis of venous blood and hypercoagulable states. Detachment of thrombi from any of the above-mentioned sites produces a thrombo-embolus that flows through venous drainage into the larger veins draining into right side of the heart.

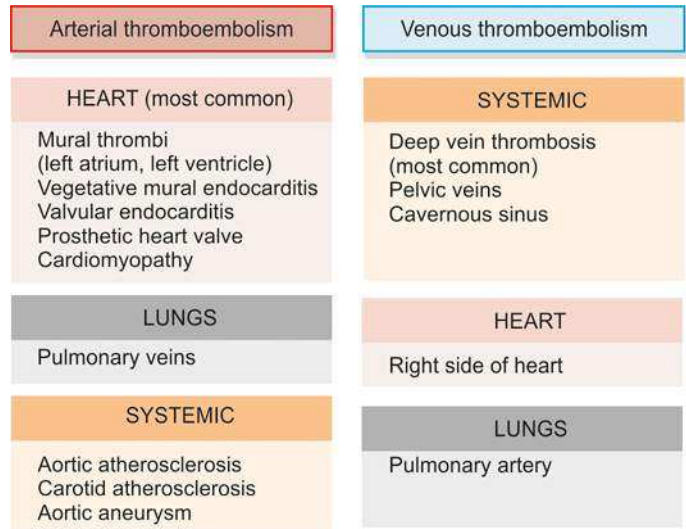

Figure 4.26 Sources of arterial and venous emboli.

◆ If the thrombus is large, it is impacted at the bifurcation of the main pulmonary artery (*saddle embolus*), or may be found in the right ventricle or its outflow tract.

◆ More commonly, there are *multiple emboli*, or a large embolus may be fragmented into many smaller emboli which are then impacted in a number of vessels, particularly affecting the lower lobes of lungs.

◆ Rarely, *paradoxical embolism* may occur by passage of an embolus from right heart into the left heart through atrial or ventricular septal defect. In this way, pulmonary emboli may reach systemic circulation.

CONSEQUENCES OF PULMONARY EMBOLISM Pulmonary embolism occurs more commonly as a complication in patients of acute or chronic debilitating diseases who are immobilised for a long duration. Women in their reproductive period are at higher risk such as in late pregnancy, following delivery and with use of contraceptive pills. The effects of pulmonary embolism depend mainly on the size of the occluded vessel, the number of emboli, and on the cardiovascular status of the patient. Natural history of pulmonary embolism may have following consequences (**Fig. 4.27**):

i) **Sudden death** Massive pulmonary embolism results in instantaneous death, without occurrence of chest pain or

Table 4.9 Contrasting features of pulmonary thrombosis and pulmonary thromboembolism.

| FEATURE | PULMONARY THROMBOSIS | PULMONARY THROMBOEMBOLISM |
|-------------------------------------|--|---|
| 1. <i>Pathogenesis</i> | Locally formed | Travelled from distance |
| 2. <i>Location</i> | In small arteries and branches | In major arteries and branches |
| 3. <i>Attachment to vessel wall</i> | Firmly adherent | Loosely attached or lying free |
| 4. <i>Gross appearance</i> | Head pale, tail red | No distinction in head and tail; smooth-surfaced dry dull surface |
| 5. <i>Microscopy</i> | Platelets and fibrin in layers Lines of Zahn seen | Mixed with blood clot Lines of Zahn rare |

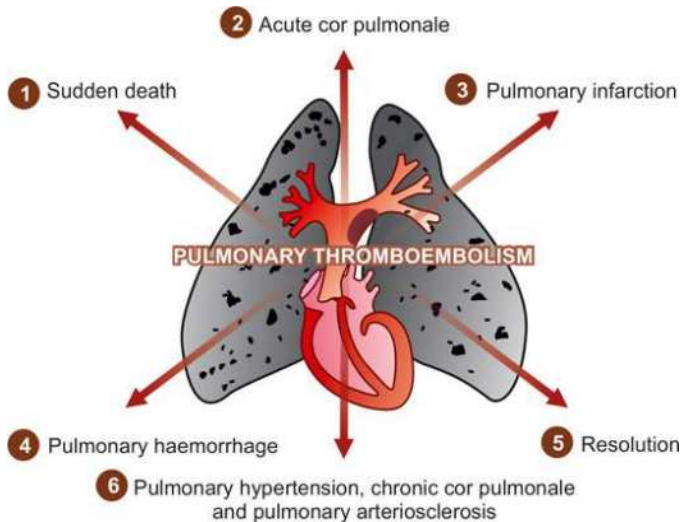

Figure 4.27 Major consequences of pulmonary embolism.

dyspnoea. However, if the death is somewhat delayed, the clinical features resemble myocardial infarction i.e. severe chest pain, dyspnoea and shock.

ii) Acute cor pulmonale Numerous small emboli may obstruct most of the pulmonary circulation resulting in acute right heart failure. Another mechanism is by release of vasoconstrictor substances from platelets or by reflex vasoconstriction of pulmonary vessels.

iii) Pulmonary infarction Obstruction of relatively small-sized pulmonary arterial branches may result in pulmonary infarction (page 112). The clinical features include chest pain due to fibrinous pleuritis, haemoptysis and dyspnoea due to reduced functioning pulmonary parenchyma.

iv) Pulmonary haemorrhage Obstruction of terminal branches (endarteries) leads to central pulmonary haemorrhage. The clinical features are haemoptysis, dyspnoea, and less commonly, chest pain due to central location of pulmonary haemorrhage. Sometimes, there may be concomitant pulmonary infarction.

v) Resolution Vast majority of small pulmonary emboli (60-80%) are resolved by fibrinolytic activity. These patients are clinically silent owing to bronchial circulation so that lung parenchyma is adequately perfused.

vi) Pulmonary hypertension, chronic cor pulmonale and pulmonary arteriosclerosis These are the sequelae of multiple small thromboemboli undergoing organisation rather than resolution.

Systemic Embolism

This is the type of arterial embolism that originates commonly from thrombi in the diseased heart, especially in the left ventricle. These heart diseases include myocardial infarction, cardiomyopathy, RHD, congenital heart disease, infective endocarditis, and prosthetic cardiac valves. The emboli are arterial and invariably cause infarction at the sites of lodgement. These sites, in descending order of frequency, are: lower extremity, brain, and internal visceral organs (spleen, kidneys, intestines). Thus, the effects and sites of arterial emboli

are in striking contrast to venous emboli which are often lodged in the lungs.

Fat Embolism

Obstruction of arterioles and capillaries by fat globules constitutes fat embolism. If the obstruction in the circulation is by fragments of adipose tissue, it is called fat-tissue embolism.

ETIOLOGY Causes of fat embolism may be traumatic and non-traumatic:

Traumatic causes:

i) *Trauma to bones* is the most common cause of fat embolism e.g. in fractures of long bones leading to passage of fatty marrow in circulation, concussions of bones, after orthopaedic surgical procedures etc.

ii) *Trauma to soft tissue* e.g. laceration of adipose tissue and in puerperium due to injury to pelvic fatty tissue.

Non-traumatic causes:

i) Extensive burns

ii) Diabetes mellitus

iii) Fatty liver

iv) Pancreatitis

v) Sickle cell anaemia

vi) Decompression sickness

vii) Inflammation of bones and soft tissues

viii) Extrinsic fat or oils introduced into the body

ix) Hyperlipidaemia

x) Cardiopulmonary bypass surgery

PATHOGENESIS Pathogenesis of fat embolism is explained by following mechanisms which may be acting singly or in combination:

i) Mechanical theory Mobilisation of fluid fat may occur following trauma to the bone or soft tissues. Fat globules released from the injured area may enter venous circulation and finally most of the fat is arrested in the small vessels in the lungs. Some of the fat globules may further pass through lungs and enter into the systemic circulation to lodge in other organs.

ii) Emulsion instability theory This theory explains the pathogenesis of fat embolism in non-traumatic cases. According to this theory, fat emboli are formed by aggregation of plasma lipids (chylomicrons and fatty acids) due to disturbance in natural emulsification of fat.

iii) Intravascular coagulation theory In stress, release of some factor activates disseminated intravascular coagulation (DIC) and aggregation of fat emboli.

iv) Toxic injury theory According to this theory, the small blood vessels of lungs are chemically injured by high plasma levels of free fatty acid, resulting in increased vascular permeability and consequent pulmonary oedema.

CONSEQUENCES OF FAT EMBOLISM The effects of fat embolism depend upon the size and quantity of fat globules, and whether or not the emboli pass through the lungs into the systemic circulation.

i) Pulmonary fat embolism In patients dying after fractures of bones, presence of numerous fat emboli in the capillaries of the lung is a frequent autopsy finding because the

small fat globules are not likely to appreciably obstruct the vast pulmonary vascular bed. However, widespread obstruction of pulmonary circulation due to extensive pulmonary embolism can occur and result in sudden death.

Microscopically, the lungs show hyperaemia, oedema, petechial haemorrhages and changes of adult respiratory distress syndrome (ARDS). Pulmonary infarction is usually not a feature of fat embolism because of the small size of globules. In routine stains, the fat globules in the pulmonary arteries, capillaries and alveolar spaces appear as vacuoles. Frozen section is essential for confirmation of globules by fat stains such as Sudan dyes (Sudan black, Sudan III and IV), oil red O and osmic acid.

ii) Systemic fat embolism Some of the fat globules may pass through the pulmonary circulation such as via patent foramen ovale, arteriovenous shunts in the lungs and vertebral venous plexuses, and get lodged in the capillaries of organs like the brain, kidney, skin etc.

◆ **Brain** The pathologic findings in the brain are petechial haemorrhages on the leptomeninges and minute haemorrhages in the parenchyma.

Microscopically, microinfarcts of brain, oedema and haemorrhages are seen. The CNS manifestations include delirium, convulsions, stupor, coma and sudden death.

◆ **Kidney** Renal fat embolism present in the glomerular capillaries, may cause decreased glomerular filtration. Other effects include tubular damage and renal insufficiency.

◆ **Other organs** Besides the brain and kidneys, other findings in systemic fat embolism are petechiae in the skin, conjunctivae, serosal surfaces, fat globules in the urine and sputum.

Gas Embolism

Air, nitrogen and other gases can produce bubbles within the circulation and obstruct the blood vessels causing damage to tissue. Two main forms of gas embolism—air embolism and decompression sickness are described below.

Air Embolism

Air embolism occurs when air is introduced into venous or arterial circulation.

VENOUS AIR EMBOLISM Air may be sucked into systemic veins under the following circumstances:

i) Operations on the head and neck, and trauma The accidental opening of a major vein of the neck like jugular, or neck wounds involving the major neck veins, may allow air to be drawn into venous circulation.

ii) Obstetrical operations and trauma During childbirth by normal vaginal delivery, caesarean section, abortions and other procedures, fatal air embolism may result from the entrance of air into the opened-up uterine venous sinuses and endometrial veins.

iii) Intravenous infusion of blood and fluid Air embolism may occur during intravenous blood or fluid infusions if only positive pressure is employed.

iv) Angiography During venous angiographic procedures, air may be entrapped into a large vein causing air embolism.

The *effects* of venous air embolism depend upon the following factors:

i) *Amount of air* introduced into the circulation. The volume of air necessary to cause death is variable but usually 100-150 ml of air entry is considered fatal.

ii) *Rapidity* of entry of a smaller volume of air is important determinant of a fatal outcome.

iii) *Position of the patient* during or soon after entry of air is another factor. The air bubbles may ascend into the superior vena cava if the position of head is higher than the trunk (e.g. in upright position) and reach the brain.

iv) *General condition* of the patient e.g. in severely ill patients, as little as 40 ml of air may have serious results.

The mechanism of death is by entrapment of air emboli in the pulmonary arterial trunk in the right heart. If bubbles of air in the form of froth pass further out into pulmonary arterioles, they cause widespread vascular occlusions. If death from pulmonary air embolism is suspected, the heart and pulmonary artery should be opened *in situ* under water so that escaping froth or foam formed by mixture of air and blood can be detected.

ARTERIAL AIR EMBOLISM Entry of air into pulmonary vein or its tributaries may occur in the following conditions:

i) Cardiothoracic surgery and trauma Arterial air embolism may occur following thoracic operations, thoracentesis, rupture of the lung, penetrating wounds of the lung, artificial pneumothorax etc.

ii) Paradoxical air embolism This may occur due to passage of venous air emboli to the arterial side of circulation through a patent foramen ovale or via pulmonary arteriovenous shunts.

iii) Arteriography During arteriographic procedures, air embolism may occur.

The *effects* of arterial air embolism are in the form of certain characteristic features:

i) Marble skin due to blockage of cutaneous vessels.

ii) Air bubbles in the retinal vessels seen ophthalmoscopically.

iii) Pallor of the tongue due to occlusion of a branch of lingual artery.

iv) Coronary or cerebral arterial air embolism may cause sudden death by much smaller amounts of air than in the venous air embolism.

Decompression Sickness

This is a specialised form of gas embolism known by various names such as caisson's disease, divers' palsy or aeroembolism.

PATHOGENESIS Decompression sickness is produced when the individual decompresses suddenly, either from high atmospheric pressure to normal level, or from normal pressure to low atmospheric pressure.

◆ In divers, workers in caissons (diving-bells), offshore drilling and tunnels, who *descend* to high atmospheric pressure, increased amount of atmospheric gases (mainly nitrogen; others are O₂, CO₂) are dissolved in blood and tissue fluids. When such an individual ascends too rapidly i.e. comes to normal level suddenly from high atmospheric pressure, the gases come out of the solution as minute bubbles, particularly

in fatty tissues which have affinity for nitrogen. These bubbles may coalesce together to form large emboli.

◆ In aeroembolism, seen in those who *ascend* to high altitudes or air flight in unpressurised cabins, the individuals are exposed to sudden decompression from low atmospheric pressure to normal levels. This results in similar effects as in divers and workers in caissons.

EFFECTS The effects of decompression sickness depend upon the following:

- i) Depth or altitude reached
- ii) Duration of exposure to altered pressure
- iii) Rate of ascent or descent
- iv) General condition of the individual

Pathologic changes are more pronounced in sudden decompression from high pressure to normal levels than in those who decompress from low pressure to normal levels. The changes are more serious in obese persons as nitrogen gas is more soluble in fat than in body fluids.

Clinical effects of decompression sickness are of 2 types—acute and chronic.

◆ **Acute form** occurs due to acute obstruction of small blood vessels in the vicinity of joints and skeletal muscles. The condition is clinically characterised by the following:

- i) *'The bends'*, as the patient doubles up in bed due to acute pain in joints, ligaments and tendons.
- ii) *'The chokes'* occur due to accumulation of bubbles in the lungs, resulting in acute respiratory distress.
- iii) *Cerebral effects* may manifest in the form of vertigo, coma, and sometimes death.

◆ **Chronic form** is due to foci of ischaemic necrosis throughout body, especially the skeletal system. Ischaemic necrosis may be due to embolism *per se*, but other factors such as platelet activation, intravascular coagulation and hypoxia might contribute. The features of chronic form are as under:

- i) *Avascular necrosis of bones* e.g. head of femur, tibia, humerus.
- ii) *Neurological symptoms* may occur due to ischaemic necrosis in the central nervous system. These include paraesthesia and paraplegia.
- iii) *Lung involvement* in the form of haemorrhage, oedema, emphysema and atelectasis may be seen. These result in dyspnoea, nonproductive cough and chest pain.
- iv) *Skin manifestations* include itching, patchy erythema, cyanosis and oedema.
- v) *Other organs* like parenchymal cells of the liver and pancreas may show lipid vacuoles.

Amniotic Fluid Embolism

This is the most serious, unpredictable and unpreventable cause of maternal mortality. During labour and in the immediate postpartum period, the contents of amniotic fluid may enter the uterine veins and reach right side of the heart resulting in fatal complications. The amniotic fluid components which may be found in uterine veins, pulmonary artery and vessels of other organs are: epithelial squames, vernix caseosa, lanugo hair, bile from meconium, and mucus. The mechanism by which these amniotic fluid contents enter the maternal circulation is not clear. Possibly, they gain entry either through tears in the myometrium and endocervix, or the amniotic fluid is forced into uterine sinusoids by vigorous uterine contractions.

MORPHOLOGIC FEATURES Notable changes are seen in the lungs such as haemorrhages, congestion, oedema and changes of ARDS, and dilatation of right side of the heart. These changes are associated with identifiable amniotic fluid contents within the pulmonary microcirculation.

The *clinical syndrome* of amniotic fluid embolism is characterised by the following features:

- i) Sudden respiratory distress and dyspnoea
- ii) Deep cyanosis
- iii) Cardiovascular shock
- iv) Convulsions
- v) Coma
- vi) Unexpected death

The *cause of death* may not be obvious but can occur as a result of the following mechanisms:

- i) Mechanical blockage of the pulmonary circulation in extensive embolism.
- ii) Anaphylactoid reaction to amniotic fluid components.
- iii) Disseminated intravascular coagulation (DIC) due to liberation of thromboplastin by amniotic fluid.
- iv) Haemorrhagic manifestations due to thrombocytopenia and afibrinogenaemia.

Atheroembolism

Atheromatous plaques, especially from aorta, may get eroded to form atherosclerotic emboli which are then lodged in medium-sized and small arteries. These emboli consist of cholesterol crystals, hyaline debris and calcified material, and may evoke foreign body reaction at the site of lodgement.

MORPHOLOGIC FEATURES Pathologic changes and their effects in atheroembolism are as under:

- i) Ischaemia, atrophy and necrosis of tissue distal to the occluded vessel.
- ii) Infarcts in the organs affected such as the kidneys, spleen, brain and heart.
- iii) Gangrene in the lower limbs.
- iv) Hypertension, if widespread renal vascular lesions are present.

Tumour Embolism

Malignant tumour cells invade the local blood vessels and may form tumour emboli to be lodged elsewhere, producing metastatic tumour deposits. Notable examples are clear cell carcinoma of kidney, carcinoma of the lung, malignant melanoma etc (Chapter 7).

Miscellaneous Emboli

Various other endogenous and exogenous substances may act as emboli. These may include the following:

- i) Fragments of tissue
- ii) Placental fragments
- iii) Red cell aggregates (sludging)
- iv) Bacteria
- v) Parasites
- vi) Barium emboli following enema
- vii) Foreign bodies e.g. needles, talc, sutures, bullets, catheters etc.

GIST BOX 4.7

Embolism

- ▣ Embolism is the process of partial or complete obstruction of some part of the cardiovascular system by any mass carried in the circulation.
- ▣ Most common forms of emboli (90%) are thromboemboli originating from thrombi or their detached parts within the heart, arteries or veins.
- ▣ Pulmonary thromboembolism is common and fatal form of venous thromboembolism, most often originating from deep vein thrombosis of the lower legs.
- ▣ Most common form of arterial embolism arises in the thrombi from the left ventricle due to heart diseases.
- ▣ Fat embolism may be traumatic (most often from surgical or accidental trauma to the bones) or from several non-traumatic causes.
- ▣ Gas embolism may be air embolism (arterial or venous) or decompression sickness (in divers or in high altitude).
- ▣ Amniotic fluid embolism is the most serious, unpredictable and unpreventable cause of maternal mortality occurring during labour and in the immediate postpartum period.
- ▣ Other forms of embolism include atheroembolism, tumour embolism etc.

ISCHAEMIA

DEFINITION Ischaemia is defined as deficient blood supply to part of a tissue relative to its metabolic needs. The cessation of blood supply may be *complete* (complete ischaemia) or *partial* (partial ischaemia). The adverse effects of ischaemia may result from 3 ways:

1. Hypoxia due to deprivation of oxygen to tissues relative to its needs; this is the most important and common cause. It may be of 4 types:

- i) *Hypoxic hypoxia*: due to low oxygen in arterial blood.
- ii) *Anaemic hypoxia*: due to low level of haemoglobin in blood.
- iii) *Stagnant hypoxia*: due to inadequate blood supply.
- iv) *Histotoxic hypoxia*: low oxygen uptake due to cellular toxicity.

2. Malnourishment of cells due to inadequate supply of nutrients to the tissue (i.e. glucose, amino acids); this is less important.

3. Inadequate clearance of metabolites which results in accumulation of metabolic waste-products in the affected tissue; this is relevant in some conditions such as muscle cramps after ischaemia from heavy exercise.

ETIOLOGY A number of causes may produce ischaemia. These causes are discussed below with regard to different levels of blood vessels:

1. Causes in the heart Inadequate cardiac output resulting from heart block, ventricular arrest and fibrillation from various causes may cause variable degree of hypoxic injury to the brain as under:

- i) If the arrest continues for 15 seconds, consciousness is lost.
- ii) If the condition lasts for more than 4 minutes, irreversible ischaemic damage to the brain occurs.
- iii) If it is prolonged for more than 8 minutes, death is inevitable.

2. Causes in the arteries The commonest and most important causes of ischaemia are due to obstruction in arterial blood supply as under:

- i) *Luminal occlusion of artery (intraluminal)*:
 - a) Thrombosis
 - b) Embolism
- ii) *Causes in the arterial walls (intramural)*:
 - a) Vasospasm (e.g. in Raynaud's disease)
 - b) Hypothermia, ergotism
 - c) Arteriosclerosis
 - d) Polyarteritis nodosa
 - e) Thromboangiitis obliterans (Buerger's disease)
 - f) Severed vessel wall
- iii) *Outside pressure on an artery (extramural)*:
 - a) Ligature
 - b) Tourniquet
 - c) Tight plaster, bandages
 - d) Torsion.

3. Causes in the veins Blockage of venous drainage may lead to engorgement and obstruction to arterial blood supply resulting in ischaemia. The examples include the following:

- i) *Luminal occlusion of vein (intraluminal)*:
 - a) Thrombosis of mesenteric veins
 - b) Cavernous sinus thrombosis
- ii) *Causes in the vessel wall of vein (intramural)*:
 - a) Varicose veins of the legs
- iii) *Outside pressure on vein (extramural)*:
 - a) Strangulated hernia
 - b) Intussusception
 - c) Volvulus

4. Causes in the microcirculation Ischaemia may result from occlusion of arterioles, capillaries and venules. The causes are as under:

- i) *Luminal occlusion in microvasculature (intraluminal)*:
 - a) By red cells e.g. in sickle cell anaemia, red cells parasitised by malaria, acquired haemolytic anaemia, sludging of the blood.
 - b) By white cells e.g. in chronic myeloid leukaemia
 - c) By fibrin e.g. defibrination syndrome
 - d) By precipitated cryoglobulins
 - e) By fat embolism
 - f) In decompression sickness.
- ii) *Causes in the microvasculature wall (intramural)*:
 - a) Vasculitis e.g. in polyarteritis nodosa, Henoch-Schönlein purpura, Arthus reaction, septicaemia.
 - b) Frost-bite injuring the wall of small blood vessels.
- iii) *Outside pressure on microvasculature (extramural)*:
 - a) Bedsores.

FACTORS DETERMINING SEVERITY OF ISCHAEMIC INJURY The extent of damage produced by ischaemia due to occlusion of arterial or venous blood vessels depends upon a number of factors as under:

1. Anatomic pattern The extent of injury by ischaemia depends upon the anatomic pattern of arterial blood supply of the organ or tissue affected. There are 4 different patterns of arterial blood supply:

- i) *Single arterial supply without anastomosis* Some organs receive blood supply from arteries which do not have significant anastomosis and are thus functional end-arteries. Occlusion of such vessels invariably results in ischaemic necrosis. For example:
 - a) Central artery of the retina
 - b) Interlobular arteries of the kidneys.

ii) *Single arterial supply with rich anastomosis* Arterial supply to some organs has rich interarterial anastomoses so that blockage of one vessel can re-establish blood supply bypassing the blocked arterial branch, and hence infarction is less common in such circumstances. For example:

- Superior mesenteric artery supplying blood to the small intestine.
- Inferior mesenteric artery supplying blood to distal colon.
- Arterial supply to the stomach by 3 separate vessels derived from coeliac axis.
- Interarterial anastomoses in the 3 main trunks of the coronary arterial system.

iii) *Parallel arterial supply* Blood supply to some organs and tissues is such that vitality of the tissue is maintained by alternative blood supply in case of occlusion of one. For example:

- Blood supply to the brain in the region of circle of Willis.
- Arterial supply to forearm by radial and ulnar arteries.

iv) *Double blood supply* The effect of occlusion of one set of vessels is modified if an organ has dual blood supply. For example:

- Lungs are perfused by bronchial circulation as well as by pulmonary arterial branches.
- Liver is supplied by both portal circulation and hepatic arterial flow.

However, collateral circulation is of little value if the vessels are severely affected with spasm, atheroma or any other such condition.

2. General and cardiovascular status The general status of an individual as regards cardiovascular function is an important determinant to assess the effect of ischaemia. Some of the factors which render the tissues more vulnerable to the effects of ischaemia are as under:

- Anaemias (sickle cell anaemia, in particular)
- Lowered oxygenation of blood (hypoxaemia)
- Senility with marked coronary atherosclerosis
- Cardiac failure
- Blood loss
- Shock.

3. Type of tissue affected Vulnerability of the tissue of the body to the effect of ischaemia is variable. Mesenchymal tissues are quite resistant to the effect of ischaemia as compared to parenchymal cells of the organs. The following tissues are more vulnerable to ischaemia:

- Brain (cerebral cortical neurons, in particular).
- Heart (myocardial cells).
- Kidney (especially epithelial cells of proximal convoluted tubules).

4. Rapidity of development Sudden vascular obstruction results in more severe effects of ischaemia than if it is gradual since there is less time for collaterals to develop.

5. Degree of vascular occlusion Complete vascular obstruction results in more severe ischaemic injury than the partial occlusion.

EFFECTS The effects of ischaemia are variable and range from 'no change' to 'sudden death'.

1. No effects on the tissues If the collateral channels develop adequately, the effect of ischaemia fails to occur.

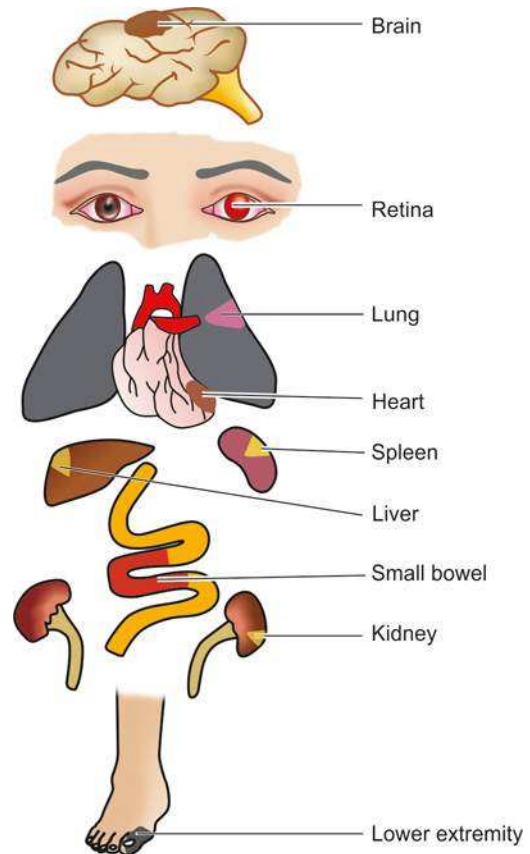

Figure 4.28 Common locations of systemic infarcts following arterial embolism.

2. Functional disturbances These result when collateral channels are able to supply blood during normal activity but the supply is not adequate to withstand the effect of exertion. The examples are angina pectoris and intermittent claudication.

3. Cellular changes Partial and gradual ischaemia may produce cellular changes such as cloudy swelling, fatty change, ischaemic atrophy and replacement fibrosis. Infarction results when the deprivation of blood supply is complete so as to cause necrosis of tissue affected.

4. Sudden death The cause of sudden death from ischaemia is usually myocardial and cerebral infarction.

The most important and common outcome of ischaemia is infarction discussed below. **Fig. 4.28** shows the organs most commonly affected by infarction.

INFARCTION

DEFINITION Infarction is the process of tissue necrosis, usually coagulative type, resulting from ischaemia; the localised area of necrosis so developed is called an *infarct*.

ETIOLOGY All the causes of ischaemia discussed above can cause infarction. However, there are a few other noteworthy features in infarction:

- Most commonly, infarcts are caused by interruption in arterial blood supply, called *ischaemic necrosis*.
- Less commonly, venous obstruction can produce infarcts termed *stagnant hypoxia*.
- Generally, *sudden, complete, and continuous occlusion* (e.g. thrombosis or embolism) produces infarcts.

iv) Infarcts may be produced by *nonocclusive circulatory insufficiency* as well e.g. incomplete atherosclerotic narrowing of coronary arteries may produce myocardial infarction due to acute coronary insufficiency.

TYPES OF INFARCTS Infarcts are classified depending upon different features:

1. According to their colour:

- i) *Pale or anaemic*, due to arterial occlusion and are seen in compact organs e.g. in the kidneys, heart, spleen.
- ii) *Red or haemorrhagic*, seen in soft loose tissues and are caused either by pulmonary arterial obstruction (e.g. in the lungs) or by arterial or venous occlusion (e.g. in the intestines).

2. According to their age:

- i) *Recent or fresh*
- ii) *Old or healed*

3. According to presence or absence of infection:

- i) *Bland*, when free of bacterial contamination
- ii) *Septic*, when infected.

PATHOGENESIS The process of infarction takes place as follows:

- i) *Localised hyperaemia* due to local anoxaemia occurs immediately after obstruction of the blood supply.
- ii) Within a few hours, the affected part becomes swollen due to *oedema and haemorrhage*. The amount of haemorrhage is variable, being more marked in the lungs and spleen, and less extensive in the kidneys and heart.
- iii) *Cellular changes* such as cloudy swelling and degeneration appear early (reversible cell injury), while cell death (irreversible cell injury or necrosis) occurs in 12-48 hours.
- iv) There is progressive *proteolysis* of the necrotic tissue and there is lysis of the red cells.
- v) *An acute inflammatory reaction and hyperaemia* appear at the same time in the surrounding tissues in response to products of proteolysis.
- vi) *Blood pigments*, haematoidin and haemosiderin, liberated by lysis of RBCs are deposited in the infarct. At this stage, most infarcts become pale-grey due to loss of red cells.
- vii) Following this, there is progressive *ingrowth of granulation tissue* from the margin of the infarct so that eventually the infarct is replaced by a fibrous scar. Dystrophic calcification may occur sometimes.

MORPHOLOGIC FEATURES Some general morphological features of infarcts characterise infarcts of all organ sites.

Grossly, general features are as follows:

- i) Infarcts of solid organs are usually wedge-shaped, the apex pointing towards the occluded artery and the wide base on the surface of the organ.
- ii) Infarcts due to arterial occlusion are generally pale while those due to venous obstruction are haemorrhagic.
- iii) Most infarcts become pale later as the red cells are lysed but pulmonary infarcts never become pale due to extensive amount of blood.
- iv) Cerebral infarcts are poorly defined with central softening (encephalomalacia).

v) Recent infarcts are generally slightly elevated over the surface while the old infarcts are shrunken and depressed under the surface of the organ.

Microscopically, the general features are as under:

- i) Pathognomonic cytologic change in all infarcts is coagulative (ischaemic) necrosis of the affected area of tissue or organ. In cerebral infarcts, however, there is characteristic liquefactive necrosis.
- ii) Some amount of haemorrhage is generally present in any infarct.
- iii) At the periphery of an infarct, inflammatory reaction is noted. Initially, neutrophils predominate but subsequently macrophages and fibroblasts appear.
- iv) Eventually, the necrotic area is replaced by fibrous scar tissue, which at times may show dystrophic calcification.
- v) In cerebral infarcts, the liquefactive necrosis is followed by gliosis i.e. replacement by microglial cells distended by fatty material (gitter cells).

Infarcts of Different Organs

A few representative examples of infarction of some organs (lungs, kidney, liver and spleen) are discussed below. Myocardial infarction (page 409), cerebral infarction (page 872) and infarction of the small intestines (page 546) are covered in detail in respective chapters of Systemic Pathology.

Table 4.10 sums up the gross appearance and the usual outcome of the common types of infarction.

INFARCT LUNG Embolism of the pulmonary arteries may produce pulmonary infarction, though not always. This is because lungs receive blood supply from bronchial arteries as well, and thus occlusion of pulmonary artery ordinarily does not produce infarcts. However, it may occur in patients who have inadequate circulation such as in chronic lung diseases and congestive heart failure.

Grossly, pulmonary infarcts are classically wedge-shaped with base on the pleura, haemorrhagic, variable in size, and most often in the lower lobes (**Fig. 4.29**). Fibrinous pleuritis usually covers the area of infarct. Cut surface is

Table 4.10 Infarcts of most commonly affected organs.

| LOCATION | GROSS APPEARANCE | OUTCOME |
|------------------------------------|----------------------|---|
| 1. <i>Myocardial infarction</i> | Pale | Frequently lethal |
| 2. <i>Pulmonary infarction</i> | Haemorrhagic | Less commonly fatal |
| 3. <i>Cerebral infarction</i> | Haemorrhagic or pale | Fatal if massive |
| 4. <i>Intestinal infarction</i> | Haemorrhagic | Frequently lethal |
| 5. <i>Renal infarction</i> | Pale | Not lethal unless massive and bilateral |
| 6. <i>Infarct spleen</i> | Pale | Not lethal |
| 7. <i>Infarct liver</i> | Pale | Not lethal |
| 8. <i>Infarcts lower extremity</i> | Pale | Not lethal |

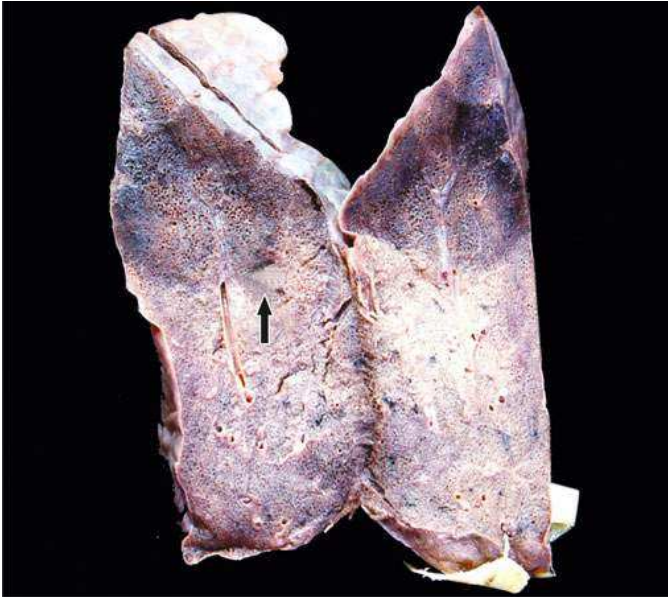

Figure 4.29 Haemorrhagic infarct lung. The sectioned surface shows dark tan firm areas (arrow) with base on the pleura.

dark purple and may show the blocked vessel near the apex of the infarcted area. Old organised and healed pulmonary infarcts appear as retracted fibrous scars.

Microscopically, the characteristic histologic feature is coagulative necrosis of the alveolar walls. Initially, there is infiltration by neutrophils and intense alveolar capillary congestion, but later their place is taken by haemosiderin, phagocytes and granulation tissue (**Fig. 4.30**).

INFARCT KIDNEY Renal infarction is common, found in up to 5% of autopsies. Majority of them are caused by thromboemboli, most commonly originating from the heart such as in mural thrombi in the left atrium, myocardial infarction, vegetative endocarditis and from aortic aneurysm. Less commonly, renal infarcts may occur due to advanced renal artery atherosclerosis, arteritis and sickle cell anaemia.

Grossly, renal infarcts are often multiple and may be bilateral. Characteristically, they are pale or anaemic and wedge-shaped with base resting under the capsule and apex pointing towards the medulla. Generally, a narrow rim of preserved renal tissue under the capsule is spared because it draws its blood supply from the capsular vessels. Cut surface of renal infarct in the first 2 to 3 days is red and congested but by 4th day the centre becomes pale yellow. At the end of one week, the infarct is typically anaemic and depressed below the surface of the kidney (**Fig. 4.31**).

Microscopically, the affected area shows characteristic coagulative necrosis of renal parenchyma i.e. there are ghosts of renal tubules and glomeruli without intact nuclei and cytoplasmic content. The margin of the infarct shows inflammatory reaction—initially acute but later macrophages and fibrous tissue predominate (**Fig. 4.32**).

INFARCT SPLEEN Spleen is one of the common sites for infarction. Splenic infarction results from occlusion of the

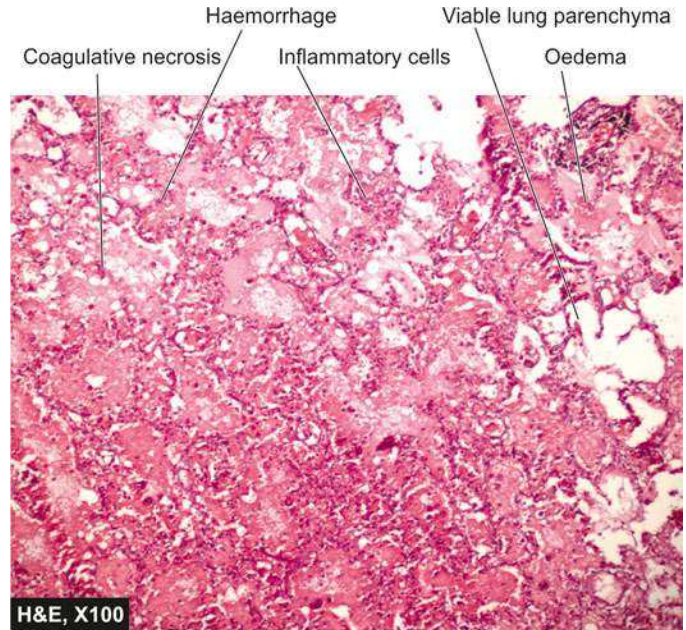

Figure 4.30 Haemorrhagic infarct lung. Infarcted area shows ghost alveoli filled with blood.

splenic artery or its branches. Occlusion is caused most commonly by thromboemboli arising in the heart (e.g. in mural thrombi in the left atrium, vegetative endocarditis, myocardial infarction), and less frequently by obstruction of microcirculation (e.g. in myeloproliferative diseases, sickle cell anaemia, arteritis, Hodgkin's disease, bacterial infections).

Grossly, splenic infarcts are often multiple. They are characteristically pale or anaemic and wedge-shaped with their base at the periphery and apex pointing towards hilum (**Fig. 4.33**).

Figure 4.31 Infarct kidney. The wedge-shaped infarct is slightly depressed on the surface. The apex lies internally and wide base is on the surface. The central area is pale while the margin is haemorrhagic.

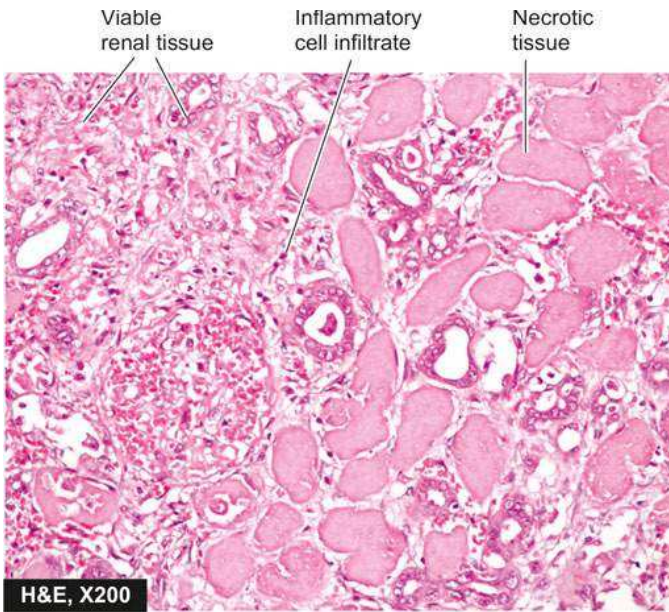

Figure 4.32 Renal infarct. Renal tubules and glomeruli show typical coagulative necrosis i.e. intact outlines of necrosed cells. There is acute inflammatory infiltrate at the periphery of the infarct.

Microscopically, the features are similar to those found in anaemic infarcts in kidney. Coagulative necrosis and inflammatory reaction are seen. Later, the necrotic tissue is replaced by shrunken fibrous scar (**Fig. 4.34**).

INFARCT LIVER Just as in lungs, infarcts in the liver are uncommon due to dual blood supply—from portal vein and from hepatic artery.

◆ Obstruction of the portal vein is usually secondary to other diseases such as hepatic cirrhosis, intravenous invasion of primary carcinoma of the liver, carcinoma of the pancreas and pylephlebitis. Occlusion of portal vein or its branches generally

Figure 4.33 Pale infarct spleen. A wedge-shaped shrunken area of pale colour is seen with base resting under the capsule, while the margin is congested.

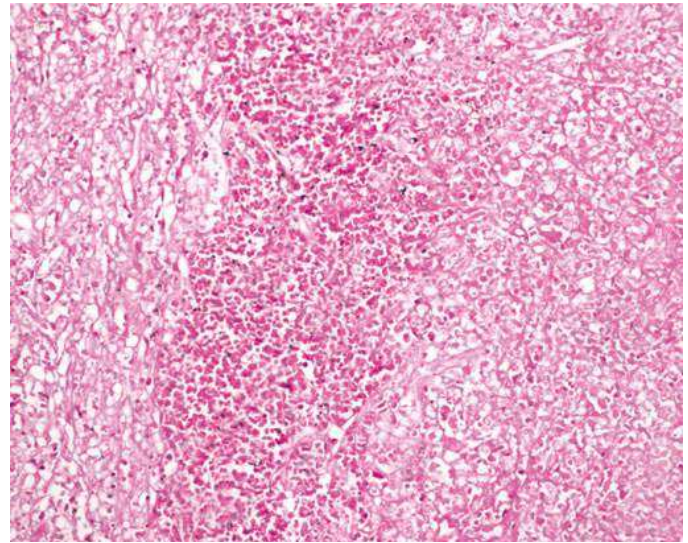

Figure 4.34 Pale infarct spleen. The affected area shows outlines of cells only due to coagulative necrosis while the margin of infarcted area shows haemorrhage.

does not produce ischaemic infarction but instead reduced blood supply to hepatic parenchyma causes non-ischaemic infarct called *infarct of Zahn*.

◆ Obstruction of the hepatic artery or its branches, on the other hand, caused by arteritis, arteriosclerosis, bland or septic emboli, results in ischaemic infarcts of the liver.

Grossly, ischaemic infarcts of the liver are usually anaemic but sometimes may be haemorrhagic due to stuffing of the site by blood from the portal vein. Infarcts of Zahn (non-ischaemic infarcts) produce sharply defined red-blue area in liver parenchyma.

Microscopically, ischaemic infarcts show characteristics of pale or anaemic infarcts as in kidney or spleen. Infarcts of Zahn occurring due to reduced portal blood flow over a long duration result in chronic atrophy of hepatocytes and dilatation of sinusoids.

GIST BOX 4.8

Ischaemia and Infarction

- ▣ Ischaemia is defined as deficient blood supply to part of a tissue relative to its metabolic needs.
- ▣ Causes of ischaemia may lie in the heart, arteries, veins and microcirculation.
- ▣ Adverse effects of ischaemia may result in 3 ways: hypoxia, malnourishment of cells and inadequate clearance of metabolites.
- ▣ Severity of ischaemic injury depends upon anatomic pattern of blood supply, general and cardiovascular status, type of tissue affected, and speed of development of ischaemia.
- ▣ Most common effect of ischaemia is infarction, generally from coagulative necrosis in most organs, but in the brain it is liquefactive necrosis.
- ▣ Some of the common locations of infarcts are: brain, heart, kidneys, spleen, small intestines, and lower extremities. Infarction of lungs and liver is less frequent due to dual blood supply to both these organs.

CLINICAL CASE 2

A 35 years old female admitted with pain lower abdomen following abortion by village midwife 3 days back. She has been having high-grade fever and bleeding from gums for 2 days. Now, she has been unconsciousness for the last 3 hours.

On examination, she is moderately built and nourished and unconscious. Her blood pressure and pulse are not recordable; while respiration rate is 40/min. She has pallor +++, oral bleeding

+ but no jaundice, cyanosis or lymphadenopathy. Auscultation of chest showed bilateral crepts and wheezing.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 906 (Appendix II)

Inflammation and Healing

INTRODUCTION

DEFINITION AND CAUSES Inflammation is defined as the local response of living mammalian tissues to injury from any agent. It is a body defense reaction in order to eliminate or limit the spread of injurious agent, followed by removal of the necrosed cells and tissues.

The injurious agents causing inflammation may be as under:

1. *Infective agents* like bacteria, viruses and their toxins, fungi, parasites.
2. *Immunological agents* like cell-mediated and antigen-antibody reactions.
3. *Physical agents* like heat, cold, radiation, mechanical trauma.
4. *Chemical agents* like organic and inorganic poisons.
5. *Inert materials* such as foreign bodies.

Thus, *inflammation is distinct from infection*—inflammation is a protective response by the body to variety of etiologic agents (infectious or non-infectious), while infection is invasion into the body by harmful microbes and their resultant ill-effects by toxins. Inflammation involves 2 basic processes with some overlapping, viz. early *inflammatory response* and later followed by *healing*. Though both these processes generally have protective role against injurious agents, inflammation and healing may cause considerable harm to the body as well e.g. anaphylaxis to bites by insects or reptiles, drugs, toxins, atherosclerosis, chronic rheumatoid arthritis, fibrous bands and adhesions in intestinal obstruction.

As discussed earlier (Chapter 3), “immunity or immune reaction” and “inflammatory response” by the host are both interlinked protective mechanisms in the body—inflammation is the visible response to an immune reaction, and activation of immune response is almost essential before inflammatory response appears.

SIGNS OF INFLAMMATION The Roman writer Celsus in 1st century A.D. named the famous 4 *cardinal signs of inflammation* as:

- i) *rubor* (redness);
- ii) *tumor* (swelling);
- iii) *calor* (heat); and
- iv) *dolor* (pain).

To these, fifth sign *functio laesa* (loss of function) was later added by Virchow. The word inflammation means burning. This nomenclature had its origin in old times but now we know that burning is only one of the features of inflammation.

TYPES OF INFLAMMATION Depending upon the defense capacity of the host and duration of response, inflammation can be classified as acute and chronic.

A. *Acute inflammation* is of short duration (lasting less than 2 weeks) and represents the early body reaction, resolves quickly and is usually followed by healing.

The main features of acute inflammation are:

1. accumulation of fluid and plasma at the affected site;
2. intravascular activation of platelets; and
3. polymorphonuclear neutrophils as inflammatory cells.

Sometimes, the acute inflammatory response may be quite severe and is termed as *fulminant acute inflammation*.

B. *Chronic inflammation* is of longer duration and occurs after delay, either after the causative agent of acute inflammation persists for a long time, or the stimulus is such that it induces chronic inflammation from the beginning. A variant, *chronic active inflammation*, is the type of chronic inflammation in which during the course of disease there are acute exacerbations of activity.

The characteristic feature of chronic inflammation is presence of chronic inflammatory cells such as lymphocytes, plasma cells and macrophages, granulation tissue formation, and in specific situations as granulomatous inflammation.

In some instances, the term *subacute inflammation* is used for the state of inflammation between acute and chronic.

GIST BOX 5.1

Introduction to Inflammation

- ▣ Inflammation is the local response of living mammalian tissues to injury from any agent which could be microbial, immunological, physical or chemical agents.
- ▣ Cardinal signs of inflammation are: redness, swelling, heat, pain and loss of function.
- ▣ Inflammation is of 2 types: acute when due to early response by the body and is of short duration, and chronic when it is for longer duration and occurs after delay and is characterised by response by chronic inflammatory cells.

ACUTE INFLAMMATION

Acute inflammatory response by the host to any agent is a continuous process but for the purpose of discussion, it can be divided into following two events:

- I. Vascular events
- II. Cellular events

Intimately linked to these two processes is the release of mediators of acute inflammation, which is also discussed just afterwards.

I. VASCULAR EVENTS

Alteration in the microvasculature (arterioles, capillaries and venules) is the earliest response to tissue injury. These

alterations include: haemodynamic changes and changes in vascular permeability.

Haemodynamic Changes

The earliest features of inflammatory response result from changes in the vascular flow and calibre of small blood vessels in the injured tissue. The sequence of these changes is as under:

1. Irrespective of the type of cell injury, immediate vascular response is of **transient vasoconstriction** of arterioles. With mild form of injury, the blood flow may be re-established in 3-5 seconds while with more severe injury the vasoconstriction may last for about 5 minutes.
2. Next follows **persistent progressive vasodilatation** which involves mainly the arterioles, but to a lesser extent, affects other components of the microcirculation like venules and capillaries. This change is obvious within half an hour of injury. Vasodilatation results in increased blood volume in microvascular bed of the area, which is responsible for redness and warmth at the site of acute inflammation.
3. Progressive vasodilatation, in turn, may elevate the **local hydrostatic pressure** resulting in transudation of fluid into the extracellular space. This is responsible for swelling at the local site of acute inflammation.
4. **Slowing or stasis** of microcirculation follows which causes increased concentration of red cells, and thus, raised blood viscosity.
5. Stasis or slowing is followed by **leucocytic margination** or peripheral orientation of leucocytes (mainly neutrophils) along the vascular endothelium. The leucocytes stick to the vascular endothelium briefly, and then move and migrate through the gaps between the endothelial cells into the extravascular space. This process is known as *emigration* (discussed later).

TRIPLE RESPONSE The features of haemodynamic changes in inflammation are best demonstrated by the **Lewis experiment**. Lewis induced the changes in the skin of inner aspect of forearm by firm stroking with a blunt point. The reaction so elicited is known as *triple response* or *red line response* consisting of the following (Fig. 5.1):

- i) **Red line** appears within a few seconds after stroking and is due to local vasodilatation of capillaries and venules.

- ii) **Flare** is the bright reddish appearance or flush surrounding the red line and results from vasodilatation of the adjacent arterioles.

- iii) **Wheal** is the swelling or oedema of the surrounding skin occurring due to transudation of fluid into the extravascular space.

These features, thus, elicit the classical signs of inflammation—redness, heat and swelling, to which fourth feature, pain, has been added.

Altered Vascular Permeability

PATHOGENESIS In and around the inflamed tissue, there is accumulation of oedema fluid in the interstitial compartment which comes from blood plasma by its escape through the endothelial wall of peripheral vascular bed. In the initial stage, the escape of fluid is due to vasodilatation and consequent elevation in hydrostatic pressure. This is transudate in nature. But subsequently, the characteristic inflammatory oedema, exudate, appears by increased vascular permeability of microcirculation. The differences between transudate and exudate, are summarised in **Table 4.1** (see page 81).

The appearance of inflammatory oedema due to increased vascular permeability of microvascular bed is explained on the basis of **Starling's hypothesis**. According to this, normally the fluid balance is maintained by two opposing sets of forces:

- i) Forces that cause **outward movement** of fluid from microcirculation: These are *intravascular hydrostatic pressure* and *colloid osmotic pressure of interstitial fluid*.
- ii) Forces that cause **inward movement** of interstitial fluid into circulation: These are *intravascular colloid osmotic pressure* and *hydrostatic pressure of interstitial fluid*.

Whatever little fluid is left in the interstitial compartment is drained away by lymphatics and, thus, no oedema results normally (Fig. 5.2,A).

However, in inflamed tissues, the endothelial lining of microvasculature becomes more leaky. Consequently, intravascular colloid osmotic pressure decreases and osmotic pressure of the interstitial fluid increases resulting in excessive outward flow of fluid into the interstitial compartment which is exudative inflammatory oedema (Fig. 5.2,B).

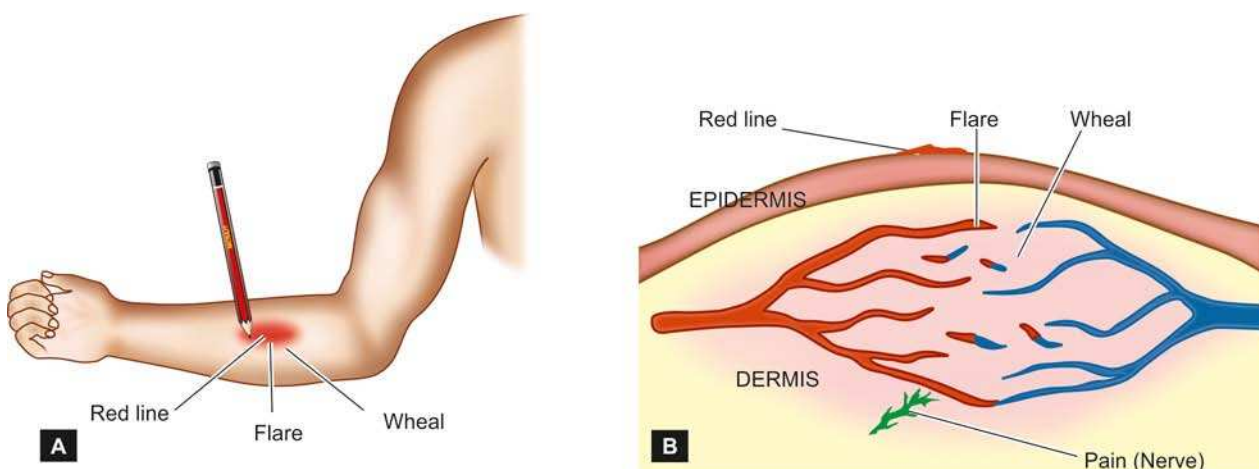

Figure 5.1 A, 'Triple response' elicited by firm stroking of skin of forearm with a pencil. B, Diagrammatic view of microscopic features of triple response of the skin.

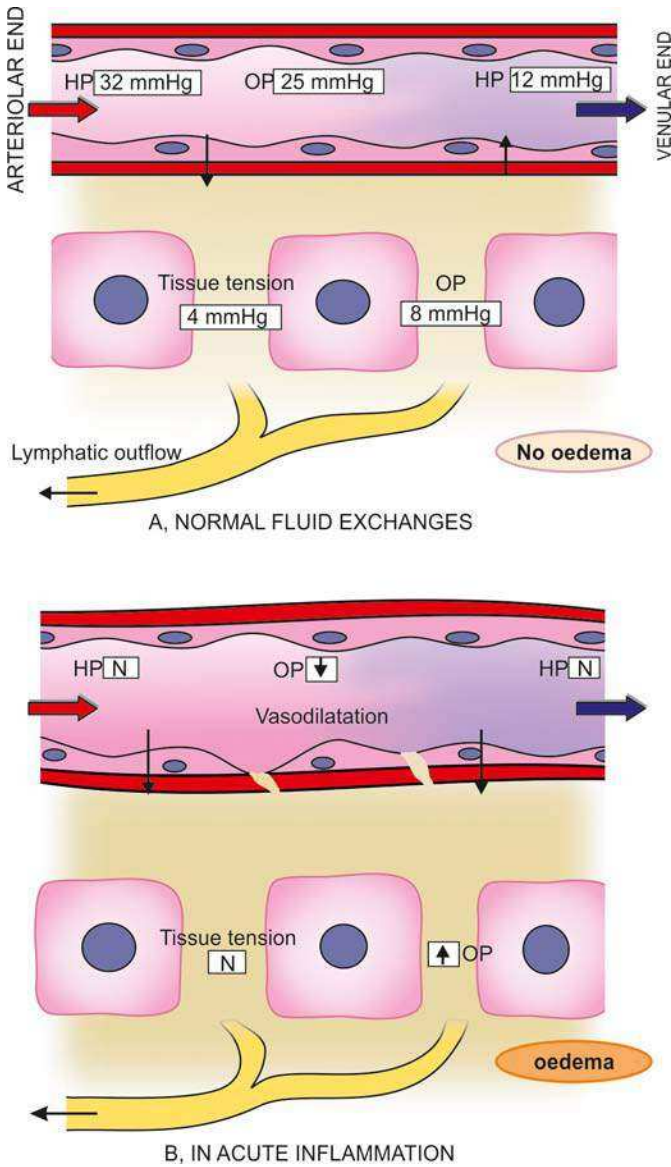

Figure 5.2 Fluid interchange between blood and extracellular fluid (ECF). (HP = hydrostatic pressure, OP = osmotic pressure).

PATTERNS OF INCREASED VASCULAR PERMEABILITY Increased vascular permeability in acute inflammation by which normally non-permeable endothelial layer of microvasculature becomes leaky can have following patterns and mechanisms which may be acting singly or more often in combination (**Fig. 5.3**):

i) Contraction of endothelial cells This is the most common mechanism of increased leakiness that affects venules exclusively while capillaries and arterioles remain unaffected. The endothelial cells develop temporary gaps between them due to their contraction resulting in vascular leakiness. It is mediated by the release of histamine, bradykinin and other chemical mediators. The response begins immediately after injury, is usually reversible, and is for short duration (15-30 minutes).

An example of such *immediate transient response* is mild thermal injury of skin of forearm.

ii) Contraction or mild endothelial damage In this mechanism, there is structural re-organisation of the cytoskeleton of endothelial cells that causes reversible retraction at the intercellular junctions or mild form of endothelial damage. This change affects venules and capillaries and is mediated by cytokines such as interleukin-1 (IL-1) and tumour necrosis factor (TNF)- α . The onset of response occurs after delay of 4-6 hours following injury and lasts for several hours to days.

Classic example of *delayed and prolonged leakage* is appearance of sunburns mediated by ultraviolet radiation.

iii) Direct injury to endothelial cells Direct injury to the endothelium causes cell necrosis and appearance of physical gaps at the sites of detached endothelial cells. Process of thrombosis involving platelets and fibrin is initiated at the site of damaged endothelial cells. The change affects all levels of microvasculature (venules, capillaries and arterioles). The increased permeability may either appear immediately after injury and last for several hours or days (*immediate sustained leakage*), or may occur after a delay of 2-12 hours and last for hours or days (*delayed prolonged leakage*).

The examples of *immediate sustained leakage* are severe bacterial infections while delayed prolonged leakage may occur following moderate thermal injury and radiation injury.

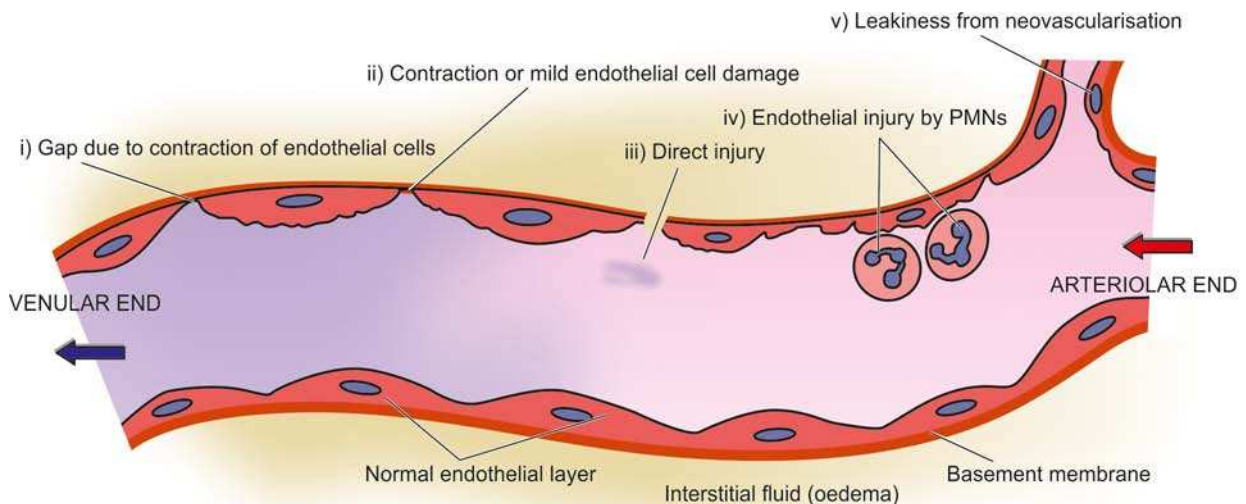

Figure 5.3 Schematic illustration of pathogenesis of increased vascular permeability in acute inflammation. The serial numbers in the figure correspond to five numbers described in the text.

Table 5.1 Mechanisms of increased vascular permeability.

| MECHANISM | MICROVASCULATURE | RESPONSE TYPE | PATHOGENESIS | EXAMPLES |
|---|----------------------------------|--|-------------------------------|--|
| 1. Endothelial cell contraction | Venules | Immediate transient (15-30 min) | Histamine, bradykinin, others | Mild thermal injury |
| 2. Contraction or mild endothelial injury | Venules, capillaries | Somewhat delayed (in 4-6 hrs) prolonged (for 24 hrs to days) | IL-1, TNF- α | Sunburns |
| 3. Direct endothelial cell injury | Arterioles, venules, capillaries | Immediate prolonged (hrs to days), or delayed (2-12 hrs) prolonged (hrs to days) | Cell necrosis and detachment | Moderate to severe burns, severe bacterial infection, radiation injury |
| 4. Leucocyte-mediated endothelial injury | Venules, capillaries | Delayed, prolonged | Leucocyte activation | Pulmonary venules and capillaries |
| 5. Neovascularisation | All levels | Any type | Angiogenesis, VEGF | Healing, tumours |

iv) Leucocyte-mediated endothelial injury Adherence of leucocytes to the endothelium at the site of inflammation may result in activation of leucocytes. The activated leucocytes release proteolytic enzymes and toxic oxygen species which may cause endothelial injury and increased vascular leakiness. This form of increased vascular leakiness affects mostly venules and is a *late response*.

The examples are seen in sites where leucocytes adhere to the vascular endothelium e.g. in pulmonary venules and capillaries.

v) Leakiness in neovascularisation In addition, the newly formed capillaries under the influence of vascular endothelial growth factor (VEGF) during the process of repair and in tumours are excessively leaky.

These mechanisms are summarised in **Table 5.1**.

II. CELLULAR EVENTS

The cellular phase of inflammation consists of 2 processes:

1. exudation of leucocytes; and
2. phagocytosis.

Exudation of Leucocytes

The escape of leucocytes from the lumen of microvasculature to the interstitial tissue is the most important feature of inflammatory response. In acute inflammation, polymorphonuclear neutrophils (PMNs) comprise the first line of body defense, followed later by monocytes and macrophages.

The changes leading to migration of leucocytes are as follows (**Fig. 5.4**):

1. CHANGES IN THE FORMED ELEMENTS OF BLOOD In the early stage of inflammation, the rate of flow of blood is

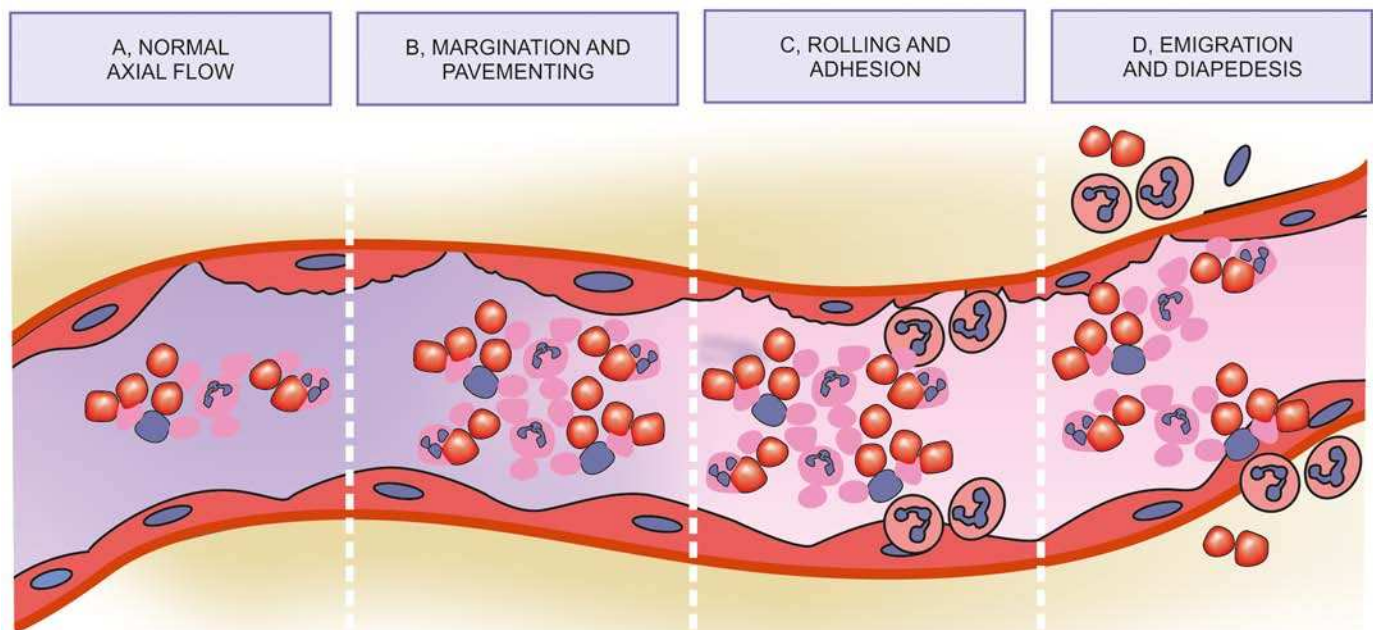

Figure 5.4 Sequence of changes in the exudation of leucocytes. A, Normal axial flow of blood with central column of cells and peripheral zone of cell-free plasma. B, Margination and pavementing of neutrophils with narrow plasmatic zone. C, Adhesion of neutrophils to endothelial cells with pseudopods in the intercellular junctions. D, Emigration of neutrophils and diapedesis with damaged basement membrane.

increased due to vasodilatation. But subsequently, there is slowing or stasis of bloodstream. With stasis, changes in the normal axial flow of blood in the microcirculation take place. The normal axial flow consists of central stream of cells comprised by leucocytes and RBCs and peripheral cell-free layer of plasma close to vessel wall. Due to slowing and stasis, the central stream of cells widens and peripheral plasma zone becomes narrower because of loss of plasma by exudation. This phenomenon is known as *margination*. As a result of this redistribution, neutrophils of the central column come close to the vessel wall; this is known as *pavementing*.

2. ROLLING AND ADHESION Peripherally margined and pavemented neutrophils slowly roll over the endothelial cells lining the vessel wall (*rolling phase*). This is followed by transient bond between the leucocytes and endothelial cells becoming firmer (*adhesion phase*). The following cell adhesion molecules (CAMs) bring about rolling and adhesion phases:

i) **Selectins** These are a group of CAMs expressed on the surface of activated endothelial cells and are structurally composed of lectins or lectin-like protein molecules the most important of which is s-Lewis X molecule. Their role is to recognise and bind to glycoproteins and glycolipids on the cell surface of neutrophils. There are 3 types of selectins:

◆ *P-selectin* (preformed and stored in endothelial cells and platelets, also called CD62) is involved in rolling.

◆ *E-selectin* (synthesised by cytokine-activated endothelial cells, also named ECAM) is associated with both rolling and adhesion.

◆ *L-selectin* (expressed on the surface of lymphocytes and neutrophils, also called L-CAM) is responsible for homing of circulating lymphocytes to the endothelial cells in lymph nodes.

ii) **Integrins** These are a family of endothelial cell surface proteins having alpha (or CD11) and beta (CD18) subunits, which are activated during the process of loose and transient adhesions between endothelial cells and leucocytes. At the same time the receptors for integrins on the neutrophils are also stimulated. This process brings about firm adhesion between leucocyte and endothelium.

iii) **Immunoglobulin gene superfamily adhesion molecules.** This group consists of a variety of immunoglobulin molecules present on most cells of the body. These partake in cell-to-cell contact through various other CAMs and cytokines. They have a major role in recognition and binding of immunocompetent cells as under:

◆ Intercellular adhesion molecule-1 (ICAM-1, also called CD54) and vascular cell adhesion molecule-1 (VCAM-1, also named CD106) allow a tighter adhesion and stabilise the interaction between leucocytes and endothelial cells.

◆ Platelet-endothelial cell adhesion molecule-1 (PECAM-1) or CD31 is involved in leucocyte migration from the endothelial surface.

3. EMIGRATION After sticking of neutrophils to endothelium, the former move along the endothelial surface till a suitable site between the endothelial cells is found where the neutrophils throw out cytoplasmic pseudopods. Subsequently, the neutrophils lodged between the endothelial cells and basement membrane cross the basement membrane by damaging it locally with secreted collagenases and escape out into the extravascular space; this is known as *emigration*. The damaged basement membrane is repaired almost

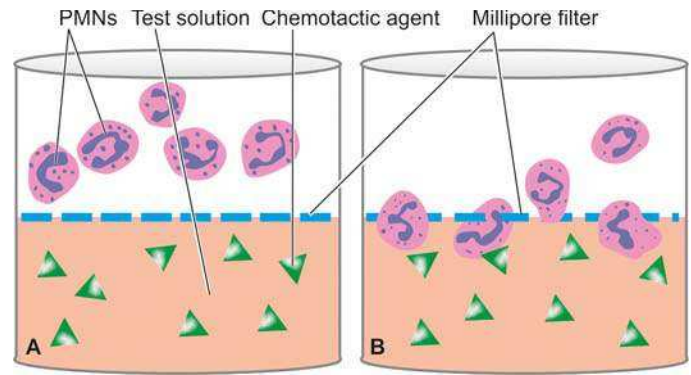

Figure 5.5 The Boyden's chamber with millipore filter, shown by dotted line. A, Suspension of leucocytes above is separated from test solution below. B, Lower half of chamber shows migration of neutrophils towards chemotactic agent.

immediately. As already mentioned, neutrophils are the dominant cells in acute inflammatory exudate in the first 24 hours, and monocyte-macrophages appear in the next 24-48 hours. However, neutrophils are short-lived (24-48 hours) while monocyte-macrophages survive much longer.

Simultaneous to emigration of leucocytes, escape of red cells through gaps between the endothelial cells, *diapedesis*, takes place. It is a passive phenomenon—RBCs being forced out either by raised hydrostatic pressure or may escape through the endothelial defects left after emigration of leucocytes. Diapedesis gives haemorrhagic appearance to the inflammatory exudate.

4. CHEMOTAXIS The transmigration of leucocytes after crossing several barriers (endothelium, basement membrane, perivascular myofibroblasts and matrix) to reach the interstitial tissues is a chemotactic factor-mediated process called chemotaxis. The concept of chemotaxis is well illustrated by *Boyden's chamber experiment*. In this, a millipore filter (3 μm pore size) separates the suspension of leucocytes from the test solution in tissue culture chamber. If the test solution contains chemotactic agent, the leucocytes migrate through the pores of filter towards the chemotactic agent (**Fig. 5.5**).

The following agents act as potent chemotactic substances for neutrophils:

- Leukotriene B4 (LT-B4), a product of lipoxygenase pathway of arachidonic acid metabolites
- Components of complement system (C5a and C3a in particular)
- Cytokines (Interleukins, in particular IL-8)
- Soluble bacterial products (such as formylated peptides).

In addition to neutrophils, other inflammatory cells too respond and partake in inflammation having specific chemokines, e.g. monocyte chemoattractant protein (MCP-1), eotaxin chemotactic for eosinophils, NK cells for recognising virally infected cells etc.

Phagocytosis

Phagocytosis is defined as the process of engulfment of solid particulate material by the cells (cell-eating). The cells performing this function are called *phagocytes*. There are 2 main types of phagocytic cells:

- Polymorphonuclear neutrophils (PMNs) which appear early in acute inflammatory response, sometimes called as *microphages*.

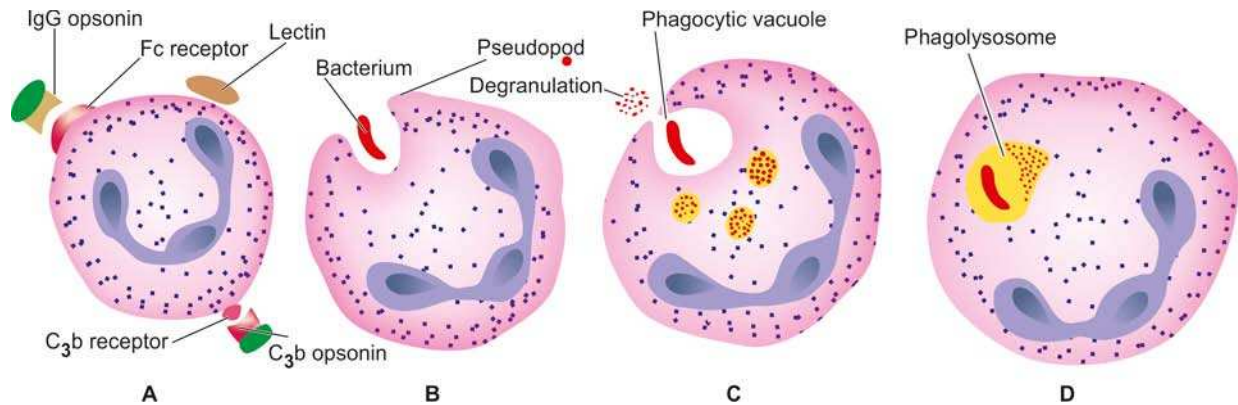

Figure 5.6 Stages in phagocytosis of a foreign particle. A, Opsonisation of the particle. B, Pseudopod engulfing the opsonised particle. C, Incorporation within the cell (phagocytic vacuole) and degranulation. D, Phagolysosome formation after fusion of lysosome of the cell.

ii) Circulating monocytes and fixed tissue mononuclear phagocytes, commonly called as *macrophages*.

Neutrophils and macrophages on reaching the tissue spaces produce several proteolytic enzymes—lysozyme, protease, collagenase, elastase, lipase, proteinase, gelatinase, and acid hydrolases. These enzymes degrade collagen and extracellular matrix. Phagocytosis of the microbe by polymorphs and macrophages involves the following 3 steps (**Fig. 5.6**):

1. Recognition and attachment
2. Engulfment
3. Killing and degradation

1. RECOGNITION AND ATTACHMENT

Phagocytosis is initiated by the expression of cell surface receptors on macrophages which recognise microorganisms: *mannose receptor* and *scavenger receptor*. The process of phagocytosis is further enhanced when the microorganisms are coated with specific proteins, *opsonins*, from the serum and the process is called opsonisation (meaning preparing for eating). Opsonins establish a bond between bacteria and the cell membrane of phagocytic cell. The main opsonins present in the serum and their corresponding receptors on the surface of phagocytic cells (PMNs or macrophages) are as under:

- i) *IgG opsonin* is the Fc fragment of immunoglobulin G; it is the naturally-occurring antibody in the serum that coats the bacteria while the PMNs possess receptors for the same.
- ii) *C3b opsonin* is the fragment generated by activation of complement pathway. It is strongly chemotactic for attracting PMNs to bacteria.
- iii) *Lectins* are carbohydrate-binding proteins in the plasma which bind to bacterial cell wall.

2. ENGULFMENT

The opsonised particle or microbe bound to the surface of phagocyte is ready to be engulfed. This is accomplished by formation of cytoplasmic pseudopods around the particle due to activation of actin filaments beneath cell wall, enveloping it in a phagocytic vacuole. Eventually, plasma membrane enclosing the particle breaks from the cell surface so that membrane-lined phagocytic vacuole or phagosome becomes internalised in the cell and lies free in the cell cytoplasm. The phagosome fuses with one or more lysosomes of the cell and form bigger vacuole called phagolysosome.

3. KILLING AND DEGRADATION

Next comes the stage of killing and degradation of micro-organism to dispose of it which is the major function of phagocytes as scavenger cells. The microorganisms after being killed by antibacterial substances are degraded by hydrolytic enzymes. However, this mechanism fails to kill and degrade some bacteria like tubercle bacilli.

In general, following mechanisms are involved in disposal of microorganisms:

A. Intracellular mechanisms:

- i) Oxidative bactericidal mechanism by oxygen free radicals
 - a) MPO-dependent
 - b) MPO-independent
- ii) Oxidative bactericidal mechanism by lysosomal granules
- iii) Non-oxidative bactericidal mechanism

B. Extracellular mechanisms:

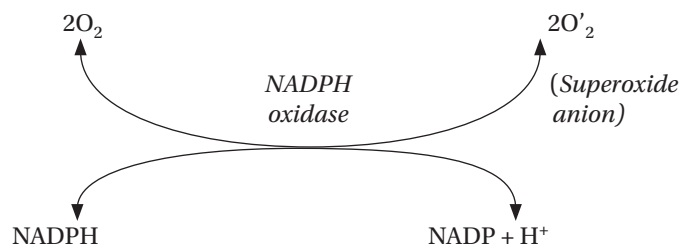

These mechanisms are discussed below.

A. INTRACELLULAR MECHANISMS Intracellular metabolic pathways are involved in killing microbes, more commonly by oxidative mechanism and less often by non-oxidative pathways.

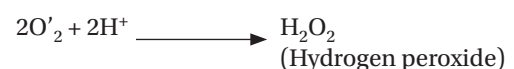

i) Oxidative bactericidal mechanism by oxygen free radicals An important mechanism of microbicidal killing is by oxidative damage by the production of reactive oxygen metabolites (O'_2 , H_2O_2 , OH' , $HOCl$, HOI , $HOBr$).

A phase of increased oxygen consumption ('respiratory burst') by activated phagocytic leucocytes requires the essential presence of NADPH oxidase.

NADPH-oxidase present in the cell membrane of phagosome reduces oxygen to superoxide ion (O'_2):

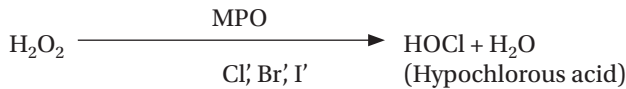

Superoxide is subsequently converted into H_2O_2 which has bactericidal properties:

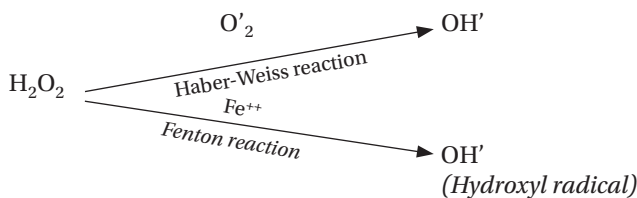

This type of bactericidal activity is carried out either via enzyme myeloperoxidase (MPO) present in the azurophilic granules of neutrophils and monocytes, or independent of enzyme MPO, as under:

a) **MPO-dependent killing.** In this mechanism, the enzyme MPO acts on H_2O_2 in the presence of halides (chloride, iodide or bromide) to form hypochlorous acid (HOCl, HOI, HOBr). This is called *H_2O_2 -MPO-halide system* and is more potent antibacterial system in polymorphs than H_2O_2 alone:

b) **MPO-independent killing.** Mature macrophages lack the enzyme MPO and they carry out bactericidal activity by producing OH^- ions and superoxide singlet oxygen ($O^{\cdot -}$) from H_2O_2 in the presence of $O^{\cdot -}_2$ (Haber-Weiss reaction) or in the presence of Fe^{++} (Fenton reaction):

Reactive oxygen metabolites are particularly useful in eliminating microbial organisms that grow within phagocytes e.g. *M. tuberculosis*, *Histoplasma capsulatum*.

ii) Oxidative bactericidal mechanism by lysosomal granules In this mechanism, the preformed granule-stored products of neutrophils and macrophages are discharged or secreted into the phagosome and the extracellular environment. While the role of MPO is already highlighted above, other substances liberated by degranulation of macrophages and neutrophils are protease, trypsinase, phospholipase, and alkaline phosphatase. Progressive degranulation of neutrophils and macrophages along with oxygen free radicals degrades proteins i.e. induces proteolysis.

iii) Non-oxidative bactericidal mechanism Some agents released from the granules of phagocytic cells do not require oxygen for bactericidal activity. These include the following:

a) **Granules.** Some of liberated lysosomal granules do not kill by oxidative damage but cause lysis of microbe within phagosome. These are lysosomal hydrolases, permeability increasing factors, cationic proteins (defensins), lipases, proteases, DNAases.

b) **Nitric oxide.** Nitric oxide is a reactive free radicals similar to oxygen free radicals which is formed by nitric oxide synthase. It is produced by endothelial cells as well as by activated macrophages. Nitric oxide is another potent mechanism of microbial killing.

B. EXTRACELLULAR MECHANISMS Following mechanisms explain the bactericidal activity at extracellular level:

i) Granules Degranulation of macrophages and neutrophils explained above continues to exert its effects of proteolysis outside the cells as well.

ii) Immune mechanisms As already discussed in Chapter 3, immune-mediated lysis of microbes takes place outside the cells by mechanisms of cytolysis, antibody-mediated lysis and by cell-mediated cytotoxicity.

GIST BOX 5.2

Acute Inflammatory Response

- ▣ The sequential haemodynamic changes are: an initial transient vasoconstriction, followed by persistent progressive vasodilatation, raised local hydrostatic pressure and transudation in extracellular space. Next, there is emigration of leucocytes from the capillary wall due to slowing and stasis in microcirculation.
- ▣ There is increased vascular permeability and appearance of inflammatory oedema. It has different mechanisms and various patterns: contraction of endothelial cells, mild to severe endothelial damage, direct or leucocyte-mediated injury to endothelial cells and leakiness in neovascularisation.
- ▣ Cellular phase of inflammation consists of exudation of leucocytes and phagocytosis.
- ▣ Leucocyte exudation begins from change of normal axial blood flow to slowing and stasis. This is followed by margination, pavementing, rolling, adhesion, and finally emigration of leucocytes to the extravascular space.
- ▣ Phagocytosis is cellular eating. The process of engulfment of foreign particulate material involves its initial recognition and opsonisation. The mechanisms of phagocytosis are largely intracellular (oxidative and non-oxidative bactericidal) and a few extracellular mechanisms.

MEDIATORS OF INFLAMMATION

These are a large and increasing number of endogenous chemical substances which mediate the process of acute inflammation.

Mediators of inflammation have some common properties as under:

1) These mediators are released either *from the cells or are derived from plasma proteins*:

- ◆ Cell-derived mediators are released either from their storage in the cell granules or are synthesised in the cells.
- ◆ The most common site of synthesis of plasma-derived mediators is the liver. After their release from the liver, these mediators require activation.

2) All mediators are *released in response to certain stimuli*. These stimuli may be a variety of injurious agents, dead and damaged tissues, or even one mediator stimulating release of another. The latter are called secondary mediators which may perform the function of the initial mediator or may have opposing action.

3) Mediators *act on different targets*. They may have similar action on different target cells or differ in their action on different target cells. They may act on cells which formed them or on other body cells.

4) *Range of actions* of different mediators are: increased vascular permeability, vasodilatation, chemotaxis, fever, pain and tissue damage.

5) Mediators have *short lifespan* after their release. After release, they are rapidly removed from the body by various mechanisms e.g. by enzymatic inactivation, antioxidants, regulatory proteins or may even decay spontaneously.

Two main groups of substances acting as chemical mediators of inflammation are those released *from the cells and those from the plasma proteins*, (Table 5.2) while

| 4. | The complement system |

their range of actions in acute inflammation are shown in Fig. 5.7.

I. Cell-derived Mediators

1. VASOACTIVE AMINES Two important pharmacologically active amines that have role in the early inflammatory response (first one hour) are histamine and 5-hydroxytryptamine (5-HT) or serotonin; another addition to this group is neuropeptides.

i) Histamine It is stored in the granules of mast cells, basophils and platelets. Histamine is released from these cells by various agents as under:

a) Stimuli or substances inducing acute inflammation e.g. heat, cold, irradiation, trauma, irritant chemicals, immunologic reactions etc.

b) Anaphylatoxins like fragments of complement C3a, and C5a, which increase vascular permeability and cause oedema in tissues.

c) Histamine-releasing factors from neutrophils, monocytes and platelets.

d) Interleukins.

The main *actions* of histamine are: vasodilatation, increased vascular (venular) permeability, itching and pain. Stimulation of mast cells and basophils also releases products of arachidonic acid metabolism including the release of *slow-reacting substances of anaphylaxis (SRS-As)*. The SRS-As consist of various leukotrienes (LTC₄, LTD₄ and LTE₄).

ii) 5-Hydroxytryptamine (5-HT or serotonin) It is present in tissues like chromaffin cells of GIT, spleen, nervous tissue, mast cells and platelets. The actions of 5-HT are similar to histamine but it is a less potent mediator of increased vascular permeability and vasodilatation than histamine. It may be mentioned here that carcinoid tumour is a serotonin-secreting tumour (page 560).

iii) Neuropeptides Another class of vasoactive amines is tachykinin neuropeptides such as substance P, neurokinin A, vasoactive intestinal polypeptide (VIP) and somatostatin. These small peptides are produced in the central and peripheral nervous systems.

The major proinflammatory *actions* of these neuropeptides are as follows:

- Increased vascular permeability.
- Transmission of pain stimuli.
- Mast cell degranulation.

2. ARACHIDONIC ACID METABOLITES (EICOSANOIDS) Arachidonic acid metabolites or eicosanoids are the most potent mediators of inflammation, much more than oxygen free radicals.

Arachidonic acid is a fatty acid, eicosatetraenoic acid; Greek word '*eikosa*' means 'twenty' because of 20 carbon atom composition of this fatty acid. Arachidonic acid is a constituent of the phospholipid cell membrane, besides its presence in

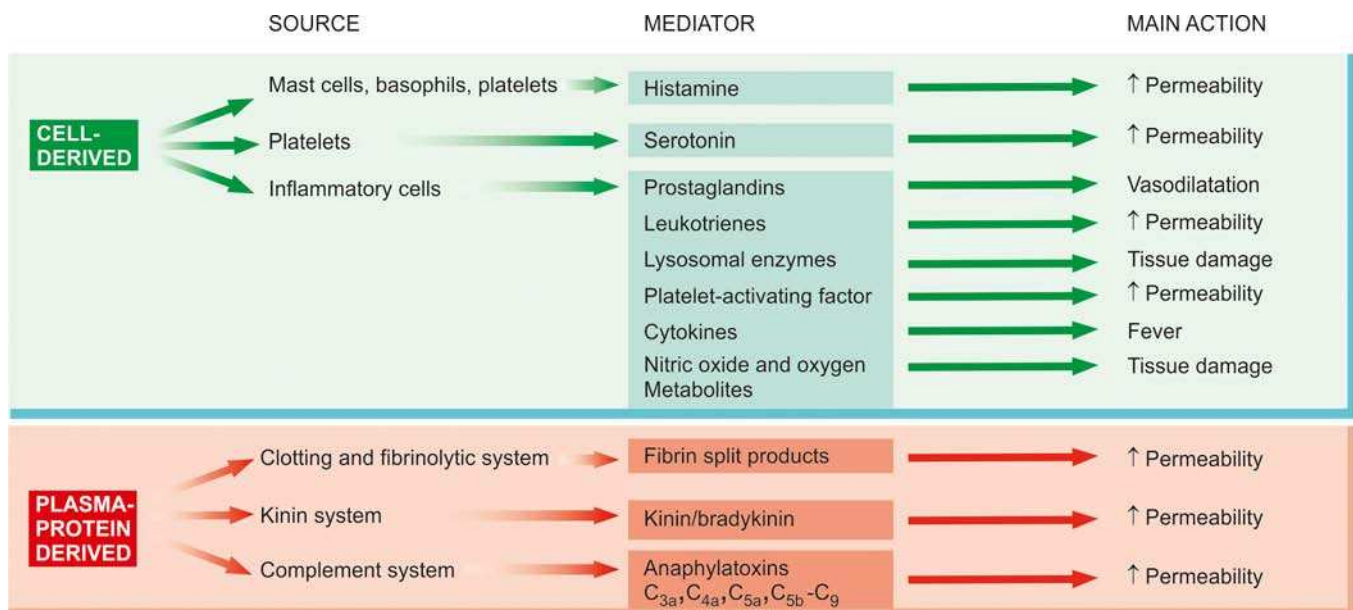

Figure 5.7 Mediators of inflammation.

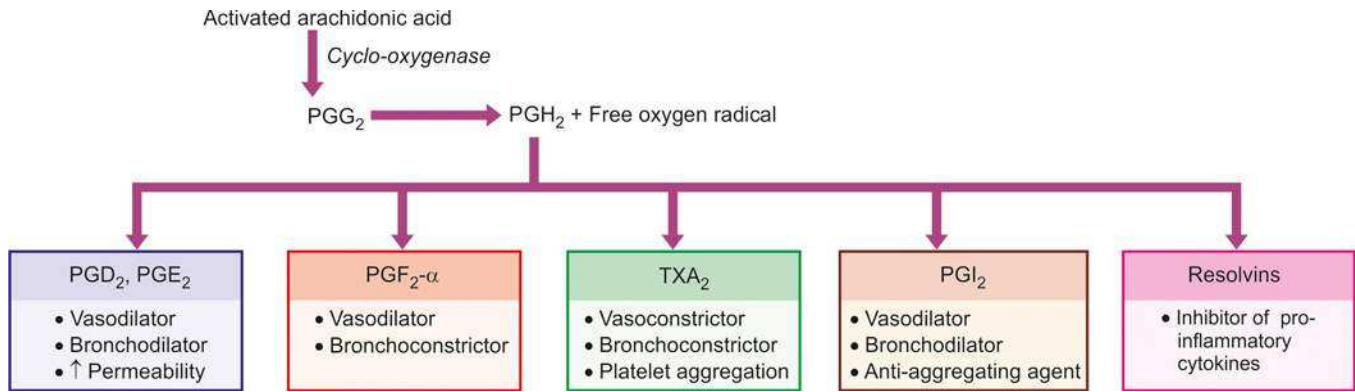

Figure 5.8 Arachidonic acid metabolites via cyclooxygenase pathway.

some constituents of diet. Arachidonic acid is released from the cell membrane by phospholipases. It is then activated to form arachidonic acid metabolites or eicosanoids by one of the following 2 pathways: via cyclo-oxygenase pathway or via lipo-oxygenase pathway:

i) Metabolites via cyclo-oxygenase pathway: Prostaglandins, thromboxane A₂, prostacyclin The name 'prostaglandin' was first given to a substance found in human seminal fluid but now the same substance has been isolated from a number of other body cells. Prostaglandins and related compounds are also called *autocoids* because these substances are mainly autocrine or paracrine agents. The terminology used for prostaglandins is abbreviation as PG followed by suffix of an alphabet and a serial number e.g. PGG₂, PGE₂ etc.

Cyclo-oxygenase (COX), a fatty acid enzyme present as COX-1 and COX-2, acts on activated arachidonic acid to form prostaglandin endoperoxide (PGG₂). PGG₂ is enzymatically transformed into PGH₂ with generation of free radical of oxygen. PGH₂ is further acted upon by enzymes and results in formation of the following 3 metabolites (**Fig. 5.8**):

a) *Prostaglandins* (PGD₂, PGE₂ and PGF₂-α). PGD₂ and PGE₂ act on blood vessels and cause increased venular permeability, vasodilatation and bronchodilatation and inhibit inflammatory cell function. PGF₂-α induces vasodilatation and bronchoconstriction.

b) *Thromboxane A₂* (TXA₂). Platelets contain the enzyme thromboxane synthetase and hence the metabolite, thromboxane A₂, formed is active in platelet aggregation, besides its role as a vasoconstrictor and broncho-constrictor.

c) *Prostacyclin* (PGI₂). PGI₂ induces vasodilatation, bronchodilatation and inhibits platelet aggregation.

d) *Resolvins* are another derivative of COX pathway which act by inhibiting production of pro-inflammatory cytokines. Thus, resolvins are actually helpful—drugs such as aspirin act by inhibiting COX activity and stimulate production of resolvins.

It may be mentioned here that some of the major anti-inflammatory drugs act by inhibiting activity of the enzyme COX; e.g. non-steroidal anti-inflammatory drugs (NSAIDs), COX-2 inhibitors.

ii) Metabolites via lipo-oxygenase pathway: 5-HETE, leukotrienes, lipoxins The enzyme, lipo-oxygenase, a predominant enzyme in neutrophils, acts on activated arachidonic acid to form hydroperoxy eicosatetraenoic acid (5-HPETE) which on further peroxidation forms following 2 metabolites (**Fig. 5.9**):

a) *5-HETE* (hydroxy compound), an intermediate product, is a potent chemotactic agent for neutrophils.

b) *Leukotrienes* (LT) are so named as they were first isolated from leucocytes. Firstly, unstable leukotriene A₄ (LTA₄) is formed which is acted upon by enzymes to form LTB₄ (chemotactic for phagocytic cells and stimulates phagocytic cell adherence) while LTC₄, LTD₄ and LTE₄ have common actions by causing smooth muscle contraction and thereby induce vasoconstriction, bronchoconstriction and increased vascular permeability; hence they are also called as slow-reacting substances of anaphylaxis (SRS-As).

c) *Lipoxins* (LX) act to regulate and counterbalance actions of leukotrienes. Lipoxygenase-12 present in platelets acts on LTA₄ derived from neutrophils and forms LXA₄ and LXB₄.

3. LYSSOMAL COMPONENTS The inflammatory cells—neutrophils and monocytes, contain lysosomal granules which on release elaborate a variety of mediators of inflammation. These are as under:

i) Granules of neutrophils Neutrophils have 3 types of granules: primary or azurophil, secondary or specific, and tertiary.

a) *Primary or azurophil granules* are large azurophil granules which contain functionally active enzymes. These are myeloperoxidase, acid hydrolases, acid phosphatase, lysozyme, defensin (cationic protein), phospholipase, cathepsin G, elastase, and protease.

b) *Secondary or specific granules* contain alkaline phosphatase, lactoferrin, gelatinase, collagenase, lysozyme, vitamin-B₁₂ binding proteins, plasminogen activator.

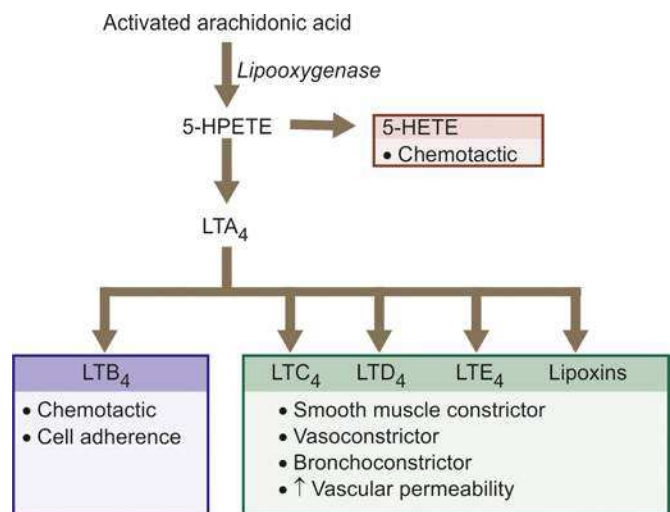

Figure 5.9 Arachidonic acid metabolites via lipoxygenase pathway.

c) *Tertiary granules or C particles* contain gelatinase and acid hydrolases.

Myeloperoxidase causes oxidative lysis by generation of oxygen free radicals, acid hydrolases act within the cell to cause destruction of bacteria in phagolysosome while proteases attack on the extracellular constituents such as basement membrane, collagen, elastin, cartilage etc.

However, degradation of extracellular components like collagen, basement membrane, fibrin and cartilage by proteases results in harmful tissue destruction which is kept in check by presence of antiproteases like α 1-antitrypsin and α 2-macroglobulin.

ii) Granules of monocytes and tissue macrophages These cells on degranulation also release mediators of inflammation like acid proteases, collagenase, elastase and plasminogen activator. However, they are more active in chronic inflammation than acting as mediators of acute inflammation.

4. PLATELET ACTIVATING FACTOR (PAF) It is released from IgE-sensitised basophils or mast cells, other leucocytes, endothelium and platelets. Apart from its action on platelet aggregation and release reaction, the actions of PAF as mediator of inflammation are:

i) increased vascular permeability;

ii) vasodilatation in low concentration and vasoconstriction otherwise;

iii) bronchoconstriction;

iv) adhesion of leucocytes to endothelium; and

v) chemotaxis.

5. CYTOKINES Cytokines are polypeptide substances produced by activated lymphocytes (*lymphokines*) and activated monocytes (*monokines*). The term *chemokine* is used for a family of substances which act as chemoattractants for inflammatory cells.

All these agents may act on 'self' cells which produced them or on other cells. Although over 200 cytokines have been described, major cytokines and their role in inflammation are as under (**Table 5.3**):

a) Interleukins (IL-1, IL-6, IL-8, IL-12, IL-17) While IL-1 and IL-6 are active in mediating acute inflammation, IL-12 and IL-17 play a potent role in chronic inflammation. IL-8 is a chemokine for acute inflammatory cells:

IL-1 is elaborated by several body cells-monocytes and macrophages, B lymphocytes, fibroblasts, endothelial and some epithelial cells. Similarly, it can target all body cells. Its major actions are:

◆ expression of adhesion molecules;

Table 5.3 Major cytokines in inflammation.

| CYTOKINE | CELL SOURCE | CELL TARGET | MAIN ACTIONS |
|---------------|---|---|---|
| IL-1 | Monocytes/macrophages, B cells, fibroblasts, endothelial cells, some epithelial cells | All cells | <ul style="list-style-type: none"> • Expression of adhesion molecules • Emigration of neutrophils and macrophages • Role in fever and shock • Hepatic production of acute phase protein |
| IL-6 | Same as for IL-1 | T and B cells, Epithelial cells, hepatocytes, Monocytes/macrophages | <ul style="list-style-type: none"> • Hepatic production of acute phase protein • Differentiation and growth of T and B cells |
| IL-8 | Monocytes/macrophages, T cells, neutrophils, fibroblasts, endothelial cells, epithelial cells | Neutrophils, basophils, T cells, monocytes/macrophages, endothelial cells | <ul style="list-style-type: none"> • Induces migration of neutrophils, macrophages and T cells • Stimulates release of histamine from basophils • Stimulates angiogenesis |
| IL-12 | Macrophages, dendritic cells, neutrophils | T cells, NK cells | <ul style="list-style-type: none"> • Induces formation of T helper cells and killer cells • Promotes CTL cytolytic activity • Increases production of IFN-γ • Decreases production of IL-17 |
| IL-17 | CD4+T cells | Fibroblasts, endothelial cells, epithelial cells | <ul style="list-style-type: none"> • Increases secretion of other cytokines • Migration of neutrophils and monocytes |
| TNF- α | Monocytes/macrophages, mast cells/basophils, eosinophils, B cells, T cells, NK cells | All cells except RBCs | <ul style="list-style-type: none"> • Hepatic production of acute phase protein • Systemic features (fever, shock, anorexia) • Expression of endothelial adhesion molecules • Enhanced leucocyte cytotoxicity • Induction of pro-inflammatory cytokines |
| IFN- γ | T cells, NK cells | All cells | <ul style="list-style-type: none"> • Activation of macrophages and NK cells • Stimulates secretion of Igs by B cells • Differentiation of T helper cells |
| MCP-1 | Fibroblasts, smooth muscle cells, blood mononuclear cells | Monocytes/macrophages, NK cells, T cells | <ul style="list-style-type: none"> • Chemoattractant for monocytes, T cells and NK cells • Stimulates release of histamine from basophils |
| Eotaxin | Alveolar cells, myocardium | Eosinophils, basophils | <ul style="list-style-type: none"> • Chemoattractant for eosinophils and Basophils • Induces allergic pulmonary disease |
| PF-4 | Platelets, megakaryocytes | Fibroblasts, endothelial cells | <ul style="list-style-type: none"> • Chemoattractant for fibroblasts • Inhibitory to haematopoietic precursors and endothelial cell proliferation |

IL=interleukin; TNF=tumour necrosis factor; IFN=interferon; MCP=monocyte chemotactic protein; PF=platelet factor.

- ◆ emigration of neutrophils and macrophages;
- ◆ role in fever and shock; and
- ◆ hepatic production of acute phase protein.

IL-6 is similar in its sources and target cells of action. Its major role are:

- ◆ hepatic production of acute phase protein; and
- ◆ differentiation and growth of T and B cells.

IL-8 is also elaborated by the same cells as for IL-2 and IL-6 except that it is secreted by T cells instead of B lymphocytes. Its target cells are neutrophils, basophils, T cells, monocytes/macrophages, endothelial cells. IL-8 is chemokine and its major actions are:

- ◆ induces migration of neutrophils, macrophages and T cells;
- ◆ stimulates release of histamine from basophils; and
- ◆ stimulates angiogenesis.

IL-12 is synthesised by macrophages, dendritic cells and neutrophils while it targets T cells and NK cells. Its major actions in chronic inflammation are as under:

- ◆ induces formation of T helper cells and killer cells;
- ◆ promotes CTL cytolytic activity;
- ◆ increases production of IFN- γ ; and
- ◆ decreases production of IL-17.

IL-17 is formed by CD4+T cells while it targets fibroblasts, endothelial cells and epithelial cells. Its action in chronic inflammation are:

- ◆ increased secretion of other cytokines; and
- ◆ migration of neutrophils and monocytes.

b) Tumour necrosis factor (TNF- α and β) TNF- α is a mediator of acute inflammation while TNF- β is involved in cellular cytotoxicity and in development of spleen and lymph nodes. TNF- α is formed by various cells (Monocytes/macrophages, mast cells/basophils, eosinophils, B cells, T cells, NK cells) while TNF- β is formed by B and T lymphocytes only. Both can target all body cells except erythrocytes. Major actions of TNF- α are:

- ◆ hepatic production of acute phase proteins;
- ◆ systemic features (fever, shock, anorexia);
- ◆ expression of endothelial adhesion molecules;
- ◆ enhanced leucocyte cytotoxicity; and
- ◆ induction of pro-inflammatory cytokines.

c) Interferon (IFN)- γ It is produced by T cells and NK cells and may act on all body cells. It acts as mediator of acute inflammation as under:

- ◆ activation of macrophages and NK cells;
- ◆ stimulates secretion of immunoglobulins by B cells; and
- ◆ role in differentiation of T helper cells.

d) Other chemokines (IL-8, MCP-1, eotaxin, PF-4) Besides IL-8, a few other chemoattractants for various cells are as under:

MCP-1 is elaborated by fibroblasts, smooth muscle cells, and peripheral blood mononuclear cells. Its actions are:

- ◆ chemoattractant for monocytes, T cells and NK cells; and
- ◆ Stimulates release of histamine from basophils.

Eotaxin is formed by alveolar cells of the lung and in the heart. Its actions are:

- ◆ chemoattractant for eosinophils and basophils; and
- ◆ induces allergic pulmonary disease.

PF-4 is formed by platelets and megakaryocytes and may act on fibroblasts and endothelial cells. Its actions are:

- ◆ chemoattractant for fibroblasts; and
- ◆ inhibitory to haematopoietic precursors and angiogenesis.

6. FREE RADICALS: OXYGEN METABOLITES AND NITRIC OXIDE

Free radicals act as potent mediator of inflammation: i) *Oxygen-derived metabolites* are released from activated neutrophils and macrophages and include superoxide oxygen (O_2^-), H_2O_2 , OH^\cdot and toxic NO products. These oxygen-derived free radicals have the following actions in inflammation:

- a) Endothelial cell damage and thereby increased vascular permeability.
- b) Activation of protease and inactivation of antiprotease causing tissue matrix damage.
- c) Damage to other cells.

The actions of free radicals are counteracted by antioxidants present in tissues and serum which play a protective role (page 14).

ii) *Nitric oxide (NO)* was originally described as vascular relaxation factor produced by endothelial cells. Now it is known that NO is formed by activated macrophages during the oxidation of arginine by the action of enzyme, NO synthase. NO plays the following roles in mediating inflammation:

- a) Vasodilatation
- b) Anti-platelet activating agent
- c) Possibly microbicidal action.

II. Plasma Protein-derived Mediators (Plasma Proteases)

These include various products derived from activation and interaction of 4 interlinked systems: kinin, clotting, fibrinolytic and complement. Each of these systems has its inhibitors and accelerators in plasma with negative and positive feedback mechanisms respectively.

Hageman factor (factor XII) of clotting system plays a key role in interactions of the four systems. Activation of factor XII *in vivo* by contact with basement membrane and bacterial endotoxins, and *in vitro* with glass or kaolin, leads to activation of clotting, fibrinolytic and kinin systems. In inflammation, activation of factor XII is brought about by contact of the factor leaking through the endothelial gaps. The end-products of the activated clotting, fibrinolytic and kinin systems activate the complement system that generate permeability factors. These permeability factors, in turn, further activate clotting system.

The inter-relationship among 4 systems is summarised in **Fig. 5.10.**

1. THE KININ SYSTEM This system on activation by factor Xlla generates bradykinin, so named because of the slow contraction of smooth muscle induced by it. First, kallikrein is formed from plasma prekallikrein by the action of prekallikrein activator which is a fragment of factor Xlla. Kallikrein then acts on high molecular weight kininogen to form bradykinin (**Fig. 5.11**).

Bradykinin acts in the early stage of inflammation and its effects include:

- i) smooth muscle contraction;
- ii) vasodilatation;
- iii) increased vascular permeability; and
- iv) pain.

2. THE CLOTTING SYSTEM Factor Xlla initiates the cascade of the clotting system resulting in formation of fibrinogen which is acted upon by thrombin to form fibrin and

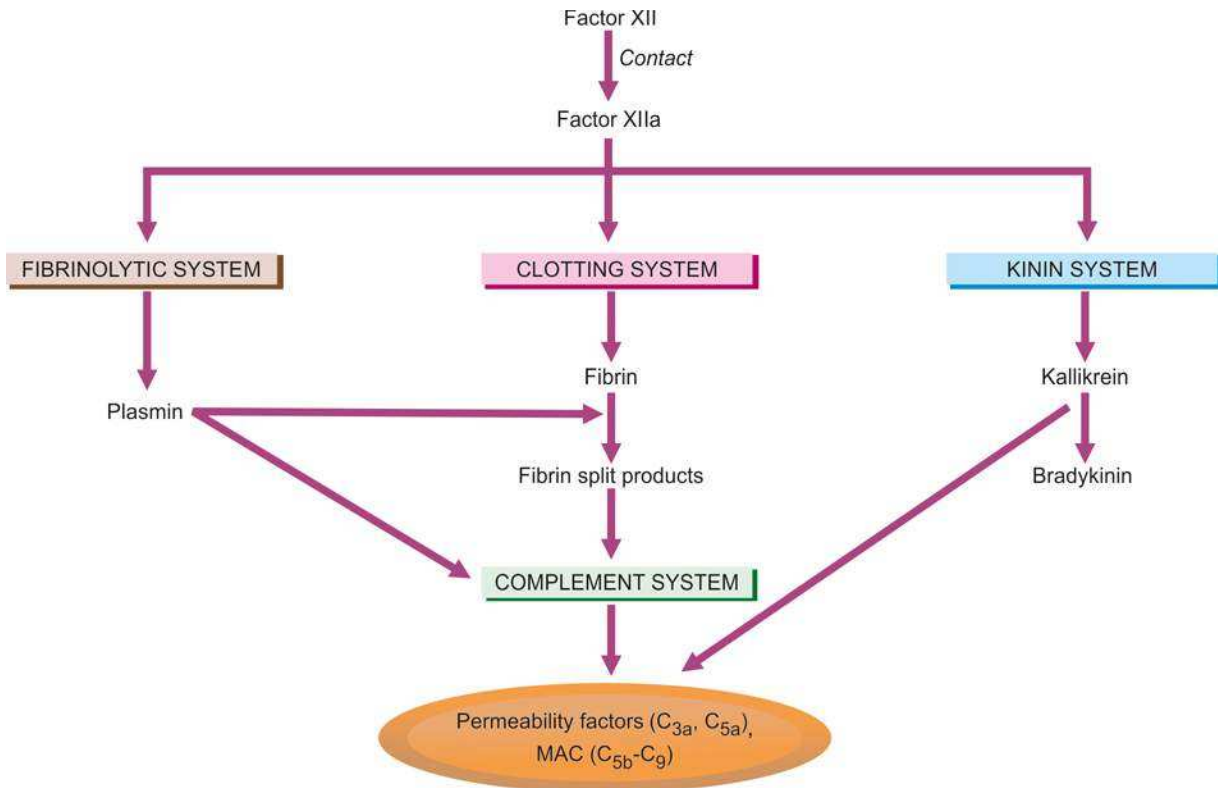

Figure 5.10 Inter-relationship among clotting, fibrinolytic, kinin and complement systems.

fibrinopeptides (Fig. 5.12).

The actions of fibrinopeptides in inflammation are:

- i) increased vascular permeability;
- ii) chemotaxis for leucocyte; and
- iii) anticoagulant activity.

3. THE FIBRINOLYTIC SYSTEM This system is activated by plasminogen activator, the sources of which include kallikrein of the kinin system, endothelial cells and leucocytes. Plasminogen activator acts on plasminogen present as component of plasma proteins to form plasmin. Further breakdown of fibrin by plasmin forms fibrinopeptides or fibrin split products (Fig. 5.13).

The actions of plasmin in inflammation are as follows:

- i) activation of factor XII to form prekallikrein activator that stimulates the kinin system to generate bradykinin;
- ii) splits off complement C3 to form C3a which is a permeability factor; and
- iii) degrades fibrin to form fibrin split products which increase vascular permeability and are chemotactic to leucocytes.

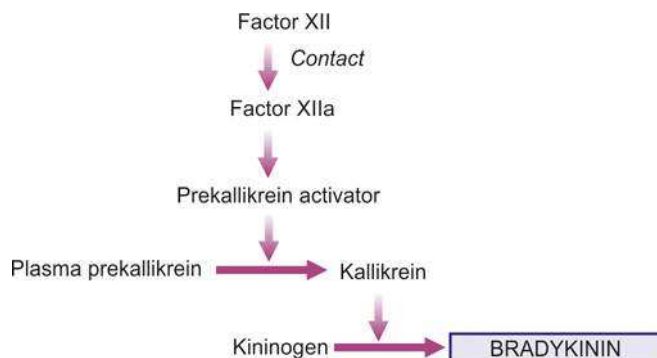

Figure 5.11 Pathway of kinin system.

4. THE COMPLEMENT SYSTEM The activation of complement system can occur either:

- i) by *classic pathway* through antigen-antibody complexes; or
- ii) by *alternate pathway* via non-immunologic agents such as bacterial toxins, cobra venoms and IgA.

Complement system on activation by either of these two pathways yields activated products which include anaphylatoxins (C3a, C4a and C5a), and membrane attack complex (MAC) i.e. C5b,C6,7,8,9.

The actions of activated complement system in inflammation are as under:

- ◆ C3a, C5a, C4a (anaphylatoxins) activate mast cells and basophils to release of histamine, cause increased vascular permeability causing oedema in tissues, augments phagocytosis.
- ◆ C3b is an opsonin.
- ◆ C5a is chemotactic for leucocytes.
- ◆ Membrane attack complex (MAC) (C5b-C9) is a lipid dissolving agent and causes holes in the phospholipid membrane of the cell.

REGULATION OF INFLAMMATION

The onset of inflammatory responses outlined above may have potentially damaging influence on the host tissues as evident in hypersensitivity conditions. Such self-damaging effects are kept in check by the host regulatory mechanisms in order to resolve inflammation. These mechanisms are as follows:

- i) Acute phase reactants** A variety of acute phase reactant (APR) proteins are released in plasma in response to tissue trauma and infection. Their major role is to protect the normal cells from harmful effects of toxic molecules generated in inflammation and to clear away the waste material. APRs include the following:

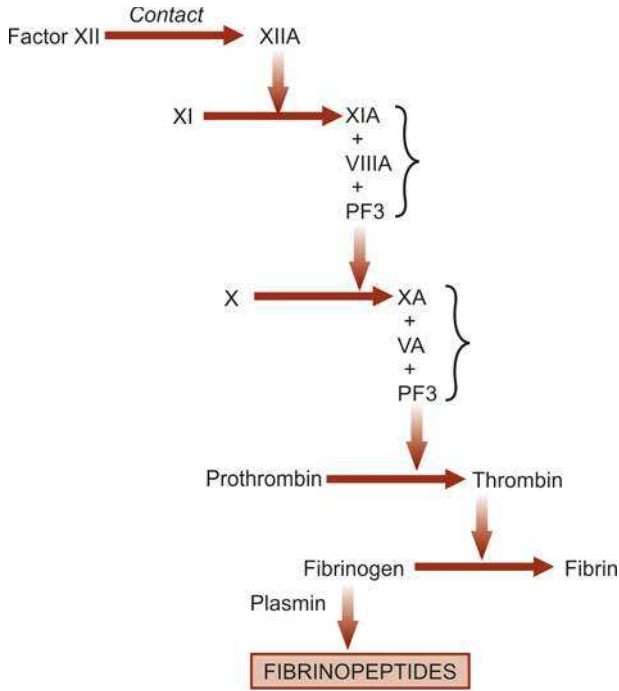

Figure 5.12 Pathway of the clotting system.

- i) *Certain cellular protection factors* (e.g. α 1-antitrypsin, α 1-chymotrypsin, α 2-antiplasmin, plasminogen activator inhibitor): They protect the tissues from cytotoxic and proteolytic damage.
- ii) *Some coagulation proteins* (e.g. fibrinogen, plasminogen, von Willebrand factor, factor VIII): They generate factors to replace those consumed in coagulation.
- iii) *Transport proteins* (e.g. ceruloplasmin, haptoglobin): They carry generated factors.
- iv) *Immune agents* (e.g. serum amyloid A and P component, C-reactive protein or CRP): CRP is an opsonising agent for phagocytosis and its levels are a useful indicator of inflammation in the body.
- v) *Stress proteins* (e.g. heat shock proteins—HSP, ubiquitin): They are molecular chaperons who carry the toxic waste within the cell to the lysosomes.
- vi) *Antioxidants* (e.g. ceruloplasmin) are active in elimination of excess of oxygen free radicals.

The APR are synthesised mainly in the liver, and to some extent in macrophages. APR along with systemic features of fever and leucocytosis is termed '*acute phase response*'. Deficient synthesis of APR leads to severe form of disease in the form of chronic and repeated inflammatory responses.

ii) Glucosteroids The endogenous glucocorticoids act as anti-inflammatory agents. Their levels are raised in infection

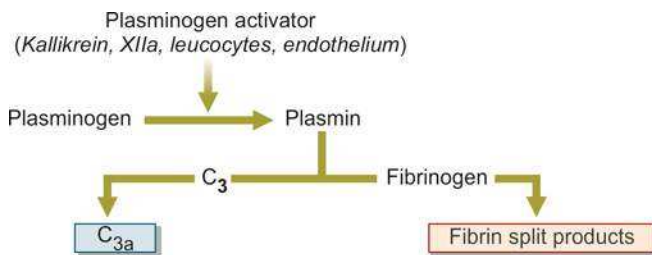

Figure 5.13 The activation of fibrinolytic system.

and trauma by self-regulating mechanism.

iii) Freecytokine receptors The presence of freely circulating soluble receptors for cytokines in the serum correlates directly with disease activity.

iv) Anti-inflammatory chemical mediators As already described, PGE₂ or prostacyclin have both pro-inflammatory as well as anti-inflammatory actions.

GIST BOX 5.3

Mediators and Regulators of Inflammation

- These are endogenous chemical substances which mediate the process of acute inflammation.
- They have some common properties: i) they are released either from the cells or are derived from plasma proteins, ii) they are released in response to certain stimuli, iii) they act on different targets, iv) they have a short lifespan after their release, v) they have several actions, most important being increased vascular permeability.
- Cell-derived mediators of inflammation are: vasoactive amines (histamine, 5HT, neuropeptides), arachidonic acid metabolites (prostaglandins, 5-HETE, leukotrienes, lipoxins), lysosomal components, platelet activating factor, cytokines (ILs, TNF, IFN, chemokines) and free radicals (oxygen metabolites and nitric oxide).
- Plasma protein derived mediators are products of kinin, clotting, fibrinolytic and complement system.
- Normally, inflammation is kept in check by the inbuilt regulatory system to resolve its harmful effects. These substances are acute phase reactant proteins, endogenous glucocorticoids, cytokine receptors and certain anti-inflammatory mediators (e.g. prostacyclin).

THE INFLAMMATORY CELLS

The cells participating in acute and chronic inflammation are circulating leucocytes, plasma cells, tissue macrophages and inflammatory giant cells. The structure, function and production of these cells are dealt with in detail in Chapter 12. Here, it is pertinent to describe their role in inflammation. Their morphology, characteristics and functions are summarised in **Table 5.4**.

POLYMPHONUCLEAR NEUTROPHILS (PMNS)

Commonly called as neutrophils or polymorphs, these cells along with basophils and eosinophils are together known as granulocytes due to the presence of granules in their cytoplasm. These granules contain many substances like proteases, myeloperoxidase, lysozyme, esterase, aryl sulfatase, acid and alkaline phosphatase, and cationic proteins. The diameter of neutrophils ranges from 10 to 15 μ m and are actively motile (**Table 5.4,A**). These cells comprise 40-75% of circulating leucocytes and their number is increased in blood (neutrophilia) and tissues in acute bacterial infections. These cells arise in the bone marrow from stem cells (page 262).

The functions of neutrophils in inflammation are as follows:

i) Initial phagocytosis of microorganisms as they form the first line of body defense in bacterial infection. The steps involved are adhesion of neutrophils to vascular endothelium, emigration through the vessel wall, chemotaxis, engulfment, degranulation, killing and degradation of the foreign material.

ii) Engulfment of antigen-antibody complexes and non-

Table 5.4 Morphology and functions of inflammatory cells.

| MORPHOLOGY | FEATURES | MEDIATORS |
|--|--|--|
|  A, POLYMORPH | i. Initial phagocytosis of bacteria and foreign body ii. Acute inflammatory cell | i. Primary granules (MPO, lysozyme, cationic proteins, acid hydrolases, elastase) ii. Secondary granules (lysozyme, alk. phosph, collagenase, lactoferrin) iii. Tertiary granules (gelatinase, cathepsin) iv. Reactive oxygen metabolites |
|  B, MONOCYTE/MACROPHAGE | i. Bacterial phagocytosis ii. Chronic inflammatory cell iii. Regulates lymphocyte response | i. Acid and neutral hydrolases (lysosomal) ii. Cationic protein iii. Phospholipase iv. Prostaglandins, leukotrienes v. IL-1 |
|  C, LYMPHOCYTE | i. Humoral and cell-mediated immune responses ii. Chronic inflammatory cell iii. Regulates macrophage response | i. B cells: antibody production ii. T cells: delayed hypersensitivity, cytotoxicity |
|  D, PLASMA CELL | i. Derived from B cells ii. Chronic inflammatory cell | i. Antibody synthesis ii. Antibody secretion |
|  E, EOSINOPHIL | i. Allergic states ii. Parasitic infestations iii. Chronic inflammatory cell | i. Reactive oxygen metabolites ii. Lysosomal (major basic protein, cationic protein, eosinophil peroxidase, neurotoxin) iii. PGE ₂ synthesis |
|  F, BASOPHIL/MAST CELL | i. Receptor for IgE molecules ii. Electron-dense granules | i. Histamine ii. Leukotrienes iii. Platelet activating factor |

microbial material.

iii) **Harmful effect** of neutrophils are by causing basement membrane destruction of the glomeruli and small blood vessels in immunologic cell injury.

EOSINOPHILS

These are slightly larger than neutrophils but are fewer in number, comprising 1 to 6% of total blood leucocytes (Table 5.4,E). Eosinophils share many structural and functional similarities with neutrophils like their production in the bone marrow, locomotion, phagocytosis, lobed nucleus and presence of granules in the cytoplasm containing a variety of enzymes, of which major basic protein and eosinophil cationic protein are the most important which have bactericidal and toxic action against helminthic parasites. However, granules

of eosinophils are richer in myeloperoxidase than neutrophils and lack lysozyme. High level of steroid hormones leads to fall in number of eosinophils and even disappearance from blood.

The absolute number of eosinophils is increased in the following conditions and, thus, they partake in inflammatory responses associated with these conditions:

- i) allergic conditions;
- ii) parasitic infestations;
- iii) skin diseases; and
- iv) certain malignant lymphomas.

BASOPHILS AND MAST CELLS

The basophils comprise about 1% of circulating leucocytes and are morphologically and functionally similar to their tissue counterparts, mast cells. These cells contain coarse basophilic

granules in the cytoplasm and a polymorphonuclear nucleus (**Table 5.4,F**). These granules are laden with heparin and histamine. Basophils and mast cells have receptors for IgE and degranulate when cross-linked with antigen.

The role of these cells in inflammation are:

- i) in immediate and delayed type of hypersensitivity reactions; and
- ii) release of histamine by IgE-sensitised basophils.

LYMPHOCYTES

Next to neutrophils, these cells are the most numerous of the circulating leucocytes in adults (20-45%). Apart from blood, lymphocytes are present in large numbers in spleen, thymus, lymph nodes and mucosa-associated lymphoid tissue (MALT). They have scanty cytoplasm and consist almost entirely of nucleus (**Table 5.4,C**).

Their role in antibody formation (B lymphocytes) and in cell-mediated immunity (T lymphocytes) has been discussed in Chapter 3; in addition these cells participate in the following types of inflammatory responses:

- i) *In tissues*, they are dominant cells in chronic inflammation and late stage of acute inflammation.
- ii) *In blood*, their number is increased (lymphocytosis) in chronic infections like tuberculosis.

PLASMA CELLS

These cells are larger than lymphocytes with more abundant cytoplasm and an eccentric nucleus which has cart-wheel pattern of chromatin (**Table 5.4,D**). Plasma cells are normally not seen in peripheral blood. They develop from B lymphocytes and are rich in RNA and γ -globulin in their cytoplasm. There is an interrelationship between plasmacytosis and hyperglobulinaemia. These cells are most active in antibody synthesis.

Their number is increased in the following conditions:

- i) prolonged infection with immunological responses e.g. in syphilis, rheumatoid arthritis, tuberculosis;
- ii) hypersensitivity states; and
- iii) multiple myeloma.

MONONUCLEAR-PHAGOCYTE SYSTEM (RETICULOENDOTHELIAL SYSTEM)

This cell system includes cells derived from 2 sources with common morphology, function and origin (**Table 5.4,B**). These are as under:

A. Blood monocytes These comprise 4-8% of circulating leucocytes.

B. Tissue macrophages These include the following cells in different tissues:

- i) Macrophages or phagocytes in inflammation.
- ii) Histiocytes which are macrophages present in connective tissues.
- iii) Epithelioid cells are modified macrophages seen in granulomatous inflammation.
- iv) Kupffer cells are macrophages of the liver.
- v) Alveolar macrophages (type II pneumocytes) in the lungs.
- vi) Reticulum cells are macrophages/histiocytes of the bone marrow.
- vii) Tingible body macrophages of germinal centres of the lymph nodes.

- viii) Littoral cells of the splenic sinusoids.
- ix) Osteoclasts in the bones.
- x) Microglial cells of the brain.
- xi) Langerhans' cells/dendritic histiocytes of the skin.
- xii) Hoffbauer cells of the placenta.
- xiii) Mesangial cells of the glomerulus.

The mononuclear phagocytes are the scavenger cells of the body as well as participate in immune system of the body (Chapter 3); their functions in inflammation are as under:

Role of macrophages in inflammation The functions of mononuclear-phagocyte cells are as under:

- i) *Phagocytosis* (cell eating) and *pinocytosis* (cell drinking).
- ii) *Macrophages on activation* by lymphokines released by T lymphocytes or by non-immunologic stimuli elaborate a variety of biologically active substances as under:
 - a) Proteases like collagenase and elastase which degrade collagen and elastic tissue.
 - b) Plasminogen activator which activates the fibrinolytic system.
 - c) Products of complement.
 - d) Some coagulation factors (factor V and thromboplastin) which convert fibrinogen to fibrin.
 - e) Chemotactic agents for other leucocytes.
 - f) Metabolites of arachidonic acid.
 - g) Growth promoting factors for fibroblasts, blood vessels and granulocytes.
 - h) Cytokines like interleukin-1 and TNF- α .
 - i) Oxygen-derived free radicals.

GIANT CELLS

A few examples of multinucleate giant cells exist in normal tissues (e.g. osteoclasts in the bones, trophoblasts in placenta, megakaryocytes in the bone marrow). However, in chronic inflammation when the macrophages fail to deal with particles to be removed, they fuse together and form multinucleated giant cells. Besides, morphologically distinct giant cells appear in some tumours also. Some of the common types of giant cells are described below (**Fig. 5.14**):

A. Giant cells in inflammation:

i) *Foreign body giant cells*. These contain numerous nuclei (up to 100) which are uniform in size and shape and resemble the nuclei of macrophages. These nuclei are scattered throughout the cytoplasm. These are seen in chronic infective granulomas, leprosy and tuberculosis.

ii) *Langhans' giant cells*. These are seen in tuberculosis and sarcoidosis. Their nuclei are like the nuclei of macrophages and epithelioid cells. These nuclei are arranged either around the periphery in the form of horseshoe or ring, or are clustered at the two poles of the giant cell.

iii) *Touton giant cells*. These multinucleated cells have vacuolated cytoplasm due to lipid content e.g. in xanthoma.

iv) *Aschoff giant cells*. These multinucleate giant cells are derived from cardiac histiocytes and are seen in rheumatic nodule (page 420).

B. Giant cells in tumours:

i) *Anaplastic cancer giant cells*. These are larger, have numerous nuclei which are hyperchromatic and vary in size

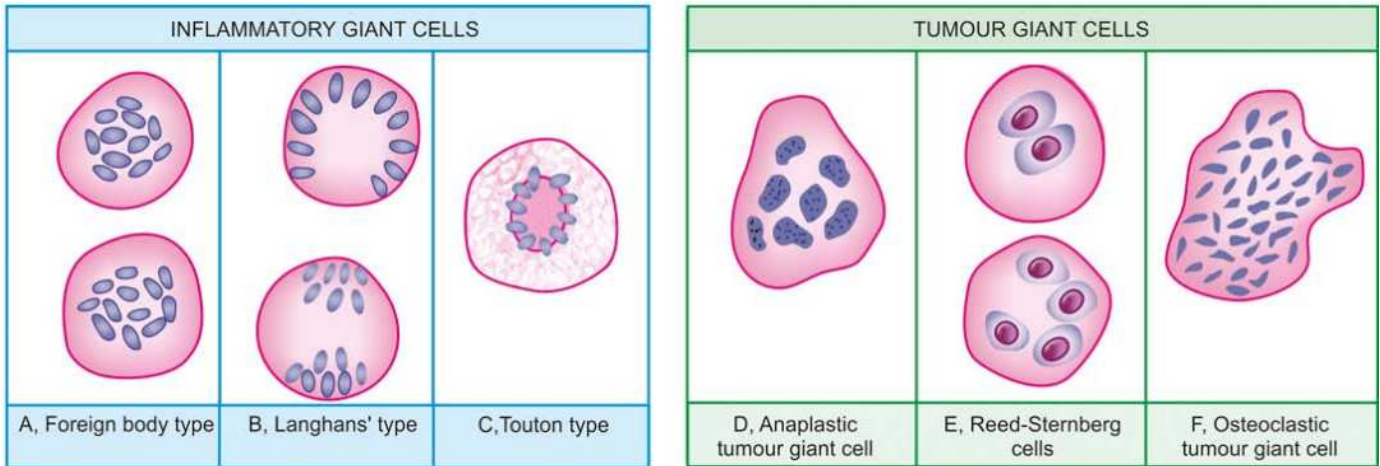

Figure 5.14 Giant cells of various types. A, Foreign body giant cell with uniform nuclei dispersed throughout the cytoplasm. B, Langhans' giant cells with uniform nuclei arranged peripherally or clustered at the two poles. C, Touton giant cell with circular pattern of nuclei and vacuolated cytoplasm. D, Anaplastic tumour giant cell with nuclei of variable size and shape. E, Reed-Sternberg cell. F, Osteoclastic tumour giant cell.

and shape. These giant cells are not derived from macrophages but are formed from dividing nuclei of the neoplastic cells e.g. carcinoma of the liver, various soft tissue sarcomas etc.

ii) *Reed-Sternberg cells*. These are also malignant tumour giant cells which are generally binucleate and are seen in various histologic types of Hodgkin's lymphomas.

iii) *Osteoclastic giant cells of bone tumour*. Giant cell tumour of the bones or osteoclastoma has uniform distribution of osteoclastic giant cells spread in the stroma.

GIST BOX 5.4 The Inflammatory Cells

- ▣ The cells participating in acute and chronic inflammation are circulating leucocytes, plasma cells, tissue macrophages and inflammatory giant cells.
- ▣ Polymorphs or neutrophils are the first line of defense against invading agents and perform initial phagocytosis.
- ▣ Eosinophils participate in allergic conditions, parasitic infestations and certain skin diseases.
- ▣ Basophils and mast cells are involved in immediate and delayed type of hypersensitivity reactions.
- ▣ Lymphocytes are immunocompetent cells—B cells in humoral immunity and T cells in cell-mediated immunity. Besides, lymphocytes are the dominant cells in chronic inflammation.
- ▣ Plasma cells develop from B cells and are immunoglobulin-synthesising cells and are seen in chronic inflammation.
- ▣ Mononuclear phagocyte system is comprised by circulating monocytes and tissue macrophages. These are scavenger cells of the body.
- ▣ Different types of giant cells are seen in different inflammatory conditions. The types of giant cells are foreign body, Langhans's, touton and Aschoff giant cells.

ACUTE INFLAMMATION—FACTORS, MORPHOLOGY, EFFECTS, FATE

FACTORS DETERMINING VARIATION IN INFLAMMATORY RESPONSE

Although acute inflammation is typically characterised by

vascular and cellular events with emigration of neutrophilic leucocytes, not all examples of acute inflammation show infiltration by neutrophils. On the other hand, some chronic inflammatory conditions are characterised by neutrophilic infiltration. For example, *typhoid fever* is an example of acute inflammatory process but the cellular response in it is lymphocytic; *osteomyelitis* is an example of chronic inflammation but the cellular response in this condition is mainly neutrophilic.

The variation in inflammatory response depends upon a number of factors and processes. These may pertain to the organisms and the host:

Factors Involving the Organisms

i) **Type of injury and infection** For example, skin reacts to herpes simplex infection by formation of vesicle and to streptococcal infection by formation of boil; lung reacts to pneumococci by occurrence of lobar pneumonia while to tubercle bacilli it reacts by granulomatous inflammation.

ii) **Virulence** Many species and strains of organisms may have varying virulence e.g. the three strains of *C. diphtheriae* (*gravis*, *intermedius* and *mitis*) produce the same diphtherial exotoxin but in different amount.

iii) **Dose** The concentration of organism in small doses produces usually local lesions while larger dose results in more severe spreading infections.

iv) **Portal of entry** Some organisms are infective only if administered by particular route e.g. *Vibrio cholerae* is not pathogenic if injected subcutaneously but causes cholera if swallowed.

v) **Product of organisms** Some organisms produce enzymes that help in spread of infections e.g. hyaluronidase by *Clostridium welchii*, streptokinase by streptococci, staphylokinase and coagulase by staphylococci.

Factors Involving the Host

i) **Systemic diseases** Certain acquired systemic diseases in the host are associated with impaired inflammatory response e.g. diabetes mellitus, chronic renal failure, cirrhosis of the

liver, chronic alcoholism, bone marrow suppression from various causes (drugs, radiation, idiopathic). These conditions render the host more susceptible to infections.

ii) Immune status of host Patients who are immunosuppressed from congenital or acquired immunodeficiency have lowered inflammatory response and spread of infections occurs rapidly e.g. in AIDS, congenital immunodeficiency diseases, diabetes mellitus, protein calorie malnutrition, starvation.

iii) Congenital neutrophil defects Congenital defects in neutrophil structure and functions result in reduced inflammatory response.

iv) Leukopenia Patients with low WBC count with neutropenia or agranulocytosis develop spreading infection.

v) Site or type of tissue involved For example, the lung has loose texture as compared to bone and, thus, both tissues react differently to acute inflammation.

vi) Local host factors For instance, ischaemia, presence of foreign bodies and chemicals cause necrosis and thus cause more harm.

MORPHOLOGY OF ACUTE INFLAMMATION

Inflammation of an organ is usually named by adding the suffix-*itis* to its Latin name e.g. appendicitis, hepatitis, cholecystitis, meningitis etc. A few morphologic varieties of acute inflammation are described below:

1. TYPES OF EXUDATE The appearance of escaped plasma determines the morphologic type of inflammation as under:

i) Serous, when the fluid exudate resembles serum or is watery e.g. pleural effusion in tuberculosis, blister formation in burns.

ii) Fibrinous, when the fibrin content of the fluid exudate is high e.g. in pneumococcal and rheumatic pericarditis.

iii) Purulent or suppurative exudate is formation of creamy pus as seen in infection with pyogenic bacteria e.g. abscess,

acute appendicitis.

iv) Haemorrhagic, when there is vascular damage e.g. acute haemorrhagic pneumonia in influenza.

v) Catarrhal, when the surface inflammation of epithelium produces increased secretion of mucus e.g. common cold.

2. PSEUDOMEMBRANOUS INFLAMMATION It is inflammatory response of mucous surface (oral, respiratory, bowel) to toxins of diphtheria or irritant gases. As a result of denudation of epithelium, plasma exudes on the surface where it coagulates, and together with necrosed epithelium, forms false membrane that gives this type of inflammation its name.

3. ULCER Ulcers are local defects on the surface of an organ produced by inflammation. Some common sites for ulcerations are the stomach, duodenum, intestinal ulcers in typhoid fever, intestinal tuberculosis, bacillary and amoebic dysentery, ulcers of legs due to varicose veins etc. In the acute stage, there is infiltration by polymorphs with vasodilatation while long-standing ulcers develop infiltration by lymphocytes, plasma cells and macrophages with associated fibroblastic proliferation and scarring.

4. SUPPURATION (ABSCESS FORMATION) When acute bacterial infection is accompanied by intense neutrophilic infiltrate in the inflamed tissue, it results in tissue necrosis. A cavity is formed which is called an abscess and contains purulent exudate or pus and the process of abscess formation is known as suppuration. The bacteria which cause suppuration are called pyogenic.

Microscopically, pus is creamy or opaque in appearance and is composed of numerous dead as well as living neutrophils, some red cells, fragments of tissue debris and fibrin. In old pus, macrophages and cholesterol crystals are also present (**Fig. 5.15**).

An abscess may be discharged to the surface due to increased pressure inside or may require drainage by the surgeon. Due to tissue destruction, resolution does not occur

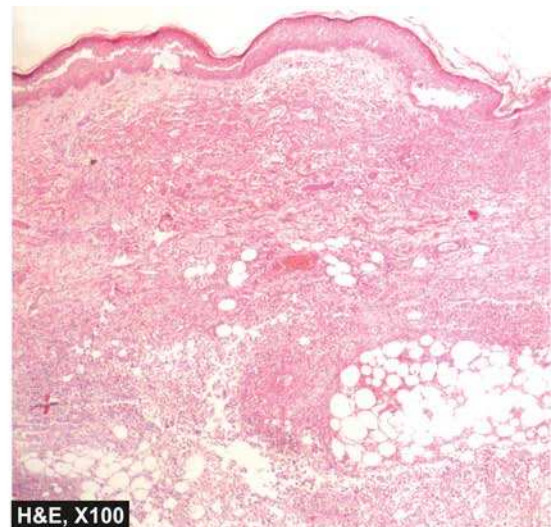

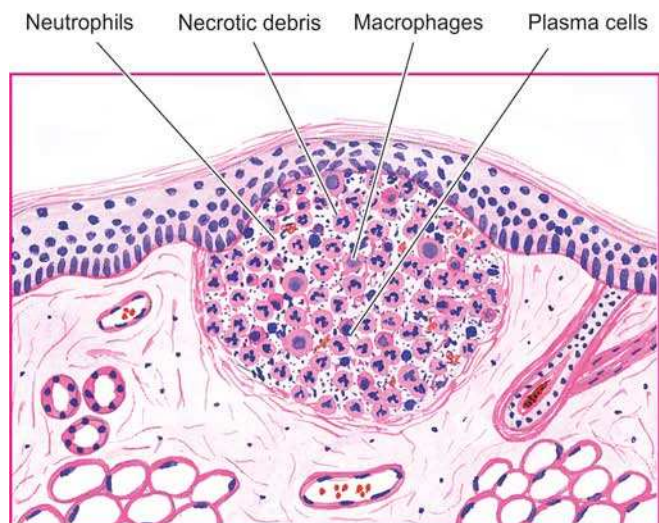

Figure 5.15 An abscess in the skin. It contains pus composed of necrotic tissue, debris, fibrin, RBCs and dead and living neutrophils. Some macrophages are seen at the periphery.

but instead healing by fibrous scarring takes place.

Some of the common examples of abscess formation are as under:

- i) *Boil or furuncle* which is an acute inflammation via hair follicles in the dermal tissues.
- ii) *Carbuncle* is seen in untreated diabetics and occurs as a loculated abscess in the dermis and soft tissues of the neck.

5. CELLULITIS It is a diffuse inflammation of the soft tissues resulting from spreading effects of substances like hyaluronidase released by some bacteria.

6. BACTERIAL INFECTION OF THE BLOOD This includes the following 3 conditions:

i) **Bacteraemia** is defined as presence of small number of bacteria in the blood which do not multiply significantly. They are commonly not detected by direct microscopy. Blood culture is done for their detection e.g. infection with *Salmonella typhi*, *Escherichia coli*, *Streptococcus viridans*.

ii) **Septicaemia** means presence of rapidly multiplying, highly pathogenic bacteria in the blood e.g. pyogenic cocci, bacilli of plague etc. Septicaemia is generally accompanied by systemic effects like toxæmia, multiple small haemorrhages, neutrophilic leucocytosis and disseminated intravascular coagulation (DIC).

iii) **Pyæmia** is the dissemination of small septic thrombi in the blood which cause their effects at the site where they are

lodged. This can result in pyæmic abscesses or septic infarcts.

- a) *Pyæmic abscesses* are multiple small abscesses in various organs such as in cerebral cortex, myocardium, lungs and renal cortex, resulting from very small emboli fragmented from septic thrombus. Microscopy of pyæmic abscess shows a central zone of necrosis containing numerous bacteria, surrounded by a zone of suppuration and an outer zone of acute inflammatory cells (**Fig. 5.16,A**).
- b) *Septic infarcts* result from lodgement of larger fragments of septic thrombi in the arteries with relatively larger foci of necrosis, suppuration and acute inflammation e.g. septic infarcts of the lungs, liver, brain, and kidneys from septic thrombi of leg veins or from acute bacterial endocarditis (**Fig. 5.16,B**).

SYSTEMIC EFFECTS OF ACUTE INFLAMMATION

The account of acute inflammation given so far now above is based on local tissue responses. However, acute inflammation is associated with systemic effects as well. These include fever, leucocytosis, lymphangitis-lymphadenitis and shock.

1. Fever occurs due to bacteraemia. It is thought to be mediated through release of factors like prostaglandins, interleukin-1 and TNF- α in response to infection.

2. Leucocytosis commonly accompanies the acute inflammatory reactions, usually in the range of 15,000-20,000/ μ l. When the counts are higher than this with 'shift to left' of myeloid cells, the blood picture is described as leukaemoid

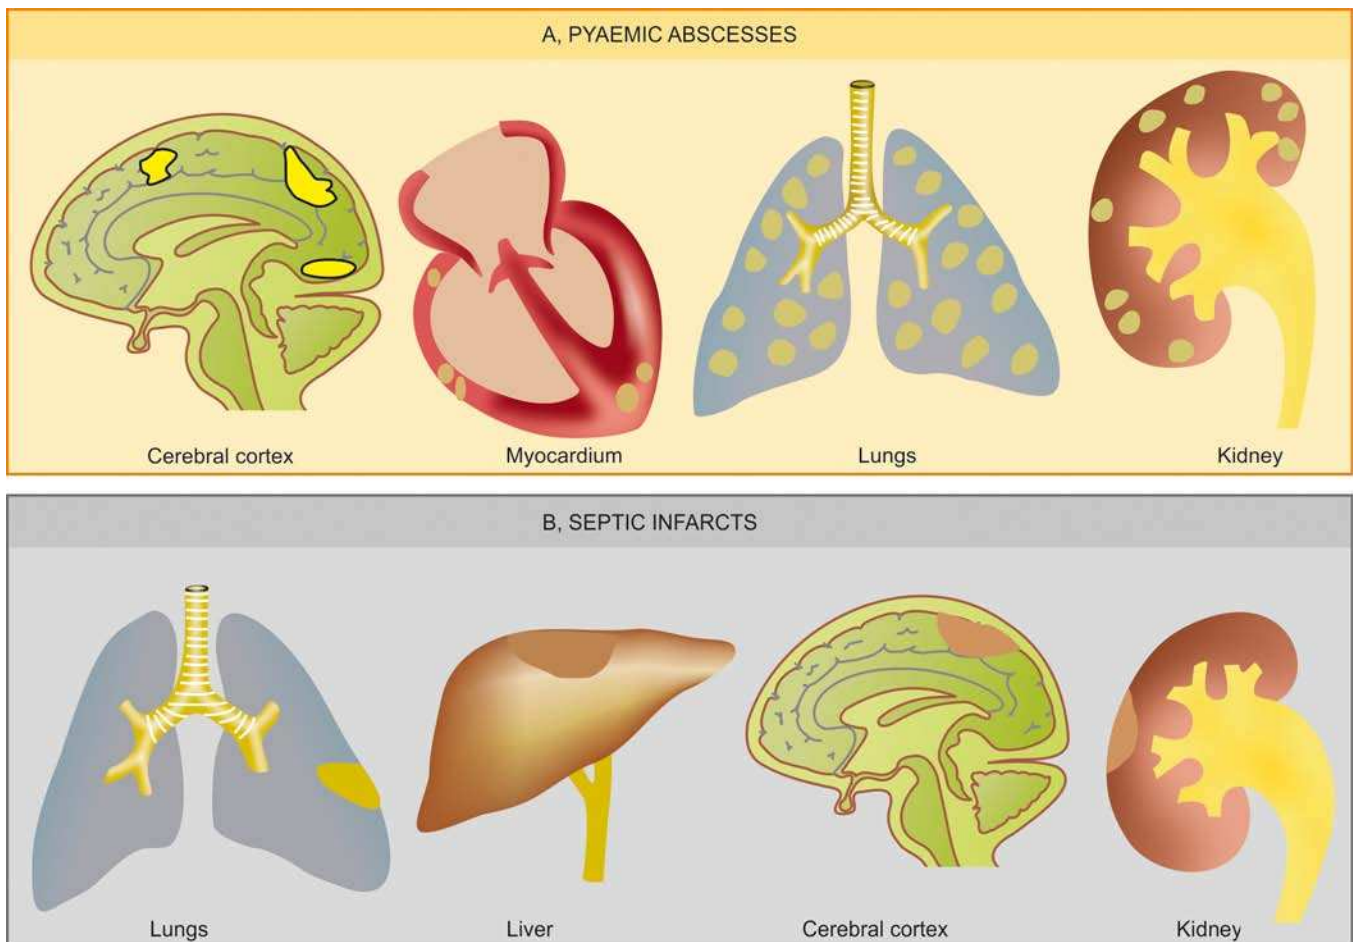

Figure 5.16 Sequelae of pyæmia.

reaction. Usually, in bacterial infections there is neutrophilia; in viral infections lymphocytosis; and in parasitic infestations, eosinophilia. Typhoid fever, an example of acute inflammation, however, induces leucopenia with relative lymphocytosis.

3. Lymphangitis-lymphadenitis is one of the important manifestations of localised inflammatory injury. The lymphatics and lymph nodes that drain the inflamed tissue show reactive inflammatory changes in the form of lymphangitis and lymphadenitis. This response represents either a nonspecific reaction to mediators released from inflamed tissue or is an immunologic response to a foreign antigen. The affected lymph nodes may show hyperplasia of lymphoid follicles (follicular hyperplasia) and proliferation of mononuclear phagocytic cells in the sinuses of lymph node (sinus histiocytosis) (Chapter 12).

4. Shock may occur in severe cases. Massive release of cytokine TNF- α , a mediator of inflammation, in response to severe tissue injury or infection results in profuse systemic vasodilatation, increased vascular permeability and intravascular volume loss. The net effect of these changes is hypotension and shock. Systemic activation of coagulation pathway may occur leading to microthrombi throughout the body and result in disseminated intravascular coagulation (DIC), bleeding and death.

FATE OF ACUTE INFLAMMATION

The acute inflammatory process can culminate in one of the following outcomes (Fig. 5.17):

1. Resolution It means complete return to normal tissue following acute inflammation. This occurs when tissue changes are slight and the cellular changes are reversible e.g. resolution in lobar pneumonia.

2. Healing When the tissue loss in acute inflammation is superficial, healing takes place by regeneration. However, when the tissue destruction is extensive, then healing occurs by fibrosis.

3. Suppuration When the pyogenic bacteria causing acute inflammation result in severe tissue necrosis, the process progresses to suppuration. Initially, there is intense neutro-

philic infiltration. Subsequently, mixture of neutrophils, bacteria, fragments of necrotic tissue, cell debris and fibrin comprise pus which is contained in a cavity to form an abscess. The abscess, if not drained, may get organised by dense fibrous tissue, and in time, get calcified.

4. Chronic inflammation Persisting or recurrent acute inflammation may progress to chronic inflammation in which the processes of inflammation and healing proceed side by side.

GIST BOX 5.5

Factors Determining Response, Morphology, Systemic Effects, Fate

- ▣ The variation in inflammatory response depends upon factors pertaining to the organisms (type, virulence, dose, route of entry) or host factors (systemic diseases, immune status, defect in neutrophil function, type of tissue).
- ▣ Morphologic patterns of acute inflammation are various forms of exudates, pseudomembranous inflammation, ulcers, abscesses, cellulitis, and bacterial infection through blood (bacteraemia, septicaemia, pyaemia).
- ▣ Besides local effects, acute inflammation produces systemic manifestations such as fever, leucocytosis, lymphangitis and shock.
- ▣ Acute inflammation may have variety of outcomes: resolution, healing (by regeneration or by fibrosis), suppuration or may end up in chronic inflammation.

CHRONIC INFLAMMATION

DEFINITION AND CAUSES Chronic inflammation is defined as prolonged process in which tissue destruction and inflammation occur at the same time.

Chronic inflammation may occur by one of the following 3 ways:

1. Chronic inflammation following acute inflammation When the tissue destruction is extensive, or the bacteria survive and persist in small numbers at the site of acute inflammation e.g. in osteomyelitis, pneumonia terminating in lung abscess.

2. Recurrent attacks of acute inflammation When repeated bouts of acute inflammation culminate in chronicity of the process e.g. in recurrent urinary tract infection leading to chronic pyelonephritis, repeated acute infection of gallbladder leading to chronic cholecystitis.

3. Chronic inflammation starting *de novo* When the infection with organisms of low pathogenicity is chronic from the beginning e.g. infection with *Mycobacterium tuberculosis*.

GENERAL FEATURES OF CHRONIC INFLAMMATION

Though there may be differences in chronic inflammatory response depending upon the tissue involved and causative organisms, there are some basic similarities amongst various types of chronic inflammation. Following general features characterise any chronic inflammation:

1. MONONUCLEAR CELL INFILTRATION Chronic inflammatory lesions are infiltrated by mononuclear inflammatory cells like phagocytes and lymphoid cells. Phagocytes are represented by circulating monocytes, tissue macrophages, epithelioid cells and sometimes, multinucleated giant cells. The macrophages comprise the most important cells in chronic inflammation. These may appear at the site of chronic

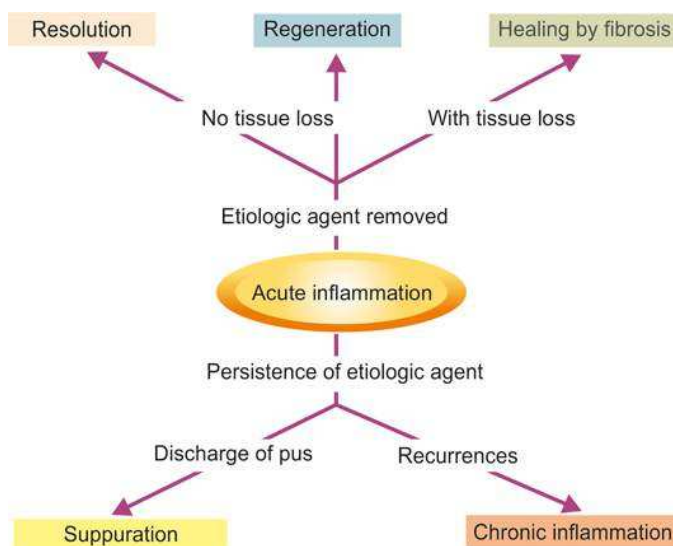

Figure 5.17 Fate of acute inflammation.

inflammation from:

- i) chemotactic factors and adhesion molecules for continued infiltration of macrophages;
- ii) local proliferation of macrophages; and
- iii) longer survival of macrophages at the site of inflammation.

The blood monocytes on reaching the extravascular space transform into tissue macrophages. Besides the role of macrophages in phagocytosis, they may get activated in response to stimuli such as cytokines (lymphokines) and bacterial endotoxins. On activation, macrophages release several biologically active substances e.g. acid and neutral proteases, oxygen-derived reactive metabolites and cytokines. These products bring about tissue destruction, neovascularisation and fibrosis.

Other chronic inflammatory cells include lymphocytes, plasma cells, eosinophils and mast cells. In chronic inflammation, lymphocytes and macrophages influence each other and release mediators of inflammation.

2. TISSUE DESTRUCTION OR NECROSIS Tissue destruction and necrosis are central features of most forms of chronic inflammatory lesions. This is brought about by activated macrophages which release a variety of biologically active substances e.g. protease, elastase, collagenase, lipase, reactive oxygen radicals, cytokines (IL-1, IL-8, TNF- α), nitric oxide, angiogenesis growth factor etc.

3. PROLIFERATIVE CHANGES As a result of necrosis, proliferation of small blood vessels and fibroblasts is stimulated resulting in formation of inflammatory granulation tissue. Eventually, healing by fibrosis and collagen laying takes place.

SYSTEMIC EFFECTS OF CHRONIC INFLAMMATION

Chronic inflammation is associated with following systemic features:

- 1. Fever** Invariably there is mild fever, often with loss of weight and weakness.
- 2. Anaemia** As discussed in Chapter 10, chronic inflammation is accompanied by anaemia of varying degree.
- 3. Leucocytosis** As in acute inflammation, chronic inflammation also has leucocytosis but generally there is relative lymphocytosis in these cases.
- 4. ESR** ESR is elevated in all cases of chronic inflammation.
- 5. Amyloidosis** Long-term cases of chronic suppurative inflammation may develop secondary systemic (AA) amyloidosis.

TYPES OF CHRONIC INFLAMMATION

Conventionally, chronic inflammation is subdivided into 2 types:

1. Chronic non-specific inflammation When the irritant substance produces a non-specific chronic inflammatory reaction with formation of granulation tissue and healing by fibrosis, it is called chronic non-specific inflammation e.g. chronic osteomyelitis, chronic ulcer, lung abscess. A variant of this type of chronic inflammatory response is chronic suppurative inflammation in which infiltration by polymorphs and abscess formation (which are seen in acute inflammation) are

additional features e.g. actinomycosis.

2. Chronic granulomatous inflammation In this, the injurious agent causes a characteristic histologic tissue response by formation of granulomas e.g. tuberculosis, leprosy, syphilis, actinomycosis, sarcoidosis etc.

GIST BOX 5.6

Chronic Inflammation—General

- ☐ Chronic inflammation may result either following acute inflammation or after its recurrent attacks, or may start afresh.
- ☐ A few general features of chronic inflammation are infiltration by mononuclear cells, tissue destruction and proliferation of blood vessels and fibroblasts.
- ☐ Chronic inflammation may produce systemic features such as fever, anaemia, leucocytosis, raised ESR and development of secondary amyloidosis in long standing cases.
- ☐ Chronic inflammation is of 2 main types: non-specific and granulomatous type.

GRANULOMATOUS INFLAMMATION

Granuloma is defined as a circumscribed, tiny lesion, about 1 mm in diameter, composed predominantly of collection of modified macrophages called epithelioid cells, and rimmed at the periphery by lymphoid cells. The word '*granuloma*' is derived from *granule* meaning circumscribed granule-like lesion, and *-oma* which is a suffix commonly used for true tumours but here it indicates a localised inflammatory mass or collection of macrophages.

PATHOGENESIS OF GRANULOMA Formation of granuloma is a type IV granulomatous hypersensitivity reaction (page 61). It is a protective defense reaction by the host but eventually causes tissue destruction because of persistence of the poorly digestible antigen e.g. *Mycobacterium tuberculosis*, *M. leprae*, suture material, particles of talc etc.

The sequence in evolution of granuloma is schematically shown in Fig. 5.18 and is briefly outlined below:

- 1. Engulfment by macrophages** Macrophages and monocytes engulf the antigen and try to destroy it. But since the antigen is poorly degradable, these cells fail to digest and degrade the antigen, and instead undergo morphologic changes to transform into epithelioid cells.
- 2. CD4+ T cells** Macrophages, being antigen-presenting cells, having failed to deal with the antigen, present it to CD4+ T lymphocytes. These lymphocytes get activated and elaborate lymphokines (IL-1, IL-2, interferon- γ , TNF- α).
- 3. Cytokines** Various cytokines formed by activated CD4+ T cells and also by activated macrophages perform the following roles:
 - i) *IL-1* and *IL-2* stimulate proliferation of more T cells.
 - ii) *Interferon- γ* activates macrophages.
 - iii) *TNF- α* promotes fibroblast proliferation and activates endothelium to secrete prostaglandins which have a role in vascular response in inflammation.
 - iv) *Growth factors* (transforming growth factor- β , platelet-derived growth factor) elaborated by activated macrophages

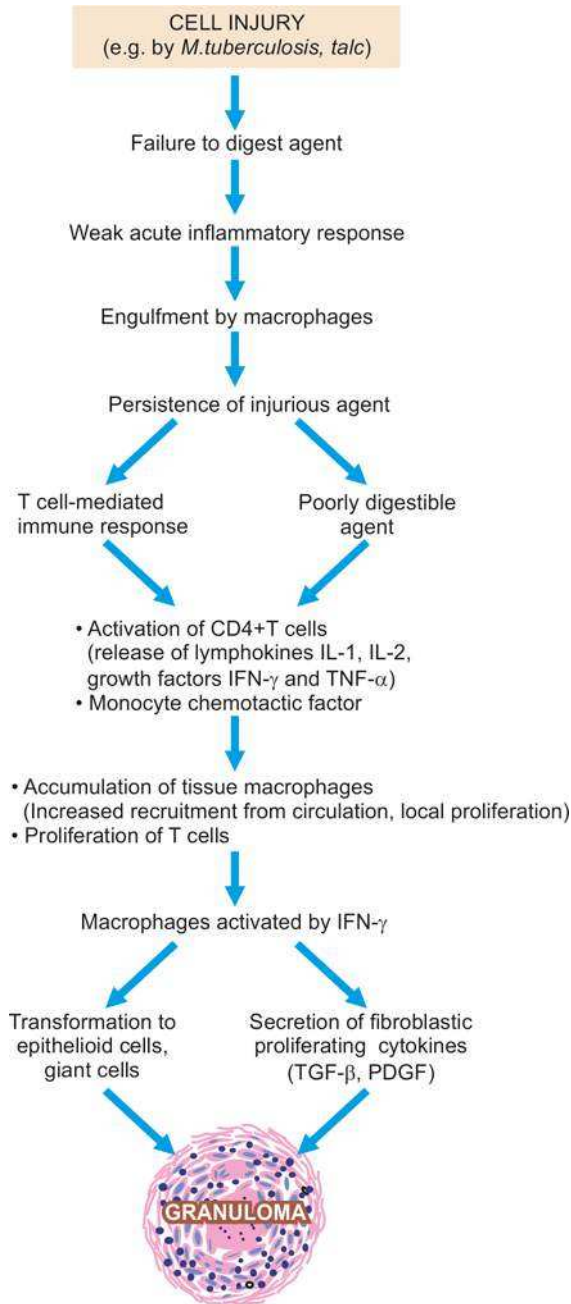

Figure 5.18 Mechanism of evolution of a granuloma (IL=interleukin; IFN= interferon; TNF = tumour necrosis factor).

stimulate fibroblast growth.

Thus, a granuloma is formed having macrophages modified as epithelioid cells in the centre, with some interspersed multinucleate giant cells, surrounded peripherally by lymphocytes (mainly T cells), and healing by fibroblasts or collagen depending upon the age of granuloma.

COMPOSITION OF GRANULOMA In general, a granuloma has the following structural composition:

1. Epithelioid cells These are so called because of their epithelial cell-like appearance. They are modified macrophages/histiocytes which are somewhat elongated cells having slipper-shaped nucleus. The nuclear chromatin of these cells is vesicular and lightly-staining, while the cytoplasm is

abundant, pale-staining with hazy outlines so that the cell membrane of adjacent epithelioid cells is closely apposed. Epithelioid cells are weakly phagocytic.

2. Multinucleate giant cells Multinucleate giant cells are formed by fusion of adjacent epithelioid cells and may have 20 or more nuclei. These nuclei may be arranged at the periphery like the horseshoe or as a ring, or may be clustered at the two poles (Langhans' giant cells), or they may be present centrally (foreign body giant cells). The former are commonly seen in tuberculosis while the latter are common in foreign body tissue reactions. Like epithelioid cells, these giant cells are weakly phagocytic but produce secretory products which help in removing the invading agents.

3. Lymphoid cells As a cell-mediated immune reaction to antigen, the host response by lymphocytes is integral to composition of a granuloma. Plasma cells indicative of accelerated humoral immune response are present in some types of granulomas.

4. Necrosis Necrosis may be a feature of some granulomatous conditions e.g. central caseation necrosis in tuberculosis, so called because of its dry cheese-like appearance.

5. Fibrosis Fibrosis is a feature of healing by proliferating fibroblasts at the periphery of granuloma.

The classical example of granulomatous inflammation is the tissue response to tubercle bacilli which is called *tubercle* seen in tuberculosis (described later). A fully-developed tubercle is about 1 mm in diameter with central area of caseation necrosis, surrounded by epithelioid cells and one to several multinucleated giant cells (commonly Langhans' type), surrounded at the periphery by lymphocytes and bounded by fibroblasts and fibrous tissue (**Fig. 5.19**).

Major differences between acute and chronic inflammation are summed up in **Table 5.5**.

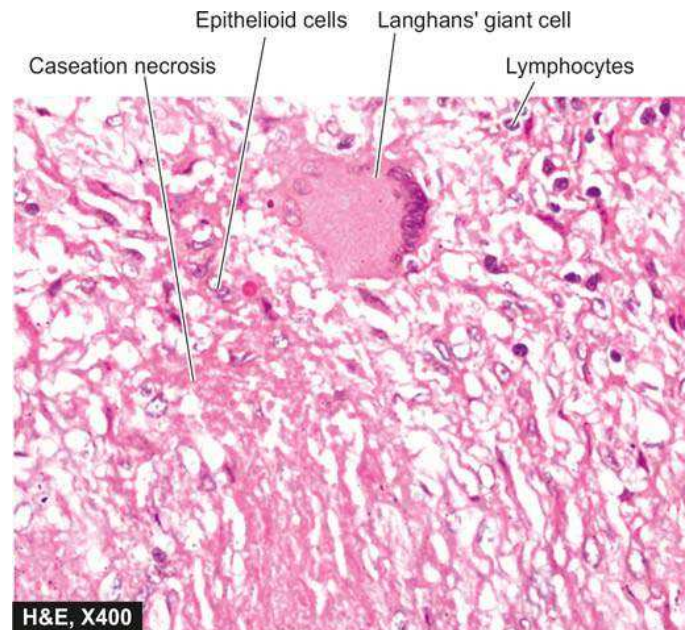

Figure 5.19 Morphology of a tubercle. There is central caseation necrosis, surrounded by elongated epithelioid cells having characteristic slipper-shaped nuclei, with interspersed Langhans' giant cells. Periphery shows lymphocytes.

Table 5.5 Major differences between acute and chronic inflammation.

**GIST BOX 5.7****Chronic Granulomatous Inflammation—General**

- ▣ A granuloma is a circumscribed collection of epithelioid cells surrounded at the periphery by lymphocytes and may contain a few multinucleate giant cells.
- ▣ A granuloma is formed as a host inflammatory response to a poorly degradable agent by eliciting delayed type hypersensitivity (type IV reaction).
- ▣ Formation of a granuloma involves engulfment of the invading agent by the macrophages, failure to degrade the antigen, morphologic change of macrophages to epithelioid cells, and incoming CD4+ T cells which elaborate various cytokines which contribute to proliferation and activation of cells.
- ▣ A granuloma may have necrosis in the centre and eventually heals by fibrosis.
- ▣ Granulomatous diseases include infections (bacterial, fungal, parasitic) autoimmune inflammatory, and foreign bodies.

EXAMPLES OF GRANULOMATOUS INFLAMMATION

Granulomatous inflammation is typical of reaction to poorly digestible agents elicited by tuberculosis, leprosy,

fungal infections, schistosomiasis, foreign particles etc. A comprehensive list of important examples of granulomatous conditions, their etiologic agents and salient features is given in **Table 5.6**. The principal examples (marked with asterisk in the table) are discussed below while a few others appear in relevant Chapters later.

TUBERCULOSIS

Tissue response in tuberculosis represents classical example of chronic granulomatous inflammation in humans.

INCIDENCE In spite of great advances in chemotherapy and immunology, tuberculosis still continues to be a major public health problem in the entire world, more common in developing countries of Asia, Africa and Latin America. In fact, half the total number of cases in the world are shared by India and China. Other factors contributing to higher incidence of tuberculosis are malnutrition, inadequate medical care, poverty, crowding, chronic debilitating conditions like uncontrolled diabetes, alcoholism and immunocompromised states. In the western countries, there has been a resurgence of tuberculosis due to HIV-AIDS. Observations in different populations suggest that besides these factors, genetic factors also play a key role in innate resistance to infection with *M. tuberculosis* and in the development of disease, which is responsible for differing degree of susceptibility to tuberculosis. However, the exact

Table 5.6 Principal granulomatous conditions.

| | CONDITIONS | ETIOLOGIC AGENT | SPECIAL CHARACTERISTICS |
|------|---|--|---|
| I. | BACTERIAL | | |
| 1. | <i>Tuberculosis*</i> | <i>Mycobacterium tuberculosis</i> | Tuberculous granulomas with central caseation necrosis; acid-fast bacilli. |
| 2. | <i>Leprosy*</i> | <i>Mycobacterium leprae</i> | Foamy histiocytes with acid-fast bacilli (lepromatous); epithelioid cell granulomas (tuberculoid). |
| 3. | <i>Syphilis*</i> | <i>Treponema pallidum</i> | Gummas composed of histiocytes; plasma cell infiltration; central necrosis. |
| 4. | <i>Granuloma inguinale (Donovanosis)</i> | <i>C. donovani (Donovan body)</i> | Anal and genital lesions; macrophages and neutrophils show Donovan bodies. |
| 5. | <i>Brucellosis (Mediterranean fever)</i> | <i>Brucella abortus</i> | Dairy infection to humans; enlarged reticuloendothelial organs (lymph nodes, spleen, bone marrow); non-specific granulomas. |
| 6. | <i>Cat scratch disease</i> | <i>Coccobacillus</i> | Lymphadenitis; reticuloendothelial hyperplasia; granulomas with central necrosis and neutrophils. |
| 7. | <i>Tularaemia (Rabbit fever)</i> | <i>Francisella (Pasteurella) tularensis</i> | Necrosis and suppuration (acute); tubercles hard or with minute central necrosis (chronic). |
| 8. | <i>Glanders</i> | <i>Actinobacillus mallei</i> | Infection from horses and mules; subcutaneous lesions and lymphadenitis; infective granulomas. |
| II. | FUNGAL | | |
| 1. | <i>Actinomycosis* (bacterial)</i> | <i>Actinomyces israelii</i> | Cervicofacial, abdominal and thoracic lesions; granulomas and abscesses with draining sinuses; sulphur granules. |
| 2. | <i>Blastomycosis</i> | <i>Blastomyces dermatitidis</i> | Cutaneous, systemic and lung lesions; suppuration; ulceration and granulomas. |
| 3. | <i>Cryptococcosis</i> | <i>Cryptococcus neoformans</i> | Meninges, lungs and systemic distribution; organism yeast-like with clear capsule. |
| 4. | <i>Coccidioidomycosis</i> | <i>Coccidioides immitis</i> | Meninges, lungs and systemic distribution; granulomas and abscesses; organism cyst containing endospores. |
| III. | PARASITIC | | |
| | <i>Schistosomiasis (Bilharziasis)</i> | <i>Schistosoma mansoni, haematobium, japonicum</i> | Eggs and granulomas in gut, liver, lung; schistosome pigment; eosinophils in blood and tissue. |
| IV. | MISCELLANEOUS | | |
| 1. | <i>Sarcoidosis*</i> | Unknown | Non-caseating granulomas (hard tubercles); asteroid and Schaumann bodies in giant cells. |
| 2. | <i>Crohn's disease (Regional enteritis)</i> | Unknown ? Bacteria, ?? Viruses | Transmural chronic inflammatory infiltrates; non-caseating sarcoid-like granulomas. |
| 3. | <i>Silicosis</i> | Silica dust | Lung lesions, fibrocollagenous nodules. |
| 4. | <i>Berylliosis</i> | Metallic beryllium | Sarcoid-like granulomas in lungs; fibrosis; inclusions in giant cells (asteroids, Schaumann bodies, crystals). |
| 5. | <i>Foreign body granulomas</i> | Talc, suture, oils, wood splinter etc. | Non-caseating granulomas with foreign body giant cells; demonstration of foreign body. |

*Diseases discussed in this chapter.

incidence of disease cannot be determined as all patients infected with *M. tuberculosis* may not develop the clinical disease and many cases remain reactive to tuberculin without developing symptomatic disease.

HIV-ASSOCIATED TUBERCULOSIS HIV-infected individuals have very high incidence of tuberculosis all over the world. Vice-versa, rate of HIV infection in patients of tuberculosis is very high. Moreover, HIV-infected individual on acquiring infection with tubercle bacilli develops active disease rapidly (within few weeks) rather than after months or years. Pulmonary tuberculosis in HIV presents in typical manner. However, it is more often sputum smear negative but often culture positive. Extra-pulmonary tuberculosis is more common in HIV disease and manifests commonly by involving

lymph nodes, pleura, pericardium, and tuberculous meningitis. Infection with *M. avium-intracellulare* (avian or bird strain) is common in patients with HIV/AIDS.

CAUSATIVE ORGANISM Tubercle bacillus or Koch's bacillus (named after discovery of the organism by Robert Koch in 1882) called *Mycobacterium tuberculosis* causes tuberculosis in the lungs and other tissues of the human body. *The organism is a strict aerobe and thrives best in tissues with high oxygen tension such as in the apex of the lung.*

Out of various pathogenic strains for human disease included in *Mycobacterium tuberculosis* complex, currently the most common is *M. tuberculosis hominis* (human strain), while *M. tuberculosis bovis* (bovine strain) used to be common pathogen to human beings during the era of consumption of

unpasteurised milk but presently constitutes a small number of human cases. Other less common strains included in the complex are *M. africanum* (isolated from patients from parts of Africa), *M. microti*, *M. pinnipedii* and *M. canettii*. A non-pathogenic strain, *M. smegmatis*, is found in the smegma and as contaminant in the urine of both men and women.

M. tuberculosis hominis is a slender rod-like bacillus, 0.5 µm by 3 µm, is neutral on Gram staining, and can be demonstrated by the following methods:

1. **Acid fast (Ziehl-Neelsen) staining.** The acid fastness of the tubercle bacilli is due to mycolic acids, cross-linked fatty acids and other lipids in the cell wall of the organism making it impermeable to the usual stains. It takes up stain by heated carbol fuchsin and resists decolourisation by acids and alcohols (acid fast and alcohol fast) and can be decolourised by 20% sulphuric acid (compared to 5% sulphuric acid for decolourisation for *M. leprae* which are less acid fast) (Fig. 5.20). However, false positive AFB staining may occur due to *Nocardia*, *Rhodococcus*, *Legionella*, and some protozoa such as *Isospora* and *Cryptosporidium*.
2. **Fluorescent methods.** This method is quite reliable and employs use of fluorescent dyes such as auramine and rhodamine. Mycobacteria also show autofluorescence which is quite an economical method of demonstration of the organism.
3. **Culture of the organism from sputum or from any other material in Lowenstein-Jensen (L.J.) medium by conventional method has high specificity but takes a long time (8-12 weeks).** Currently, rapid methods (e.g. Bactec culture, high pressure liquid chromatography or HPLC of mycolic acids) are also available reducing the bacteriologic confirmation to 2-3 weeks.
4. **Guinea pig inoculation method by subcutaneous injection of the organisms is rarely used now.**
5. **Molecular methods** such as nucleic acid amplification (e.g. PCR) are the most useful methods for species confirmation and for distinction between *M. tuberculosis* and non-tuberculous mycobacteria because the treatment between the two is quite different.

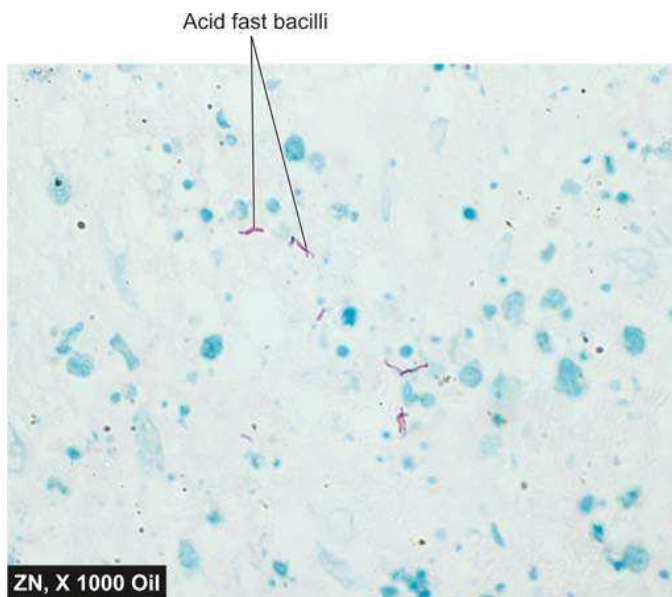

Figure 5.20 Tuberculosis of the lymph nodes showing presence of acid-fast bacilli in Ziehl-Neelsen staining.

6. **Immunohistochemical stain** with anti-MBP 64 antibody stain can be used to demonstrate the organism.

ATYPICAL MYCOBACTERIA (NON-TUBERCULOUS MYCOBACTERIA) The term atypical mycobacteria or non-tuberculous mycobacteria (NTM) is used for mycobacterial species other than *M. tuberculosis* complex and *M. leprae*. NTM are widely distributed in the environment and are, therefore, also called as *environmental mycobacteria*. They too are acid fast. Occasionally, human tuberculosis may be caused by NTM which are non-pathogenic to guinea pigs and resistant to usual anti-tubercular drugs.

Conventionally, NTM are classified on the basis of colour of colony produced in culture and the speed of growth in media:

Rapid growers These organisms grow fast on solid media (within 7 days) but are less pathogenic than others. Examples include *M. abscessus*, *M. fortuitum*, *M. chelonae*.

Slow growers These species grow mycobacteria on solid media (in 2-3 weeks). Based on the colour of colony formed, they are further divided into following:

Photochromogens: These organisms produce yellow pigment in the culture grown in light.

Scotochromogens: Pigment is produced, whether the growth is in light or in dark.

Non-chromogens: No pigment is produced by the bacilli and the organism is closely related to avium bacillus.

The examples of slow growers are *M. avium-intracellulare*, *M. kansasii*, *M. ulcerans* and *M. fortuitum*.

The infection by NTM is acquired directly from the environment, unlike person-to-person transmission of classical tuberculosis. They produce human disease, *atypical mycobacteriosis*, similar to tuberculosis but are much less virulent. The lesions produced may be granulomas, nodular collection of foamy cells, or acute inflammation.

Five patterns of the disease are recognised:

- i) Pulmonary disease produced by *M. kansasii* or *M. avium-intracellulare*.
- ii) Lymphadenitis caused by *M. avium-intracellulare* or *M. scrofulaceum*.
- iii) Ulcerated skin lesions produced by *M. ulcerans* or *M. marinum*.
- iv) Abscesses caused by *M. fortuitum* or *M. chelonae*.
- v) Bacteraemias by *M. avium-intracellulare* as seen in immunosuppressed patients of AIDS.

MODE OF TRANSMISSION Human beings acquire infection with tubercle bacilli by one of the following routes:

1. **Inhalation** of organisms present in fresh cough droplets or in dried sputum from an open case of pulmonary tuberculosis.
2. **Ingestion** of the organisms leads to development of tonsillar or intestinal tuberculosis. This mode of infection of human tubercle bacilli is from self-swallowing of infected sputum of an open case of pulmonary tuberculosis, or ingestion of bovine tubercle bacilli from milk of diseased cows.
3. **Inoculation** of the organisms into the skin may rarely occur from infected postmortem tissue.
4. **Transplacental route** results in development of congenital tuberculosis in foetus from infected mother and is a rare mode of transmission.

SPREAD OF TUBERCULOSIS The disease spreads in the body by various routes:

1. **Local spread** This takes place by macrophages carrying the bacilli into the surrounding tissues.
2. **Lymphatic spread** Tuberculosis is primarily an infection of lymphoid tissues. The bacilli may pass into lymphoid follicles of pharynx, bronchi, intestines or regional lymph nodes resulting in regional tuberculous lymphadenitis which is typical of childhood infections. Primary complex is primary focus with lymphangitis and lymphadenitis.
3. **Haematogenous spread** This occurs either as a result of tuberculous bacillaemia because of the drainage of lymphatics into the venous system or due to caseous material escaping through ulcerated wall of a vein. This produces millet seed-sized lesions in different organs of the body like lungs, liver, kidneys, bones and other tissues and is known as miliary tuberculosis.
4. **By the natural passages** Infection may spread from:
 - i) lung lesions into pleura (tuberculous pleurisy);
 - ii) transbronchial spread into the adjacent lung segments;
 - iii) tuberculous salpingitis into peritoneal cavity (tuberculous peritonitis);
 - iv) infected sputum into larynx (tuberculous laryngitis);
 - v) swallowing of infected sputum (ileocaecal tuberculosis); and
 - vi) renal lesions into ureter and down to trigone of bladder.

PATHOGENESIS (HYPERSENSITIVITY AND IMMUNITY)

Hypersensitivity or allergy, and immunity or resistance, play a major role in the development of lesions in tuberculosis. Tubercle bacilli as such do not produce any toxins. Tissue changes seen in tuberculosis are not the result of any exotoxin or endotoxin but are instead the result of host response to the organism which is by way of development of delayed type hypersensitivity (or type IV hypersensitivity) and immunity. Both these host responses develop as a consequence of several lipids present in the microorganism as under:

1. **Mycosides** such as 'cord factor' which are essential for growth and virulence of the organism in the animals.
2. **Glycolipids** present in the mycobacterial cell wall like 'Wax-D' which acts as an adjuvant acting along with tuberculo-protein.

Hypersensitivity and immunity are closely related and are initiated through CD4+ T lymphocytes sensitised against specific antigens in tuberculin (i.e. cell-mediated immunity). As a result of this sensitisation, lymphokines are released from T cells which induce increased microbicidal activity of the macrophages.

It has been known since the time of Robert Koch that the tissue reaction to tubercle bacilli is different in healthy animal not previously infected (primary infection) from an animal who is previously infected (secondary infection), the best experiment being on guinea pig because this animal does not possess any natural resistance to tubercle bacilli.

1. **In the primary infection**, intradermal injection of tubercle bacilli into the skin of a healthy guinea pig evokes no visible reaction for 10-14 days. After this period, a nodule develops at the inoculation site which subsequently ulcerates and heals poorly as the guinea pig, unlike human beings, does not possess any natural resistance. The regional lymph nodes also develop tubercles. This process is a manifestation of delayed

type hypersensitivity (type IV reaction) and is comparable to primary tuberculosis in children although healing invariably occurs in children.

2. **In the secondary infection**, the sequence of changes is different. When the tubercle bacilli are injected into the skin of the guinea pig who has been previously infected with tuberculosis 4-6 weeks earlier, the sequence and duration of development of lesions is different. In 1-2 days, the site of inoculation is indurated and dark, attaining a diameter of about 1 cm. The skin lesion ulcerates which heals quickly and the regional lymph nodes are not affected. This is called *Koch's phenomenon* and is indicative of hypersensitivity and immunity in the host which is guinea pig in this case.

Similar type of changes can be produced if injection of live tubercle bacilli is replaced with old tuberculin (OT) which is made use in skin tests in human beings.

Immunisation against tuberculosis Protective immunisation against tuberculosis is induced by injection of attenuated strains of bovine type of tubercle bacilli, *Bacille Calmette-Guérin* (BCG). Cell-mediated immunity with consequent delayed hypersensitivity reaction develops with healing of the lesion, but the cell-mediated immunity persists, rendering the host tuberculin-positive and hence immune. While BCG vaccination is routinely done at birth in countries with high prevalence of tuberculosis, it has never been recommended in US for general use due to lower prevalence of tuberculosis and the impact of the test on interpretation of skin test.

Tuberculin (Mantoux) skin test (TST) This test is done by intradermal injection of 0.1 ml of tuberculo-protein, purified protein derivative (PPD). Delayed type of hypersensitivity develops in individuals who are having or have been previously infected with tuberculous infection which is identified as an indurated area of more than 15 mm in 72 hours; reaction larger than 15 mm is unlikely to be due to previous BCG vaccination. Patients having disseminated tuberculosis may show negative test due to release of large amount of tuberculo-proteins from the endogenous lesions masking the hypersensitivity test. A positive test is indicative of cell-mediated hypersensitivity to tubercular antigens but does not distinguish between infection and disease.

The test may be *false positive* in atypical mycobacterial infection and previous BCG vaccination, *false negative* in cutaneous anergy (due to weakened immune system), sarcoidosis, some viral infections, Hodgkin's disease, recent tuberculous (8-10 weeks of exposure) infection and fulminant tuberculosis.

EVOLUTION OF TUBERCLE The sequence of events which take place when tubercle bacilli are introduced into the tissue culminating in development of a tubercle are as under (**Fig. 5.21**):

1. When the tubercle bacilli are injected intravenously into the guinea pig, the bacilli are lodged in pulmonary capillaries where an *initial response of neutrophils* is evoked which are rapidly destroyed by the organisms. However, in general, 2 types of cells are essential for a response to tubercle bacilli: *macrophages and T cells*.

2. After about 12 hours, there is *progressive infiltration by macrophages*. This is due to coating of tubercle bacilli with serum complement factors C2a and C3b which act as opsonins and attract the macrophages. Macrophages dominate the

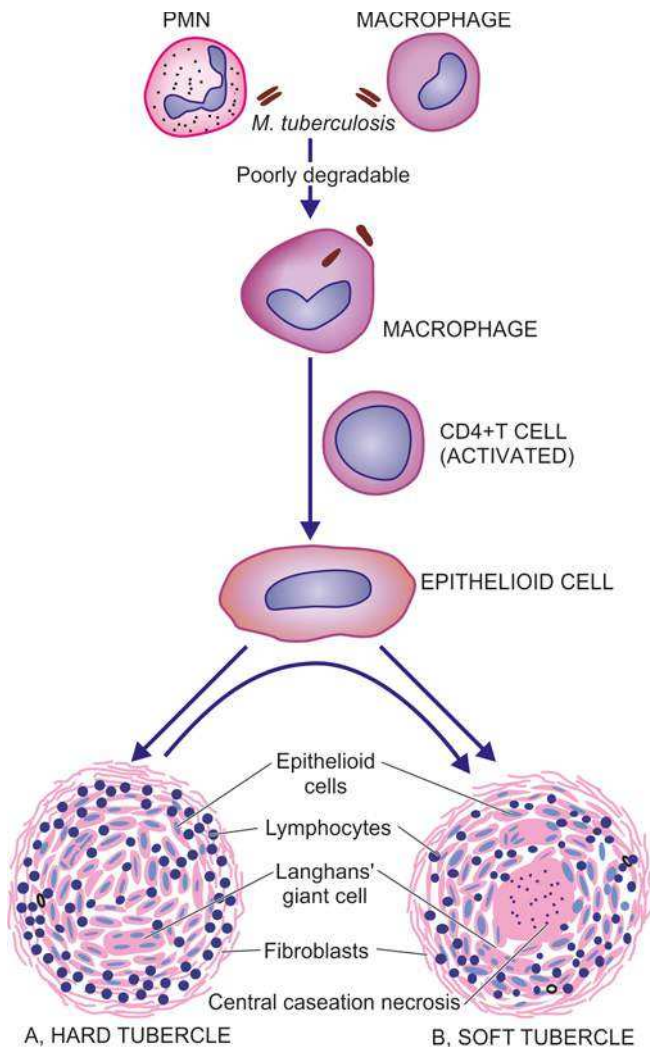

Figure 5.21 Schematic evolution of tubercle. In fully formed granuloma, the centre is composed of granular caseation necrosis, surrounded by epithelioid cells and Langhans' giant cells and peripheral rim of lymphocytes bounded by fibroblasts.

picture throughout the remaining life of the lesions. If the tubercle bacilli are, however, inhaled into the lung alveoli, macrophages predominate the picture from the beginning.

3. The macrophages start *phagocytosing* the tubercle bacilli and either try to kill the bacteria or die away themselves. In the latter case, there is production of nitric oxide radicals having antimycobacterial properties and also cause increased synthesis of cytokines (TNF- α and IL-1) resulting in proliferation of macrophages locally as well as increased recruitment from blood monocytes.

4. As a part of body's immune response, T and B cells are activated. Activated CD4+ T cells elaborate cytokines, IFN- γ and IL-2. These cytokines and their regulators determine the host's response by infiltrating macrophages-monocytes and develop the cell-mediated *delayed type hypersensitivity reaction*. Qualitative and quantitative defects of CD4+ cells in HIV explain their poor ability to deal with tubercle bacilli and hence their proneness to disseminated tuberculosis.

5. B cells form antibodies but *humoral immunity* has plays little role in body's defense against tubercle bacilli. However, recent evidence suggests the role of LAM (lipoarabinomannan)

antibodies in preventing dissemination of tuberculosis in children.

6. In 2-3 days, the macrophages undergo structural changes as a result of immune mechanisms—the cytoplasm becomes pale and eosinophilic and their nuclei become elongated and vesicular. These modified macrophages resemble epithelial cells and are called *epithelioid cells* (i.e. epithelial like).

7. The epithelioid cells in time aggregate into tight clusters or *granulomas*. Release of cytokines in response to sensitised CD4+ T cells and some constituents of mycobacterial cell wall play a role in formation of granuloma.

8. Some macrophages, unable to destroy tubercle bacilli, fuse together and form *multinucleated giant cells*. These giant cells may be Langhans' type having peripherally arranged nuclei in the form of horseshoe or ring, or clustered at the two poles of the giant cell; or they may be foreign body type having centrally-placed nuclei.

9. Around the mass or cluster of epithelioid cells and a few giant cells, a zone of lymphocytes and plasma cells is formed which is further surrounded by fibroblasts. The lesion at this stage is called *hard tubercle* due to absence of central necrosis.

10. Within 10-14 days, the centre of the cellular mass begins to undergo caseation necrosis, characterised by cheesy appearance and high lipid content. This stage is called *soft tubercle* which is the hallmark of tuberculous lesions. The development of caseation necrosis is possibly due to interaction of mycobacteria with activated T cells (CD4+ helper T cells via IFN- γ and CD8+ suppressor T cells directly) as well as by direct toxicity of mycobacteria on macrophages. *Microscopically*, caseation necrosis is structureless, eosinophilic and granular material with nuclear debris.

11. The soft tubercle which is a fully-developed granuloma with caseous centre does not favour rapid proliferation of tubercle bacilli. *Acid-fast bacilli* are difficult to find in these lesions and may be demonstrated at the margins of recent necrotic foci and in the walls of the cavities.

The **fate of a granuloma** is variable:

- i) The caseous material may undergo liquefaction and extend into surrounding soft tissues, discharging the contents on the surface. This is called *cold abscess* although there are no pus cells in it.
- ii) In tuberculosis of tissues like bones, joints, lymph nodes and epididymis, sinuses are formed and the *sinus tracts* are lined by tuberculous granulation tissue.
- iii) The adjacent granulomas may *coalesce* together enlarging the lesion which is surrounded by progressive fibrosis.
- iv) In the granuloma enclosed by fibrous tissue, calcium salts may get deposited in the caseous material (*dystrophic calcification*) and sometimes the lesion may even get ossified over the years.

TYPES OF TUBERCULOSIS

Lung is the main organ affected in tuberculosis while amongst the extra-pulmonary sites, lymph node involvement is most common. Depending upon the type of tissue response and age, the infection with tubercle bacilli is of 2 main types: primary and secondary tuberculosis; their salient differences are given in **Table 5.7**.

Table 5.7 Differences between primary and secondary tuberculosis.

| FEATURE | PRIMARY TUBERCULOSIS | SECONDARY TUBERCULOSIS |
|------------|---|--|
| 1. Age | Mostly children | Children and adults |
| 2. Organs | Almost exclusive in lungs | Lungs, lymph nodes, other organs (genitourinary tract, bones, meninges, brain, eye, liver, spleen, intestines, skin etc.) |
| 3. Lesions | Ghon's complex (lung lesion as consolidation, lymphatic vessel and hilar lymph nodes lesions) | Tubercles, extensive caseation, miliary lesions, cavitation, fibrocaseous lesions, caseous pneumonia, pleurisy/effusion |
| 4. Fate | Healing by fibrosis, calcification, may get reactivated in weakened immunity | Consolidation, parenchymal nodules, thickened pleura, amyloidosis, reactivation of healed lesion in impaired immunity and AIDS |

A. Primary Tuberculosis

The infection of an individual who has not been previously infected or immunised is called *primary tuberculosis* or *Ghon's complex* or *childhood tuberculosis*.

Primary complex or Ghon's complex is the lesion produced in the tissue of portal of entry with foci in the draining lymphatic vessels and lymph nodes. The most commonly involved tissues for primary complex are lungs and hilar lymph nodes. Other tissues which may show primary complex are tonsils and cervical lymph nodes, and in the case of ingested bacilli the lesions may be found in small intestine and mesenteric lymph nodes.

The incidence of disseminated form of progressive primary tuberculosis is particularly high in immunocompromised host e.g. in patients of AIDS.

Primary complex or Ghon's complex in lungs consists of 3 components (Fig. 5.22):

1. Pulmonary component Lesion in the lung is the primary focus or Ghon's focus. It is 1-2 cm solitary area of tuberculous pneumonia located peripherally under a patch of pleurisy, in any part of the lung but more often in subpleural focus in the upper part of lower lobe.

2. Lymphatic vessel component The lymphatics draining the lung lesion contain phagocytes containing bacilli and may develop beaded, miliary tubercles along the path of hilar lymph nodes.

3. Lymph node component This consists of enlarged hilar and tracheo-bronchial lymph nodes in the area drained. The affected lymph nodes are matted and show caseation necrosis. Nodal lesions are potential source of re-infection later (Fig. 5.23, A).

Microscopically, the lesions of primary tuberculosis have following features (Fig. 5.23, B):

- i) Tuberculous granulomas with peripheral fibrosis.
- ii) Extensive caseation necrosis in the centers of granulomas.
- iii) Old lesions have fibrosis and calcification.

In the case of primary tuberculosis of the alimentary tract due to ingestion of tubercle bacilli, a small primary focus is seen in the intestine with enlarged mesenteric lymph nodes producing *tuberculous mesenterica* (page 553). The enlarged and caseous mesenteric lymph nodes may rupture into peritoneal cavity and cause tuberculous peritonitis.

FATE OF PRIMARY TUBERCULOSIS Primary complex may have one of the following sequelae (Fig. 5.24):

1. The lesions of primary tuberculosis of the lung commonly do not progress but instead heal by *fibrosis*, and in time undergo *calcification* and even *ossification*.
2. In some cases, the primary focus in the lung continues to grow and the caseous material is disseminated through bronchi to the other parts of the same lung or the opposite lung. This is called *progressive primary tuberculosis*.
3. At times, bacilli may enter the circulation through erosion in a blood vessel and spread by haematogenous route to other tissues and organs. This is called *primary miliary tuberculosis* and the lesions may be seen in organs like the liver, spleen, kidney, brain and bone marrow.
4. In certain circumstances like in lowered resistance and increased hypersensitivity of the host, the healed lesions of primary tuberculosis may get reactivated. The bacilli lying dormant in acellular caseous material or healed lesion are activated and cause *progressive secondary tuberculosis*. It affects children more commonly but immunocompromised adults may also develop this kind of progression.

B. Secondary Tuberculosis

The infection of an individual who has been previously infected or sensitised is called *secondary*, or *post-primary* or *reinfection*, or *chronic tuberculosis*.

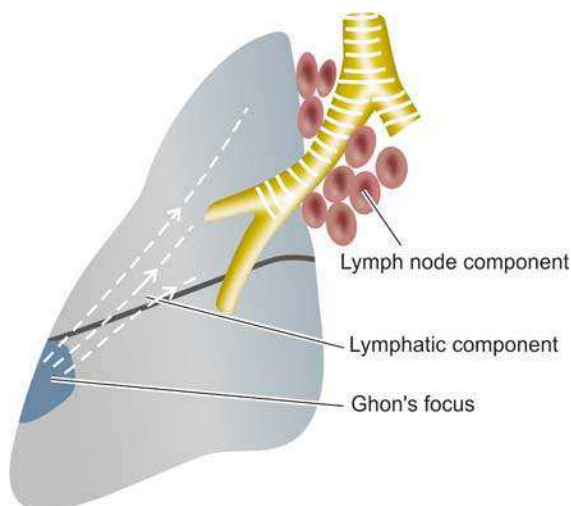

Figure 5.22 The primary complex is composed of 3 components: Ghon's focus, draining lymphatics, and hilar lymph nodes.

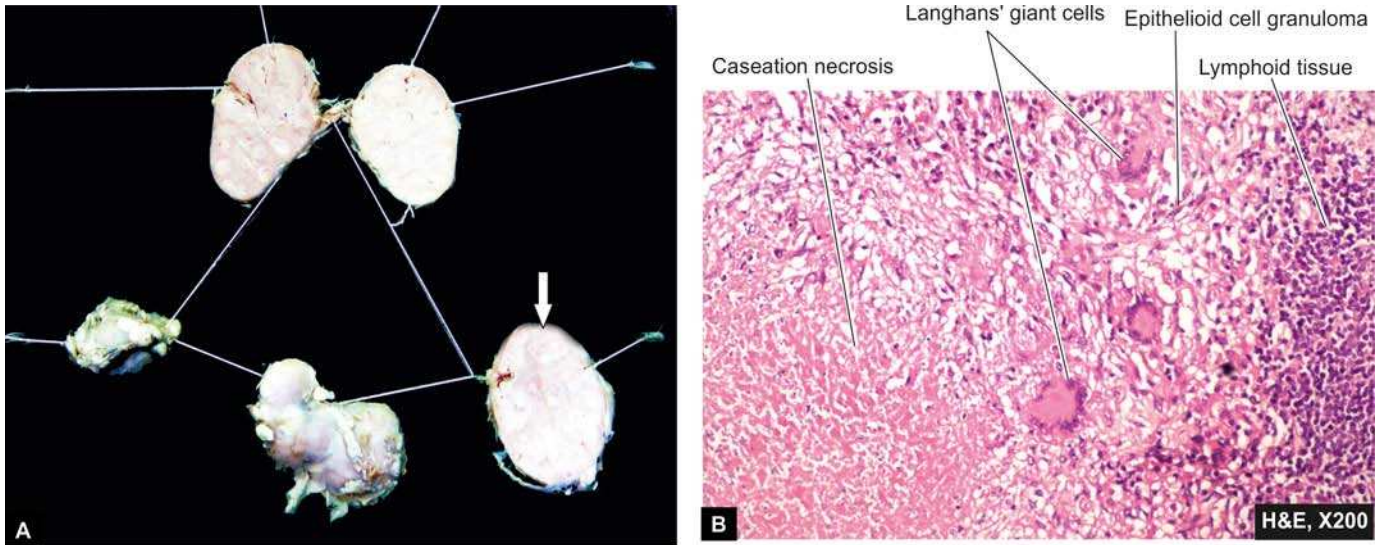

Figure 5.23 Caseating granulomatous lymphadenitis. A, Cut section of matted mass of lymph nodes shows merging capsules and large areas of caseation necrosis (arrow). B, Caseating epithelioid cell granulomas with a few Langhans' giant cells in the cortex of lymph node.

The infection may occur from (Fig. 5.25):

- ◆ *endogenous source* such as reactivation of dormant primary complex; or
- ◆ *exogenous source* such as fresh dose of reinfection by the tubercle bacilli.

Secondary tuberculosis occurs most commonly in lungs. Other sites and tissues which can be involved are lymph nodes, tonsils, pharynx, larynx, small intestine and skin. Secondary tuberculosis of other organs and tissues is described in relevant chapters later while that of lungs is discussed here.

Secondary Pulmonary Tuberculosis

The lesions in secondary pulmonary tuberculosis usually begin as 1-2 cm apical area of consolidation of the lung, which, in time, may develop a small area of central caseation necrosis and peripheral fibrosis. It occurs by lymphohaematogenous spread of infection from primary complex to the apex of the affected lung where the oxygen tension is high and favourable

for growth of aerobic tubercle bacilli. *Microscopically*, the appearance is typical of tuberculous granulomas with caseation necrosis.

Patients with HIV infection previously exposed to tuberculous infection have particularly high incidence of reactivation of primary tuberculosis. The pattern of lesions in such cases is similar to that of primary tuberculosis i.e. with involvement of hilar lymph nodes rather than cavitory and apical lesions in the lung. In addition, infection with *M. avium-intracellulare* occurs more frequently in cases of AIDS.

FATE OF SECONDARY PULMONARY TUBERCULOSIS The subapical lesions in lungs can have the following course:

1. The lesions may *heal* with fibrous scarring and calcification.
2. The lesions may *coalesce* together to form larger area of tuberculous pneumonia and produce progressive secondary pulmonary tuberculosis with the following pulmonary and extrapulmonary involvements:

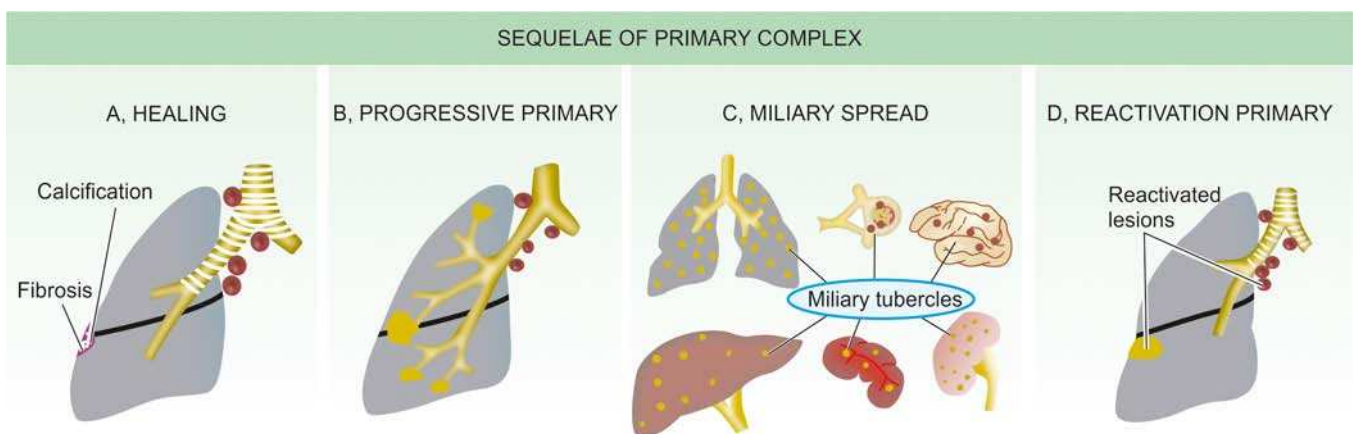

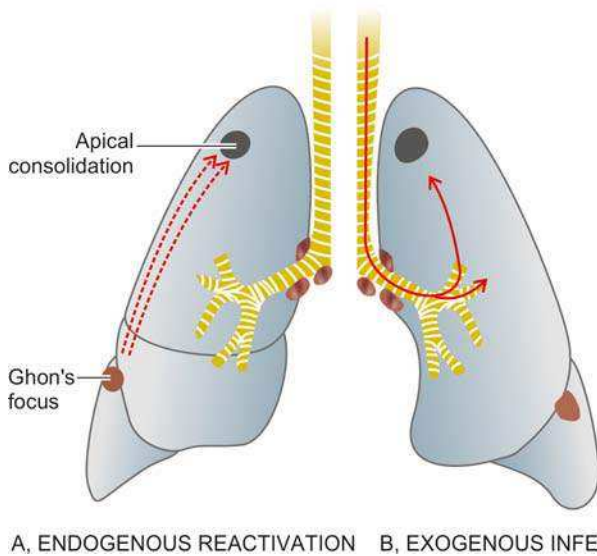

Figure 5.24 Sequelae of primary complex. A, Healing by fibrosis and calcification. B, Progressive primary tuberculosis spreading to the other areas of the same lung or opposite lung. C, Miliary spread to lungs, liver, spleen, kidneys and brain. D, Progressive secondary pulmonary tuberculosis from reactivation of dormant primary complex.

A, ENDOGENOUS REACTIVATION B, EXOGENOUS INFECTION

Figure 5.25 Progressive secondary tuberculosis. A, Endogenous infection from reactivation of dormant primary complex. B, Exogenous infection from fresh dose of tubercle bacilli.

- i) Fibrocasseous tuberculosis
- ii) Tuberculous caseous pneumonia
- iii) Miliary tuberculosis
- iv) Tuberculous empyema

FIBROCASSEOUS TUBERCULOSIS The original area of tuberculous pneumonia undergoes peripheral healing and massive central caseation necrosis which may:

- ◆ either break into a bronchus from a cavity (*cavitary or open fibrocasseous tuberculosis*); or
- ◆ remain, as a soft caseous lesion without drainage into a bronchus or bronchiole to produce a non-cavitary lesion (*chronic fibrocasseous tuberculosis*).

The cavity provides favourable environment for proliferation of tubercle bacilli due to high oxygen tension. The cavity may communicate with bronchial tree and becomes the source of spread of infection ('*open tuberculosis*'). The open case of secondary tuberculosis may implant tuberculous lesion on the mucosal lining of air passages producing *endobronchial and endotracheal tuberculosis*. Ingestion of sputum containing

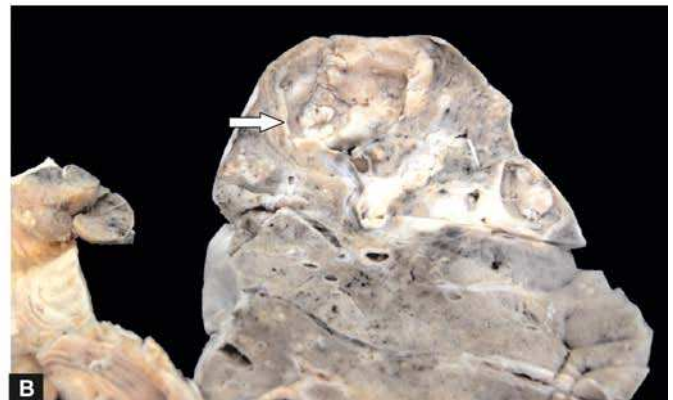

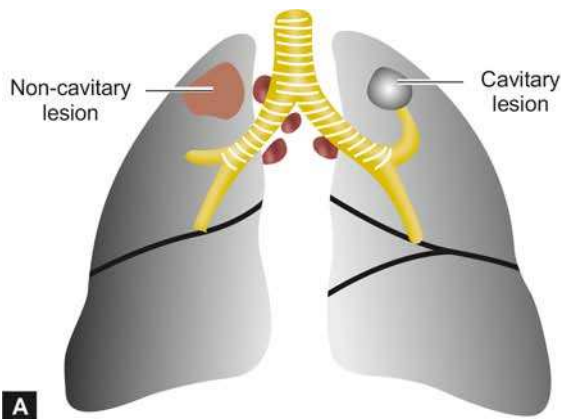

Figure 5.26 Fibrocasseous tuberculosis. A, Non-cavitary (chronic) fibrocasseous tuberculosis (left) and cavitary/open fibrocasseous tuberculosis (right). B, Chronic fibrocasseous tuberculosis lung. Sectioned surface shows a cavity in the apex of the lung (arrow). There is consolidation of lung parenchyma surrounding the cavity.

tubercle bacilli from endogenous pulmonary lesions may produce *laryngeal and intestinal tuberculosis*.

Grossly, tuberculous cavity is spherical with thick fibrous wall, lined by yellowish, caseous, necrotic material and the lumen is traversed by thrombosed blood vessels. Around the wall of cavity are seen foci of consolidation. The overlying pleura may also be thickened (**Fig. 5.26**).

Microscopically, the wall and lumen of cavity shows eosinophilic, granular, caseous material which may show foci of dystrophic calcification. Widespread coalesced tuberculous granulomas composed of epithelioid cells, Langhans' giant cells and peripheral mantle of lymphocytes and having central caseation necrosis are seen. The outer wall of cavity shows fibrosis (**Fig. 5.27**).

Complications of cavitary secondary tuberculosis are as follows:

- a) Aneurysms of patent arteries crossing the cavity producing haemoptysis.
- b) Extension to pleura producing bronchopleural fistula.
- c) Tuberculous empyema from deposition of caseous material on the pleural surface.
- d) Thickened pleura from adhesions of parietal pleura.

TUBERCULOUS CASEOUS PNEUMONIA The caseous material from a case of secondary tuberculosis in an individual with high degree of hypersensitivity may spread to rest of the lung producing caseous pneumonia (**Fig. 5.28, A**).

Microscopically, the lesions show exudative reaction with oedema, fibrin, polymorphs and monocytes but numerous tubercle bacilli can be demonstrated in the exudates (**Fig. 5.28, B**).

MILIARY TUBERCULOSIS This is lymphohaematogenous spread of tuberculous infection from primary focus or later stages of tuberculosis. The spread may occur to systemic organs or isolated organ. The spread is either by entry of infection into pulmonary vein producing disseminated or isolated organ lesion in different extra-pulmonary sites (e.g. liver, spleen, kidney, brain, meninges, genitourinary tract and bone marrow) (**Fig. 5.29**), or into pulmonary artery restricting the development of miliary lesions within the lung (**Fig. 5.30**).

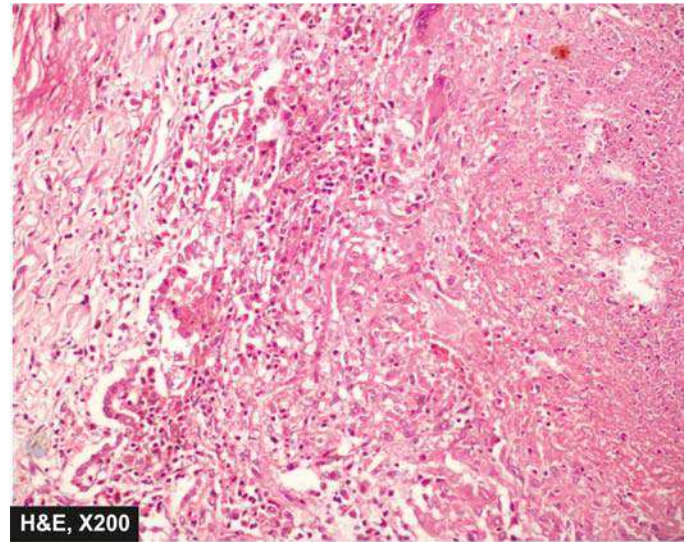

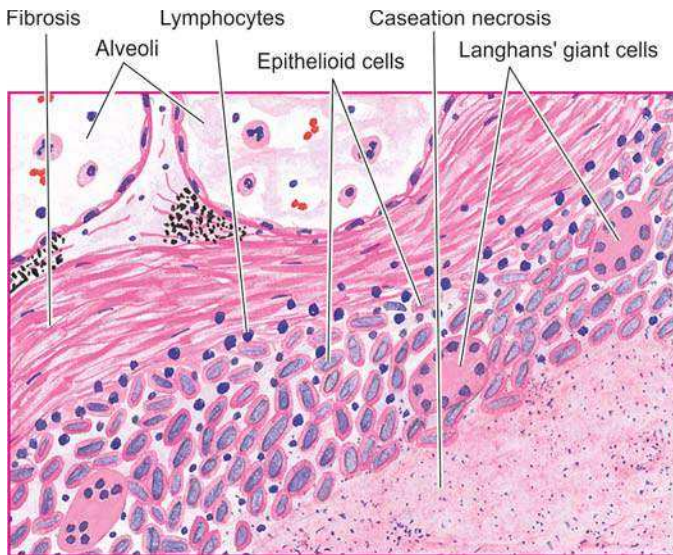

Figure 5.27 Microscopic appearance of lesions of secondary fibrocaceous tuberculosis of the lung showing wall of the cavity.

Grossly, the miliary lesions are millet seed-sized (1 mm diameter), yellowish, firm areas without grossly visible caseation necrosis.

Microscopically, the lesions show the structure of tubercles with minute areas of caseation necrosis (**Fig. 5.31**).

TUBERCULOUS EMPYEMA The caseating pulmonary lesions of tuberculosis may be associated with pleurisy (pleuritis, pleural effusion) as a reaction and is expressed as a serous or fibrinous exudates. Pleural effusion may heal by fibrosis and obliterate the pleural space (thickened pleura by chronic pleuritis). Occasionally, pleural cavity may contain caseous material and develop into tuberculous empyema.

Fig. 5.32 depicts various pulmonary and pleural lesions in tuberculosis.

Clinical Features and Diagnosis of Tuberculosis

The clinical manifestations in tuberculosis may be variable depending upon the location, extent and type of lesions.

However, in secondary pulmonary tuberculosis which is the common type, the usual clinical features are as under:

1. Referable to lungs—such as productive cough (may be with haemoptysis), pleural effusion, dyspnoea, orthopnoea etc. Chest X-ray may show typical apical changes like pleural effusion, nodularity, and miliary or diffuse infiltrates in the lung parenchyma.

2. Systemic features—such as fever, night sweats, fatigue, loss of weight and appetite. Long-standing and untreated cases of tuberculosis may develop systemic secondary amyloidosis.

The *diagnosis* is made by the following tests:

- AFB microscopy* of diagnostic specimen such as sputum, aspirated material.
- Mycobacterial culture* (traditional method on LJ medium for 4-8 weeks, newer rapid method by HPLC of mycolic acid with result in 2-3 weeks).
- Molecular methods* such as PCR.
- Complete haemogram* (lymphocytosis and raised ESR).

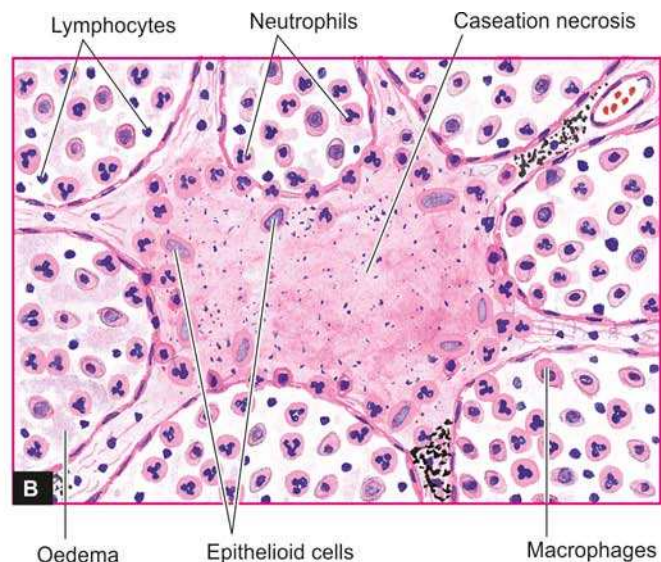

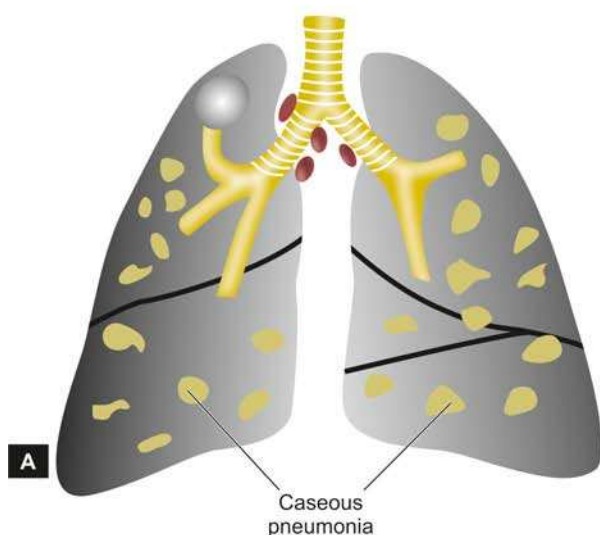

Figure 5.28 A, Bilateral tuberculous caseous pneumonia. B, Tuberculous caseous pneumonia showing exudative reaction. In AFB staining, these cases have numerous acid-fast bacilli (not shown here).

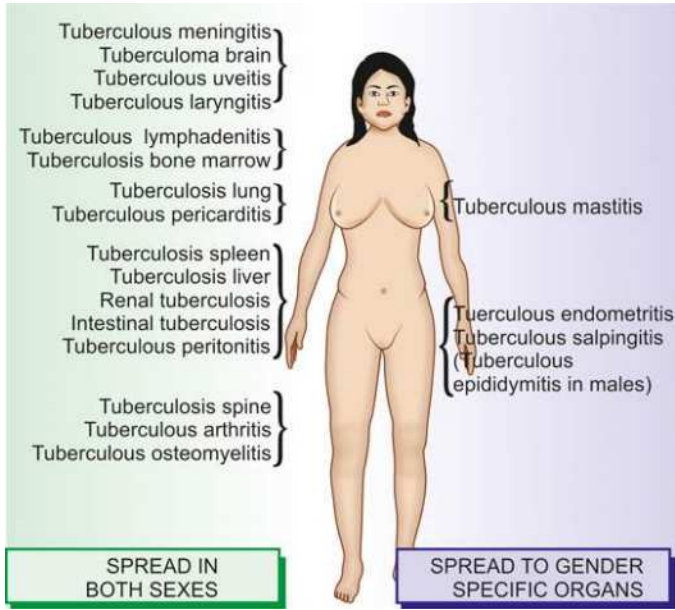

Figure 5.29 Miliary spread by lymphohaematogenous route.

v) *Radiographic procedures* e.g. chest X-ray showing characteristic hilar nodules and other parenchymal changes).

vi) *Mantoux skin test* (discussed on page 140).

vii) *Serologic tests* based on detection of antibodies are not useful although these are being advocated in some developing countries.

viii) *Fine needle aspiration cytology* of an enlarged peripheral lymph node is quite useful and easy way for confirmation of diagnosis and has largely replaced the biopsy diagnosis of tuberculosis (see Appendix I).

Causes of death in pulmonary tuberculosis are usually pulmonary insufficiency, pulmonary haemorrhage, sepsis due to disseminated miliary tuberculosis, cor pulmonale or secondary amyloidosis.

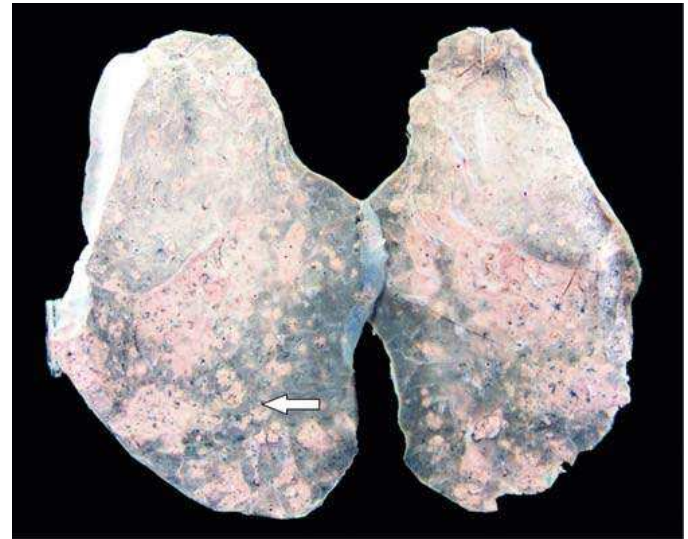

Figure 5.30 Miliary tuberculosis lung. The sectioned surface of the lung parenchyma shows presence of minute millet-seed sized tubercles.

GIST BOX 5.8

Tuberculosis

- ▣ In tuberculosis, tissue response to the causative organism, *Mycobacterium tuberculosis*, (a strict aerobe) is a classic example of caseating granulomatous inflammation associated with Langhans' and foreign body giant cells.
- ▣ The organism is acid-fast bacillus (AFB) which can be demonstrated by Ziehl-Neelsen staining.
- ▣ Tubercle bacilli contain mycoside cord factor essential for growth of the organism and glycolipids in the bacterial cell wall.
- ▣ Tuberculosis is worldwide in distribution, more common in developing countries. Other factors include malnutrition, poverty and chronic debilitating diseases and immunocompromised states like AIDS.

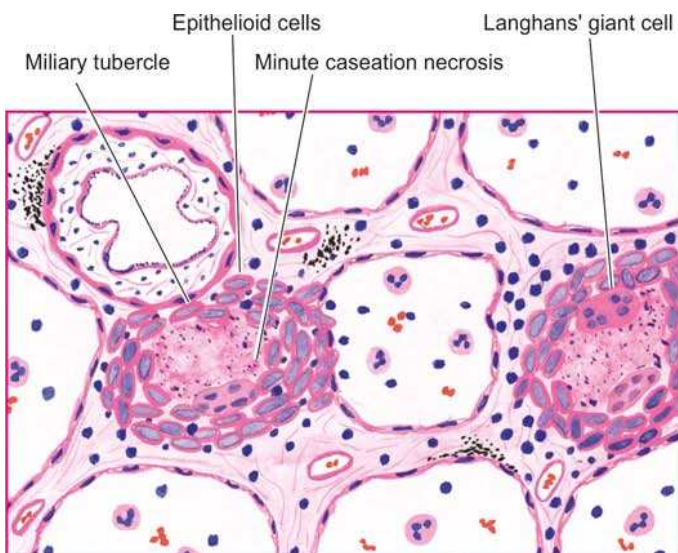

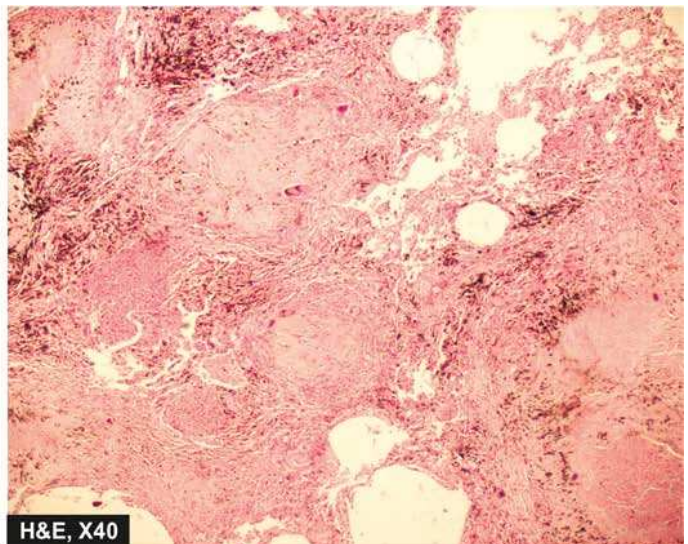

Figure 5.31 Miliary tubercles in lung having minute areas of central caseation necrosis.

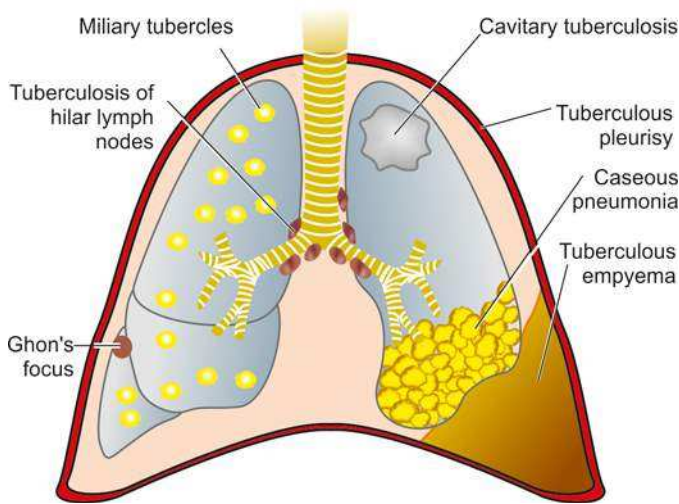

Figure 5.32 The spectrum of lesions in the lungs and pleura in all types of pulmonary tuberculosis.

- ▣ The infection is commonly transmitted by inhalation of cough droplets from an infected individual and self-ingestion of infected sputum. The disease may spread locally, and by lymphohaematogenous route.
- ▣ Primary tuberculosis is infection of an individual who has not been previously infected, also called childhood tuberculosis or Ghon's complex. It affects lung most commonly and the tissue response is by formation of a small area of consolidation in the lung, and granulomatous involvement of lymphatic vessel and hilar lymph nodes.
- ▣ Secondary pulmonary tuberculosis includes fibrocavitory (cavitory) type, tuberculous caseous pneumonia, military spread to various organs and tuberculous pleurisy.
- ▣ Common methods of diagnosis of pulmonary tuberculosis are demonstration of the organism in the sputum, haematologic tests (raised ESR), positive Mantoux skin test, and X-ray chest. Fine needle aspiration of enlarged lymph nodes is a convenient method of confirmation of diagnosis.

LEPROSY

Leprosy or Hansen's disease (after discovery of the causative organism by Hansen in 1874), was first described in ancient Indian text going back to 6th Century BC, is a chronic non-fatal infectious disease. It affects mainly the cooler parts of the body such as the skin, mouth, respiratory tract, eyes, peripheral nerves, superficial lymph nodes and testis. The earliest and main involvement in leprosy is of the skin and nerves. However, in bacteraemia from endothelial colonisation or by bacilli filtered from blood by reticuloendothelial system, other organs such as the liver, spleen, bone marrow and regional lymph nodes are also involved. Advanced cases may develop secondary amyloidosis and renal disease, both of which are of immunologic origin.

Causative Organism

The disease is caused by *Mycobacterium leprae* which closely resembles *Mycobacterium tuberculosis* but is less acid-fast. The

organisms in tissues appear as compact rounded masses (*globi*) or are arranged in parallel fashion like *cigarettes-in-pack*.

M. leprae can be demonstrated in tissue sections, in split skin smears by splitting the skin, scrapings from cut edges of dermis, and in nasal smears by the following techniques:

1. *Acid-fast (Ziehl-Neelsen or ZN) staining*. The staining procedure is similar as for demonstration of *M. tuberculosis* but can be decolourised by lower concentration (5%) of sulphuric acid (less acid-fast).
2. *Fite-Faraco staining* procedure is a modification of Z.N. procedure and is considered better for more adequate staining of tissue sections (**Fig. 5.33**).
3. *Gomori methenamine silver (GMS) staining* can also be employed.
4. *Molecular methods* e.g. PCR.
5. *IgM antibodies to PGL-1 antigen* seen in 95% cases of lepromatous leprosy but only in 60% cases of tuberculoid leprosy.

The slit smear technique gives a reasonable quantitative measure of *M. leprae* when stained with Z.N. method and examined under 100x oil objective for determining the density of bacteria in the lesion (*bacterial index, BI*). B.I. is scored from 1+ to 6+ (range from 1 to 10 bacilli per 100 fields to > 1000 per field) as *multibacillary* leprosy while B.I. of 0+ is termed *paucibacillary*.

Although lepra bacilli were the first bacteria identified for causing human disease, *M. leprae* remains one of the few bacterial species which is yet to be cultured on artificial medium. Nine-banded armadillo, a rodent, acts as an experimental animal model as it develops leprosy which is histopathologically and immunologically similar to human leprosy.

Incidence

The disease is endemic in areas with hot and moist climates and in poor tropical countries. Leprosy is almost exclusively a disease of a few developing countries in Asia, Africa and Latin America. According to the WHO, 8 countries—India, China, Nepal, Brazil, Indonesia, Myanmar (Burma), Madagascar

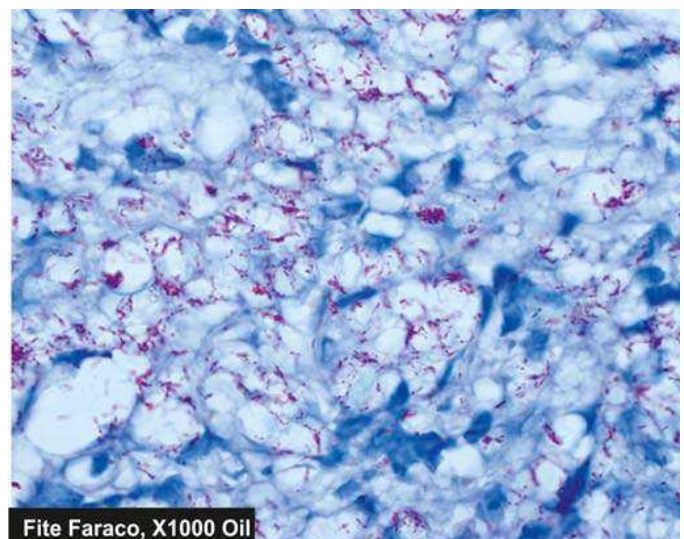

Figure 5.33 Lepra bacilli in LL are seen as globi and cigarettes-in-a-pack appearance inside the foam macrophages (Fite-Faraco stain).

and Nigeria, together constitute about 80% of leprosy cases, of which India accounts for one-third of all registered leprosy cases globally. In India, the disease is seen more commonly in states of Tamil Nadu, Bihar, Puducherry, Andhra Pradesh, Odisha, West Bengal and Assam. Very few cases are now seen in Europe and the United States.

Mode of Transmission

Leprosy is a slow communicable disease and the incubation period between first exposure and appearance of signs of disease varies from 2 to 20 years (average about 3 years). The infectivity may be from the following sources:

1. *Direct contact* with untreated leprosy patients who shed numerous bacilli from damaged skin, nasal secretions, mucous membrane of mouth and hair follicles.
2. *Materno-foetal transmission* across the placenta.
3. Transmission from *milk* of leprosy affected mother to infant.

Immunology of Leprosy

Like in tuberculosis, the immune response in leprosy is also T cell-mediated delayed hypersensitivity (type IV reaction) but the two diseases are quite dissimilar as regards immune reactions and lesions. *M. leprae* do not produce any toxins but instead the damage to tissues is immune-mediated. This is due to following peculiar aspects in immunology of leprosy:

1. Antigens of leprosy bacilli Lepra bacilli have several antigens. The bacterial cell wall contains large amount of *M. leprae*-specific phenolic glycolipid (PGL-1) and another surface antigen, lipo-arabinomannan (LAM). These antigens of the bacilli determine the immune reaction of host lymphocytes and macrophages. Another unique feature of leprosy bacilli is invasion in peripheral nerves which is due to binding of trisaccharide of *M. leprae* to basal lamina of Schwann cells.

2. Genotype of the host Genetic composition of the host as known by MHC class (or HLA type) determines which antigen of leprosy bacilli shall interact with host immune cells. Accordingly, the host response to the leprosy bacilli in different individuals is variable.

3. T cell response There is variation in T cell response in two main forms of leprosy:

- i) Unlike tubercle bacilli, there is not only *activation* of CD4+ T cells but also of CD8+ T cells.

- ii) CD4+ T cells in lepra bacilli infected persons act not only as helper and promoter cells but also assume the role of *cytotoxicity*.

- iii) The two subpopulations of CD4+ T cells (or T helper cells)— $T_H 1$ cells and $T_H 2$ cells, elaborate different types of *cytokines* in response to stimuli from the lepra bacilli and macrophages.

- iv) In tuberculoid leprosy, the response is largely by CD4+ T cells, while in lepromatous leprosy although there is excess of CD8+ T cells (suppressor T) but the macrophages and suppressor T cells fail to destroy the bacilli due to *CD8+ T cell defect*.

4. Humoral response Though the patients of lepromatous leprosy have humoral components such as high levels of immunoglobulins (IgG, IgA, IgM) and antibodies to mycobacterial antigens but these antibodies do not have any protective role against lepra bacilli.

Based on above unique immunologic features in leprosy, lesions in leprosy are classified into 5 distinct clinico-pathologic types and three forms of reactional leprosy (described below), and an intradermal immunologic test, lepromin test.

LEPROMIN TEST It is not a diagnostic test but is used for classifying leprosy on the basis of immune response. Intra-dermal injection of lepromin, an antigenic extract of *M. leprae*, reveals delayed hypersensitivity reaction in patients of tuberculoid leprosy:

- 1) An early positive reaction appearing as an indurated area in 24-48 hours is called *Fernandez reaction*.
- 2) A delayed granulomatous lesion appearing after 3-4 weeks is called *Mitsuda reaction*.

Patients of lepromatous leprosy are negative by the lepromin test.

The test indicates that cell-mediated immunity is greatly suppressed in lepromatous leprosy while patients of tuberculoid leprosy show good immune response. Delayed type of hypersensitivity is conferred by T helper cells. The granulomas of tuberculoid leprosy have sufficient T helper cells and fewer T suppressor cells at the periphery while the cellular infiltrates of lepromatous leprosy lack T helper cells.

Classification

RIDLEY AND JOPLING'S CLASSIFICATION Traditionally, two main forms of leprosy are distinguished:

1. Lepromatous type representing *low resistance*; and
2. Tuberculoid type representing *high resistance*.

Salient differences between these two forms of leprosy are summarised in **Table 5.8**.

Table 5.8 Differences between lepromatous and tuberculoid leprosy.

| FEATURE | LEPROMATOUS LEPROSY | TUBERCULOID LEPROSY |
|-----------------------------|---|---|
| 1. <i>Skin lesions</i> | Symmetrical, multiple, hypopigmented, erythematous, maculopapular or nodular (leonine facies). | Asymmetrical, single or a few lesions, hypopigmented and erythematous macular. |
| 2. <i>Nerve involvement</i> | Present but sensory disturbance is less severe. | Present with distinct sensory disturbance. |
| 3. <i>Histopathology</i> | Collection of foamy macrophages or lepra cells in the dermis separated from epidermis by a 'clear zone'. | Hard tubercle similar to granulomatous lesion, eroding the basal layer of epidermis; no clear zone. |
| 4. <i>Bacteriology</i> | Lepra cells highly positive for lepra bacilli seen as 'globi' or 'cigarettes-in-pack' appearance (multibacillary type). | Lepra bacilli few, seen in destroyed nerves as granular or beaded forms (paucibacillary type). |
| 5. <i>Immunity</i> | Suppressed (low resistance). | Good immune response (high resistance). |
| 6. <i>Lepromin test</i> | Negative | Positive |

Since both these types of leprosy represent two opposite poles of host immune response, these are also called *polar forms* of leprosy. Cases not falling into either of the two poles are classified as *borderline* and *indeterminate types*.

Based on clinical, histologic and immunologic features, modified Ridley and Jopling's classification divides leprosy into 5 groups as under:

- TT—Tuberculoid Polar (*High resistance*)
- BT—Borderline Tuberculoid
- BB—Mid Borderline (dimorphic)
- BL—Borderline Lepromatous
- LL—Lepromatous Polar (*Low resistance*)

VARIANTS In addition, not included in Ridley-Jopling's classification are following types:

- ◆ *Indeterminate leprosy*. This is an initial non-specific stage of any type of leprosy.
- ◆ *Pure neural leprosy*. In these cases, skin lesions which are the cardinal feature of leprosy are absent but instead neurologic involvement is the main feature.
- ◆ *Histoid leprosy*. Described by Wade in 1963, this is a variant of LL in which the skin lesions resemble nodules of dermatofibroma and is the lesions are highly positive for lepra bacilli.

REACTIONAL LEPROSY Based on shift in immune status or in patients of leprosy on treatment, two types of reactional leprosy are distinguished: type I (reversal reactions), and type II (erythema nodosum leprosum).

Type I: Reversal reactions The polar forms of leprosy do not undergo any change in clinical and histopathological picture. The borderline groups are unstable and may move across the spectrum in either direction with upgrading or downgrading of patient's immune state. Accordingly, there may be two types of borderline reaction:

- ◆ *Upgrading reaction* is characterised by increased cell-mediated immunity and occurs in patients of borderline lepromatous (BL) type on treatment who upgrade or shift towards tuberculoid type.
- ◆ *Downgrading reaction* is characterised by lowering of cellular immunity and is seen in borderline tuberculoid (BT) type who downgrade or shift towards lepromatous type.

Type II: Erythema nodosum leprosum (ENL) ENL occurs in lepromatous patients after treatment. It is characterised by tender cutaneous nodules, fever, iridocyclitis, synovitis and lymph node involvement.

Histopathology of Leprosy

Usually, skin biopsy from the margin of lesions is submitted for diagnosis and for classification of leprosy. The histopathologic diagnosis of multibacillary leprosy like LL and BL offers no problem while the indeterminate leprosy and tuberculoid lesions are paucibacillary and their diagnosis is made together with clinical evidence.

In general, for histopathologic evaluation in all suspected cases of leprosy the following general *features* should be looked for:

- i) Cell type of granuloma
- ii) Nerve involvement
- iii) Bacterial load
- iv) Presence and absence of lymphocytes
- v) Relation of granuloma with epidermis and adnexa.

The salient features in major types of leprosy are as follows.

1. Lepromatous leprosy:

The following features characterise lepromatous polar leprosy (**Fig. 5.34**):

- i) In the dermis, there is proliferation of macrophages with foamy change, particularly around the blood vessels, nerves and dermal appendages. The foamy macrophages are called '*lepra cells*' or *Virchow cells*.
- ii) The lepra cells are heavily laden with acid-fast bacilli demonstrated with AFB staining. The AFB may be seen as compact globular masses (*globi*) or arranged in parallel fashion like '*cigarettes-in-pack*' (see Fig. 5.32).
- iii) The dermal infiltrate of lepra cells characteristically does not encroach upon the basal layer of epidermis and is separated from epidermis by a subepidermal uninvolved *clear zone*.
- iv) The *epidermis* overlying the lesions is thinned out, flat and may even ulcerate.

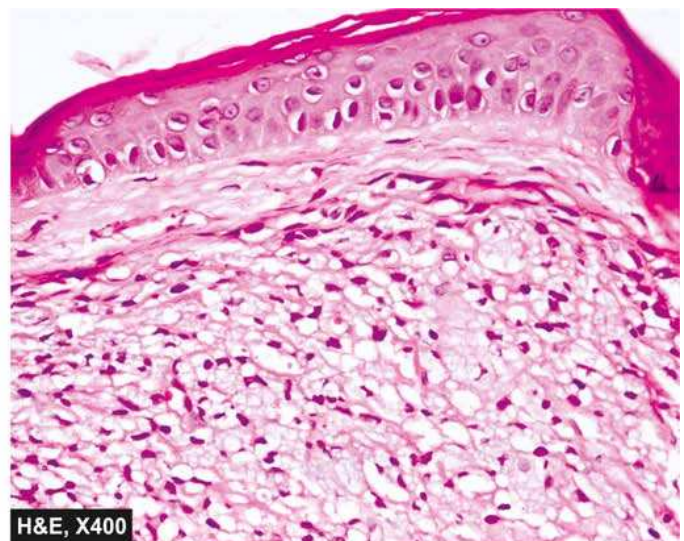

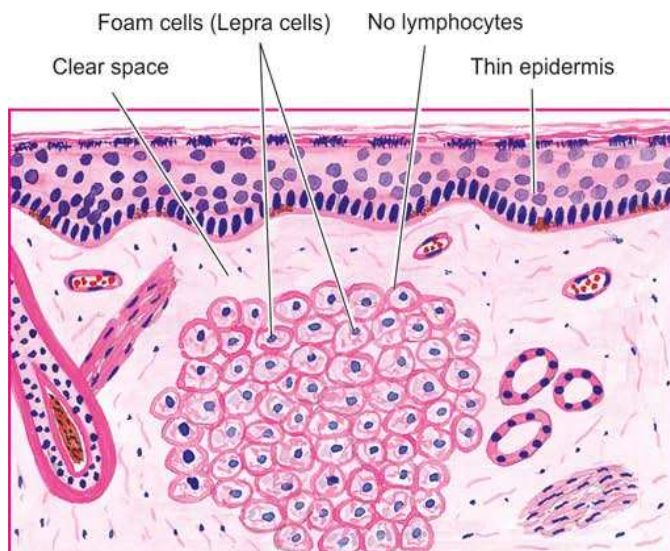

Figure 5.34 Lepromatous leprosy (LL). There is collection of proliferating foam macrophages (lepra cells) in the dermis, sparse lymphocytes and a clear subepidermal zone.

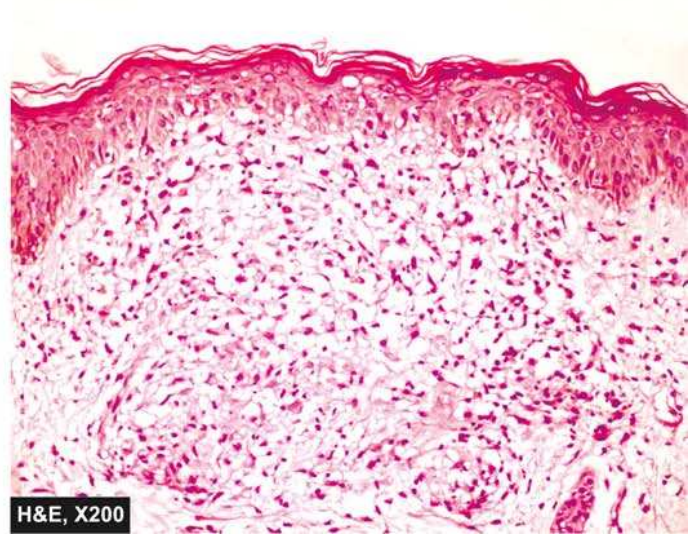

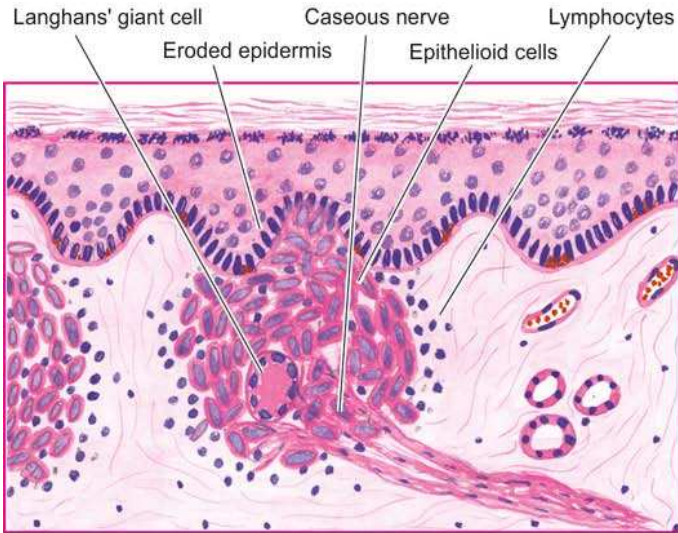

Figure 5.35 Tuberculoid leprosy (TT). Granuloma eroding the basal layer of the epidermis. The granuloma is composed of epithelioid cells with sparse Langhans' giant cells and many lymphocytes.

2. Tuberculoid leprosy:

The polar tuberculoid form presents the following histological features (**Fig. 5.35**):

- i) The dermal lesions show granulomas resembling *hard tubercles* composed of epithelioid cells, Langhans' giant cells and peripheral mantle of lymphocytes.
- ii) Lesions of tuberculoid leprosy have predilection for *dermal nerves* which may be destroyed and infiltrated by epithelioid cells and lymphocytes.
- iii) The granulomatous infiltrate erodes the basal layer of epidermis i.e. there is *no clear zone*.
- iv) The *lepra bacilli* are few and seen in destroyed nerves.

3. Borderline leprosy:

The histopathologic features of the three forms of borderline leprosy are as under:

- i) *Borderline tuberculoid (BT)* form shows epithelioid cells and plentiful lymphocytes. There is a narrow clear subepidermal zone. *Lepra bacilli* are scanty and found in nerves.
- ii) *Borderline lepromatous (BL)* form shows predominance of histiocytes, a few epithelioid cells and some irregularly dispersed lymphocytes. Numerous *lepra bacilli* are seen.
- iii) *Mid-borderline (BB)* or dimorphic form shows sheets of epithelioid cells with no giant cells. Some lymphocytes are seen in the peri-neurium. *Lepra bacilli* are present, mostly in nerves.

4. Indeterminate leprosy:

The histopathologic features are non-specific so that the diagnosis of non-specific chronic dermatitis may be made. However, a few features help in suspecting leprosy as under:

- i) Lymphocytic or mononuclear cell infiltrate, localised particularly around skin adnexal structures like hair follicles and sweat glands or around blood vessels.
- ii) Nerve involvement, if present, is strongly supportive of diagnosis.

- iii) Confirmation of diagnosis is made by finding of *lepra bacilli*.

5. Pure neural leprosy: Histopathologic features described in skin lesion of various forms of leprosy may be seen in the nerve biopsy specimens. Pure neural leprosy may be AFB positive or AFB negative.

6. Histoid leprosy:

Following features characterise these lesions:

- i) Whorls and fascicles of spindle cells in the upper dermis after a clear subepidermal space.
- ii) On close scrutiny, these cells have foamy cytoplasm.
- iii) The cytoplasm of these cells is laden with *lepra bacilli*.

7. Reactional leprosy:

Two types of reactional leprosy show following features:

Type I reaction: Reversal reactions. These may be upgrading or downgrading type of reaction:

Upgrading reaction shows an increase of lymphocytes, oedema of the lesions, necrosis in the centre and reduced B.I.

Downgrading reaction shows dispersal and spread of the granulomas and increased presence of *lepra bacilli*.

Type II: ENL The lesions in ENL show infiltration by neutrophils and eosinophils and prominence of vasculitis. Inflammation often extends deep into the subcutaneous fat causing panniculitis. Bacillary load is increased. Secondary amyloidosis may follow repeated attacks of ENL in leprosy.

Clinical Features

The two main forms of leprosy show distinctive clinical features:

1. Lepromatous leprosy:

- i) The skin lesions in LL are generally symmetrical, multiple, slightly hypopigmented and erythematous macules, papules, nodules or diffuse infiltrates. The nodular lesions may coalesce to give *leonine facies* appearance.

ii) The lesions are hypoaesthetic or anaesthetic but the sensory disturbance is not as distinct as in TT.

2. Tuberculoid leprosy:

i) The skin lesions in TT occur as either single or as a few asymmetrical lesions which are hypopigmented and erythematous macules.

ii) There is a distinct sensory impairment.

Long term cases of either type may develop secondary amyloidosis. Anti-leprosy vaccines have been developed but are undergoing human trials yet. Since the incubation period of leprosy is quite long, the efficacy of such vaccines will be known after a number of years.

GIST BOX 5.9

Leprosy

- ▣ Leprosy or Hansen's disease, is a chronic infectious disease that affects mainly the cooler parts of the body such as the skin, mouth, respiratory tract, eyes, peripheral nerves, superficial lymph nodes and testis.
- ▣ The disease is caused by *Mycobacterium leprae* which closely resembles *Mycobacterium tuberculosis* but is less acid-fast.
- ▣ The disease spreads by close contact for a long duration, often lasting for several years.
- ▣ Based on clinical, pathologic and immunologic features, leprosy is classified into polar tuberculoid (high resistance), polar lepromatous (low resistance), and borderline towards either type. A few variants are reactional (type I upgrading and downgrading, type II or ENL) histoid, and pure neural leprosy.
- ▣ Lepromatous type has foam cell granulomas (multibacillary on lepra stain) while tuberculoid type has epithelioid cell granulomas (paucibacillary on lepra stain).

SYPHILIS

Syphilis is a venereal (sexually-transmitted) disease caused by spirochaetes, *Treponema pallidum*. Other treponemal diseases are yaws, pinta and bejel. The word 'syphilis' is derived from the name of the mythological handsome boy, Syphilus, who was cursed by Greek god Apollo with the disease.

Causative Organism

T. pallidum is a coiled spiral filament 10 µm long that moves actively in fresh preparations. The organism cannot be stained by the usual methods and can be demonstrated in the exudates and tissues by:

1. *dark ground illumination (DGI)* in fresh preparation;
2. *fluorescent antibody technique*;
3. *silver impregnation techniques*; and
4. *nucleic acid amplification* technique by PCR.

The organism has not been cultivated in any culture media but experimental infection can be produced in rabbits and chimpanzees. The organism is rapidly destroyed by cold, heat, and antiseptics.

Incidence

Since the advent of penicillin therapy in 1943, syphilis has shown a decline in incidence. However, the disease continues

to have global presence. Most commonly affected regions in the world are in Sub-Saharan Africa, South America, and South East Asia. Male homosexuals are at greater risk. Some African countries have very high incidence of congenital syphilis and also responsible for high rate of stillbirths.

Immunology

T. pallidum does not produce any endotoxin or exotoxin. The pathogenesis of the lesions appears to be due to host immune response.

There are two types of serological tests for syphilis: treponemal and non-treponemal.

A. Treponemal serological tests These tests measure antibody to *T. pallidum* antigen and are more useful and sensitive for the diagnosis of syphilis:

- i) *Fluorescent treponemal antibody-absorbed (FTA-ABS) test*.
- ii) *Agglutinin assays* e.g. microhaemagglutination assay for *T. pallidum* (MHA-TP), and Serodia TP-PA; the latter is more sensitive.
- iii) *T. pallidum passive haemagglutination (TPHA) test*.

B. Non-treponemal serological tests These tests measure non-specific reaginic antibodies IgM and IgG immunoglobulins directed against cardiolipin-lecithin-cholesterol complex and are more commonly used. These tests are as under:

- i) *Reiter protein complement fixation (RPCF) test*: test of choice for rapid diagnosis.
- ii) *Venereal Disease Research Laboratory (VDRL) or Rapid Plasma Reagin (RPR) test*: Wassermann described a complement fixing antibody against antigen of human syphilitic tissue. This antigen is used in the Standard Test for Syphilis (STS) in Wassermann complement fixing test and VDRL test.

Mode of Transmission

Syphilitic infection can be transmitted by the following routes:

1. *Sexual intercourse* is the most common route of infection and results in lesions on glans penis, vulva, vagina and cervix.
2. *Intimate person-to-person contact* with lesions on lips, tongue or fingers.
3. *Transfusion* of infected blood.
4. *Materno-foetal transmission* in congenital syphilis if the mother is infected.

Stages of Acquired Syphilis

Acquired syphilis is divided into 3 stages depending upon the period after which the lesions appear and the type of lesions. These are: primary, secondary and tertiary syphilis.

PRIMARY SYPHILIS Typical lesion of primary syphilis is *chancre* which appears on genitals or at extra-genital sites in 2-4 weeks after exposure to infection (**Fig. 5.36,A**). Initially, the lesion is a painless papule which ulcerates in the centre. The fully-developed chancre is an indurated lesion with central ulceration accompanied by regional lymphadenitis. The chancre heals without scarring, even in the absence of treatment.

Histologically, the chancre has following features:

- i) Dense infiltrate of mainly plasma cells, some lymphocytes and a few macrophages.

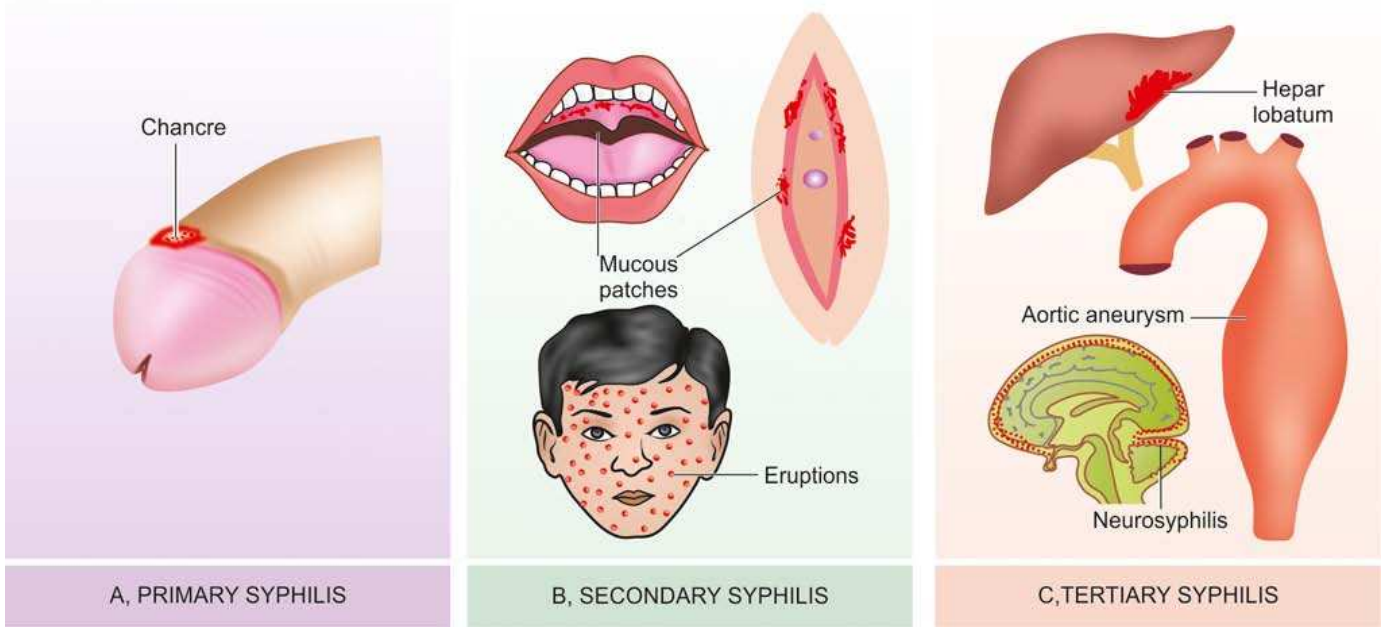

Figure 5.36 Organ involvement in various stages of acquired syphilis.

A, Primary syphilis: Primary lesion is 'chancre' on glans penis. **B, Secondary syphilis:** Mucocutaneous lesions—mucous patches on oral and vaginal mucosa and generalised skin eruptions. **C, Tertiary syphilis:** Localised lesion as gumma of liver with scarring (hepar lobatum); diffuse lesions (right) in aorta (aneurysm, narrowing of mouths of coronary ostia and incompetence of aortic valve ring) and nervous system.

- ii) Perivascular aggregation of mononuclear cells, particularly plasma cells (periarteritis and endarteritis).
- iii) Proliferation of vascular endothelium.

Antibody tests are positive in 1-3 weeks after the appearance of chancre. Spirochaetes can be demonstrated in the exudates by DGI.

SECONDARY SYPHILIS Inadequately treated patients of primary syphilis develop *mucocutaneous lesions* and painless lymphadenopathy in 2-3 months after the exposure (**Fig. 5.36,B**). Mucocutaneous lesions may be in the form of the mucous patches on mouth, pharynx and vagina; and generalised skin eruptions and condyloma lata in anogenital region.

Antibody tests are always positive at this stage. Secondary syphilis is *highly infective stage* and spirochaetes can be easily demonstrated in the mucocutaneous lesions.

TERTIARY SYPHILIS After a latent period of appearance of secondary lesions and about 2-3 years following first exposure, tertiary lesions of syphilis appear. Lesions of tertiary syphilis are much less infective than the other two stages and spirochaetes can be demonstrated with great difficulty. These lesions are of 2 main types (**Fig. 5.36,C**):

i) Syphilitic gumma It is a solitary, localised, rubbery lesion with central necrosis, seen in organs like liver, testis, bone and brain. In the liver, the gumma is associated with scarring of hepatic parenchyma (*hepar lobatum*).

Histologically, the structure of gumma shows the following features (**Fig. 5.37**):

a) Central coagulative necrosis resembling caseation but is less destructive so that outlines of necrosed cells can still be faintly seen.

b) Surrounding zone of palisaded macrophages with many plasma cells, some lymphocytes, giant cells and fibroblasts.

ii) Diffuse lesions of tertiary syphilis The lesions appear following widespread dissemination of spirochaetes in the body. The diffuse lesions are predominantly seen in cardiovascular and nervous systems which are described in detail later in the relevant chapters. Briefly, these lesions are as under:

a) *Cardiovascular syphilis* mainly involves thoracic aorta. The wall of aorta is weakened and dilated due to syphilitic aortitis and results in aortic aneurysm, incompetence of aortic valve and narrowing of mouths of coronary ostia (page 381).

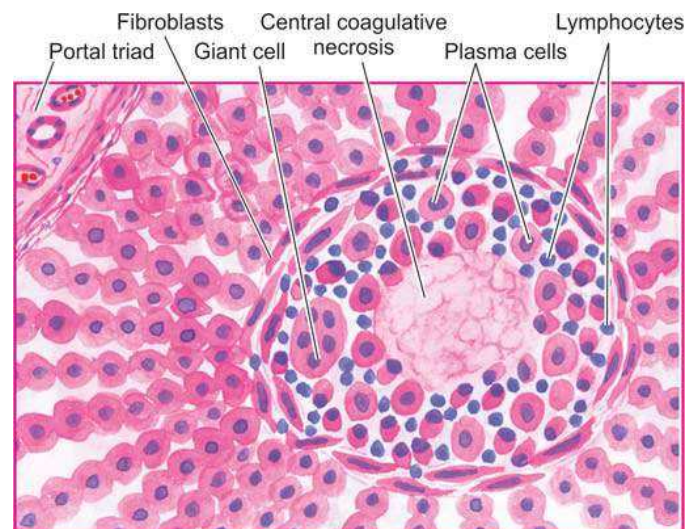

Figure 5.37 Typical microscopic appearance in the case of syphilitic gumma of the liver. Central coagulative necrosis is surrounded by palisades of macrophages and plasma cells margined peripherally by fibroblasts.

- b) *Neurosyphilis* may manifest as:
- ◆ meningovascular syphilis affecting chiefly the meninges;
 - ◆ tabes dorsalis affecting the spinal cord; and
 - ◆ general paresis affecting the brain.

CONGENITAL SYPHILIS Congenital syphilis may develop in a foetus of more than 16 weeks gestation who is exposed to maternal spirochaetaemia. The major morphologic features are as under:

- i) Saddle-shaped nose deformity due to destruction of bridge of the nose.
- ii) The characteristic 'Hutchinson's teeth' which are small, widely spaced, peg-shaped permanent teeth.
- iii) Mucocutaneous lesions of acquired secondary syphilis.
- iv) Bony lesions like epiphysitis and periostitis.
- v) Interstitial keratitis with corneal opacity.
- vi) Diffuse fibrosis in the liver.
- vii) Interstitial fibrosis of lungs.
- viii) If the foetus with congenital syphilis is born dead, it is premature, with macerated skin, enlarged spleen and liver, and with syphilitic epiphysitis.

Histologically, the basic morphology of lesions in syphilis is seen in all the affected organs: perivascular plasma cell rich inflammatory infiltrate and endothelial cell proliferation. Many spirochaetes can be demonstrated in involved tissues.

GIST BOX 5.10 Syphilis

- ▣ Syphilis is a venereal (sexually-transmitted) disease caused by spirochaetes, *Treponema pallidum*, most often by sexual intercourse.
- ▣ The organism can be demonstrated directly in tissue fluids by dark ground immunisation, fluorescent method. Supportive laboratory tests are antibody tests such as VDRL, STS, FTA.
- ▣ Syphilis has 3 clinicopathologic stages: primary, secondary and tertiary. Characteristically, these lesions are plasma cell rich.
- ▣ Typical lesion of primary syphilis is *chancre* which appears on genitals or at extra-genital sites in 2-4 weeks after exposure to infection. These lesions are positive for spirochaetes.
- ▣ Secondary syphilis has mucocutaneous lesions and painless lymphadenopathy. Spirochaetes may be seen in the lesions.
- ▣ Tertiary stage occurs after a latent period lasting 2-3 years and its lesions are in form of gummas (in liver or testis), and as diffuse lesions (cardiovascular and neurosyphilis).
- ▣ Babies with congenital syphilis have saddle nose deformity and wide short teeth.

ACTINOMYCOSIS

Actinomycosis is a chronic suppurative disease caused by anaerobic bacteria, *Actinomyces israelii*. The disease is conventionally included in mycology though the causative organism is filamentous bacteria and not true fungus although its name sounds like one. The disease is worldwide in distribution. The organisms are commensals in the oral cavity, alimentary tract and vagina. The infection is always endogeneous in origin and not by person-to-person contact. The organisms invade,

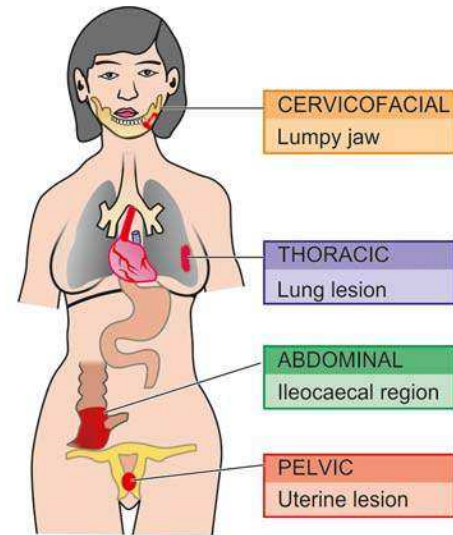

Figure 5.38 Actinomycosis, sites and routes of infection.

proliferate and disseminate in favourable conditions like break in mucocutaneous continuity, some underlying disease etc.

MORPHOLOGIC FEATURES Depending upon the anatomic location of lesions, actinomycosis is of 4 types: cervicofacial, thoracic, abdominal, and pelvic (**Fig. 5.38**).

1. Cervicofacial actinomycosis. This is the commonest form (60%) and has the best prognosis. The infection enters from tonsils, carious teeth, periodontal disease or trauma following tooth extraction. Initially, a firm swelling develops in the lower jaw ('lumpy jaw'). In time, the mass breaks down and abscesses and sinuses are formed. The discharging pus contains typical tiny yellow sulphur granules. The infection may extend into adjoining soft tissues and may destroy the bone.

2. Thoracic actinomycosis. The infection in the lungs is due to aspiration of the organism from oral cavity or extension of infection from abdominal or hepatic lesions. Initially, the disease resembles pneumonia but subsequently the infection spreads to the whole of lung, pleura, ribs and vertebrae.

3. Abdominal actinomycosis. This type is common in appendix, caecum and liver. The abdominal infection results from swallowing of organisms from oral cavity or extension from thoracic cavity.

4. Pelvic actinomycosis. Infection in the pelvis occurs as a complication of intrauterine contraceptive devices (IUCDs).

Microscopically, irrespective of the location of actinomycosis, the following features are seen (**Fig. 5.39**):

- i) The inflammatory reaction is a granuloma with central suppuration. There is formation of abscesses in the centre of lesions and at the periphery chronic inflammatory cells, giant cells and fibroblasts are seen.
- ii) The centre of each abscess contains the bacterial colony, 'sulphur granule', characterised by radiating filaments (hence previously known as *ray fungus*) with hyaline, eosinophilic, club-like ends representing secreted immunoglobulins.
- iii) Bacterial stains reveal the organisms as gram-positive filaments, nonacid-fast, which stain positively with Gomori's methenamine silver (GMS) staining.

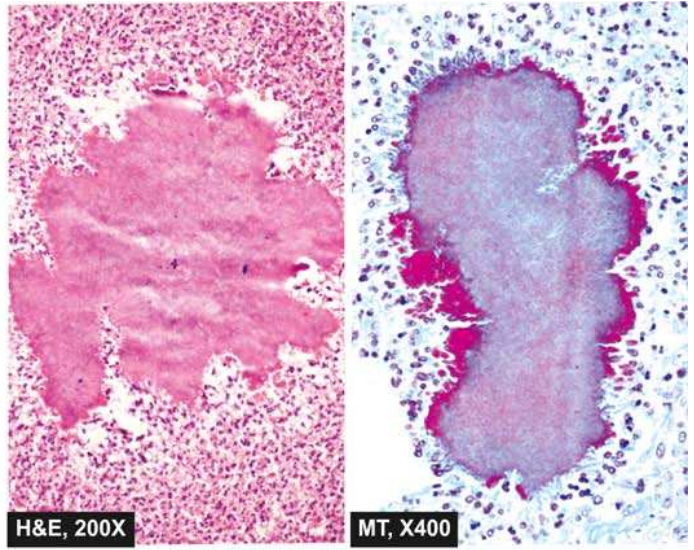

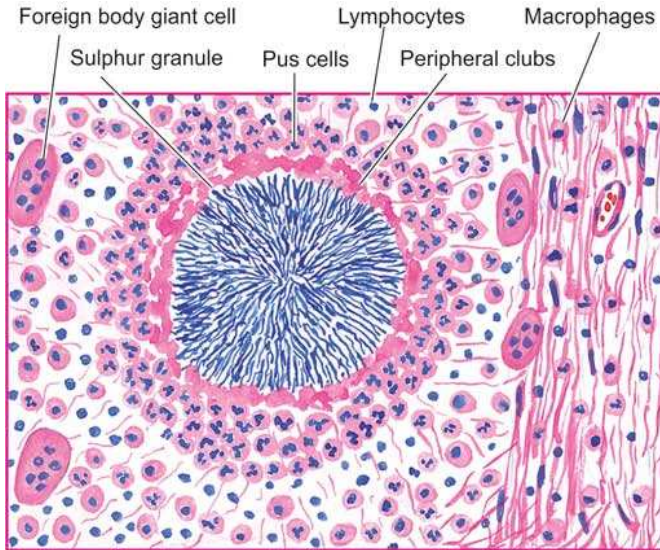

Figure 5.39 Actinomycosis. Microscopic appearance of sulphur granule lying inside an abscess. The margin of the colony shows hyaline filaments highlighted by Masson's trichrome stain (right photomicrograph).

GIST BOX 5.11 Actinomycosis

- ☐ Actinomycosis is a chronic suppurative disease caused by *Actinomyces israelii*. Though the name of disease sounds like a fungus, it is caused by anaerobic bacteria.
- ☐ Depending upon the anatomic location, actinomycosis is of 4 types: cervicofacial (commonest as lumpy jaw), thoracic, abdominal, and pelvic.
- ☐ Microscopically, the lesions have an abscess containing the bacterial colony as sulphur granule.

SARCOIDOSIS (BOECK'S SARCOID)

Sarcoidosis is a multisystem disease of unknown etiology. It is worldwide in distribution and affects adults from 20-40 years of age. The disease may be asymptomatic or may have organ dysfunction such as respiratory complaints or cutaneous or ocular lesions. The disease is characterised by the presence of non-caseating epithelioid cell granulomas ('sarcoid granuloma') in the affected tissues and organs, notably lymph nodes, lungs and skin. Other sites are the uvea of the eyes, spleen, salivary glands, liver and bones of hands and feet.

ETIOLOGY AND PATHOGENESIS The cause of sarcoidosis remains unknown. However, the disease has immune pathogenesis but the antigenic trigger that stimulates the disease process is still unknown. No single etiologic agent or consistent genetic locus has been identified. However, the disease appears to involve 3 interlinked factors:

1. Disturbed immune system
2. Genetic predisposition
3. Exposure to environmental agent

1. Disturbed immune system The disease is characterised by granulomatous tissue reaction, indicative of expression of cell-mediated immune mechanism.

◆ Antigen-presenting cells (i.e. macrophages) present an unknown antigen to helper T cells.

◆ These clusters of macrophages and helper T cells on activation release several cytokines—IL-2, IFN- γ , IL-8, IL-10, IL-12, IL-18 and TNF.

◆ These multiple cytokines form the granuloma in which macrophages predominate but T cells have a necessary role in initial inflammatory reaction.

2. Genetic predisposition Although no consistent genetic loci have been found, there is increased risk of development of sarcoidosis in certain HLA haplotype, HLA-DRB1, HLA-A1, HLA-B8.

3. Exposure to environmental agent The environmental agent acting as antigen which initiates the immunologic response has eluded the workers. Infectious agents have been suspected; these include mycobacteria or their antigenic proteins, *Propionibacter acnes*, rickettsia, and atypical mycobacteria.

KVEIM'S TEST It is a useful intradermal diagnostic test based on immune pathogenesis of disease. The antigen prepared from involved lymph node or spleen is injected intradermally. In a positive test, nodular lesion appears in 3-6 weeks at the inoculation site which on microscopic examination shows presence of non-caseating granulomas.

MORPHOLOGIC FEATURES The lesions in sarcoidosis are generalised and may affect various organs and tissues at sometime in the course of disease, but brunt of the disease is borne by the lungs and lymph nodes (**Fig. 5.40**).

Microscopically, the diagnosis is generally made by exclusion of other causes of granulomatous inflammation. However, following features are seen (**Fig. 5.41**):

1. The diagnostic feature in sarcoidosis of any organ or tissue is the *non-caseating sarcoid granuloma*, composed of epithelioid cells, Langhans' and foreign body giant cells and surrounded peripherally by fibroblasts. However, at times fibrinoid necrosis may be seen in the centre of granuloma.

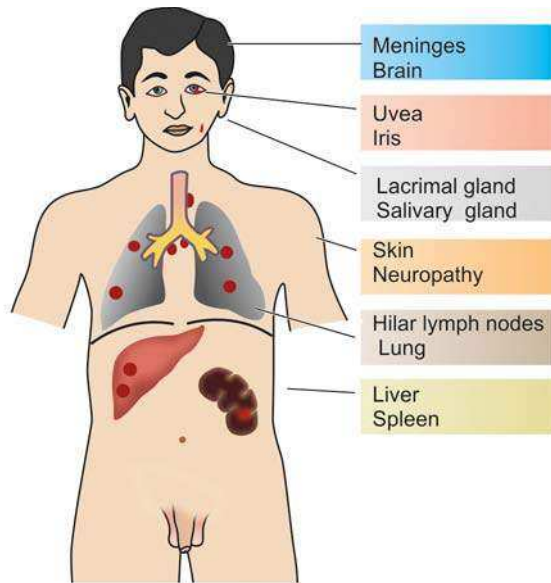

Figure 5.40 Common location of lesions in sarcoidosis. The lesions are predominantly seen in lymph nodes and throughout lung parenchyma.

2. Typically, granulomas of sarcoidosis are 'naked' i.e. either devoid of peripheral rim of lymphocytes or there is paucity of lymphocytes.

3. In late stage, the granuloma is either *enclosed by hyalinised fibrous tissue* or is replaced by hyalinised fibrous mass.

4. The giant cells in sarcoid granulomas contain certain *cytoplasmic inclusions* as follows:

i) *Asteroid bodies* which are eosinophilic and stellate-shaped structures.

ii) *Schaumann's bodies or conchoid (conch like) bodies* which are concentric laminations of calcium and of iron salts, complexed with proteins.

iii) *Birefringent cytoplasmic crystals* which are colourless. Similar types of inclusions are also observed in chronic berylliosis (page 474).

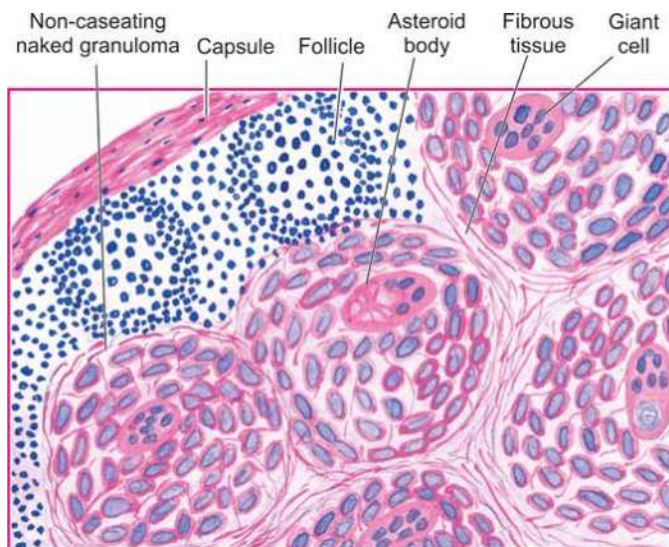

Figure 5.41 Sarcoidosis in lymph node. Characteristically, there are non-caseating epithelioid cell granulomas which have paucity of lymphocytes. A giant cell with inclusions is also seen in the photomicrograph (arrow).

GIST BOX 5.12 Sarcoidosis

- ▣ Sarcoidosis is a multisystem disease of unknown etiology. It is worldwide in distribution and affects adults from 20-40 years of age.
- ▣ The disease is characterised by the presence of non-caseating epithelioid cell granulomas ('sarcoid granuloma') in the affected tissues and organs, notably lymph nodes, lungs, skin and eyes.
- ▣ The cause of sarcoidosis remains unknown. However, the disease has immune pathogenesis and involves interplay of 3 factors: disturbed cellular immune function, genetic predisposition and exposure to an unknown environmental agent.

HEALING

Healing is the body's response to injury in an attempt to restore normal structure and function. It involves 2 processes:

◆ *Regeneration* when healing takes place by proliferation of parenchymal cells and usually results in complete restoration of the original tissues.

◆ *Repair* when healing takes place by proliferation of connective tissue resulting in fibrosis and scarring.

At times, both these processes take place simultaneously.

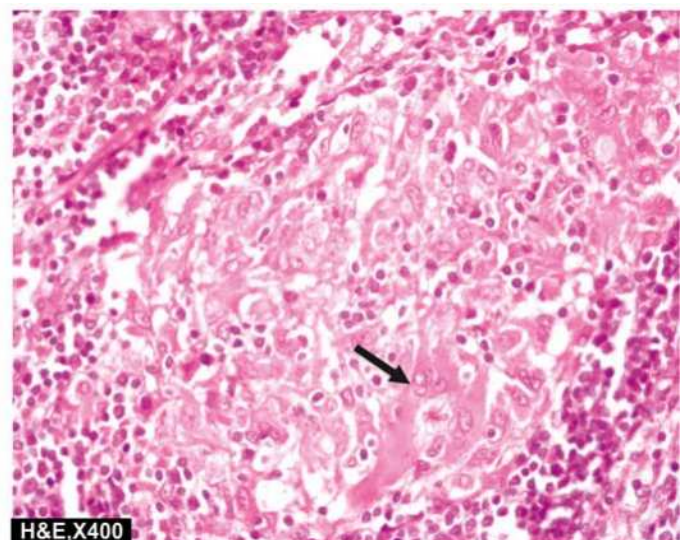

REGENERATION AND REPAIR

REGENERATION

Some parenchymal cells are short-lived while others have a longer lifespan. In order to maintain proper structure of tissues, these cells are under the constant regulatory control of their cell cycle. These include growth factors such as: epidermal growth factor, fibroblast growth factor, platelet-derived growth factor, endothelial growth factor, transforming growth factor- β .

Cell cycle is defined as the period between two successive cell divisions and is divided into 4 unequal phases (**Fig. 5.42**):

◆ *M (mitosis) phase*: Phase of mitosis.

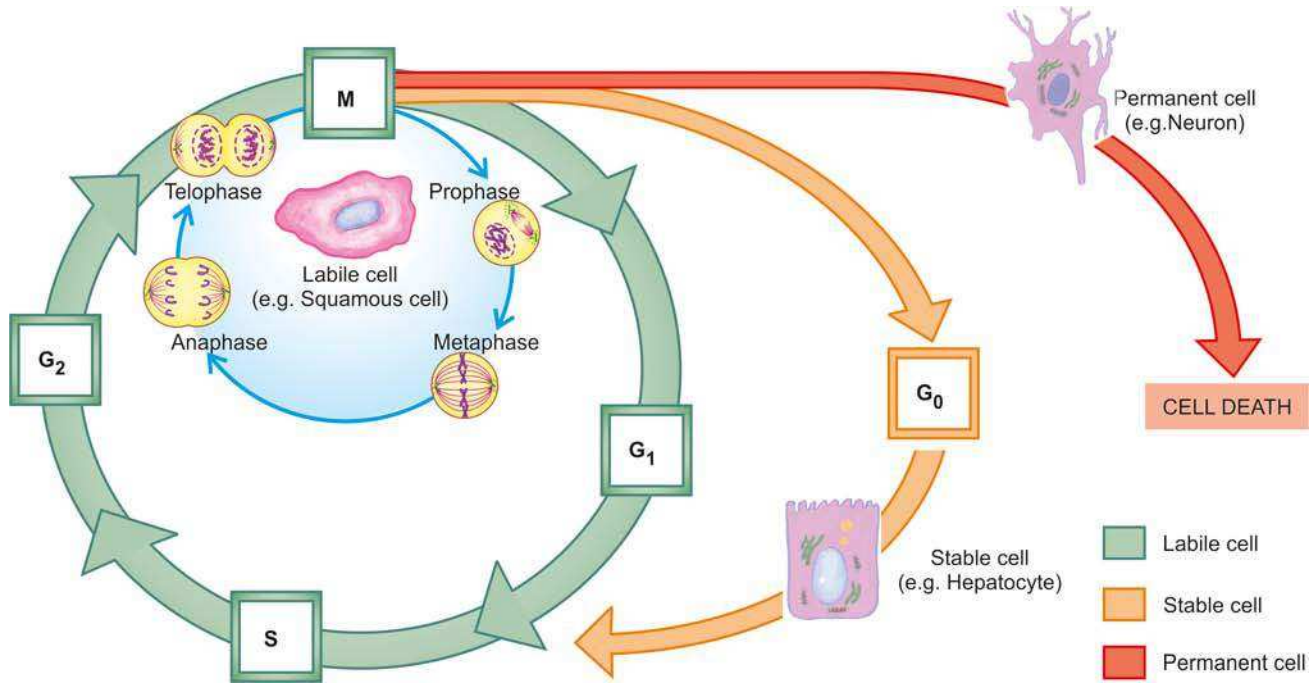

Figure 5.42 Parenchymal cells in relation to cell cycle (G_0 —Resting phase; G_1 , G_2 —Gaps; S—Synthesis phase; M—Mitosis phase). The inner circle shown with green line represents cell cycle for labile cells; circle shown with yellow-orange line represents cell cycle for stable cells; and the circle shown with red line represents cell cycle for permanent cells. Compare them with traffic signals—green stands for ‘go’ applies here to dividing labile cells; yellow-orange signal for ‘ready to go’ applies here to stable cells which can be stimulated to enter cell cycle; and red signal for ‘stop’ here means non-dividing permanent cells.

- ◆ **G_1 (gap 1) phase:** The daughter cell enters G_1 phase after mitosis.
- ◆ **S (synthesis) phase:** During this phase, the synthesis of nuclear DNA takes place.
- ◆ **G_2 (gap 2) phase:** After completion of nuclear DNA duplication, the cell enters G_2 phase.
- ◆ **G_0 (gap 0) phase:** This is the quiescent or resting phase of the cell after an M phase.
- ◆ Period between the mitosis is called *interphase*.

Not all cells of the body divide at the same pace. Some mature cells do not divide at all while others complete a cell cycle every 16-24 hours. The main difference between slowly-dividing and rapidly-dividing cells is the duration of G_1 phase.

Depending upon their capacity to divide, the cells of the body can be divided into 3 groups: labile cells, stable cells, and permanent cells.

1. Labile cells These cells continue to multiply throughout life under normal physiologic conditions. These include: surface epithelial cells of the epidermis, alimentary tract, respiratory tract, urinary tract, vagina, cervix, uterine endometrium, haematopoietic cells of bone marrow and cells of lymph nodes and spleen.

2. Stable cells These cells decrease or lose their ability to proliferate after adolescence but retain the capacity to multiply in response to stimuli throughout adult life. These include: parenchymal cells of organs like liver, pancreas, kidneys, adrenal and thyroid; mesenchymal cells like smooth muscle cells, fibroblasts, vascular endothelium, bone and cartilage cells.

3. Permanent cells These cells lose their ability to proliferate around the time of birth. These include: neurons of nervous system, skeletal muscle and cardiac muscle cells.

RELATIONSHIP OF PARENCHYMAL CELLS WITH CELL CYCLE If the three types of parenchymal cells described above are correlated with the phase of cell cycle, following inferences can be derived (Fig. 5.42):

1. Labile cells which are continuously dividing cells remain in the cell cycle from one mitosis to the next.
2. Stable cells are in the resting phase (G_0) but can be stimulated to enter the cell cycle.
3. Permanent cells are non-dividing cells which have left the cell cycle and die after injury.

Regeneration of any type of parenchymal cells involves the following 2 processes:

- i) Proliferation of original cells from the margin of injury with migration so as to cover the gap.
- ii) Proliferation of migrated cells with subsequent differentiation and maturation so as to reconstitute the original tissue.

CELL CYCLE SIGNALING PATHWAYS Mitosis is controlled by genes which encode for release of specific protein molecules that promote or inhibit the process of mitosis at different steps. Mitosis-promoting protein molecules are *cyclins A, B and E*. These cyclins activate *cyclin-dependent kinases (CDKs)* which act in conjunction with cyclins. After the mitosis is complete, cyclins and CDKs are degraded and the residues of used molecules are taken up by cytoplasmic caretaker proteins, *ubiquitin*, to the peroxisome for further degradation.

REPAIR

Repair is the replacement of injured tissue by fibrous tissue. Two processes are involved in repair:

- ◆ Granulation tissue formation
- ◆ Contraction of wounds

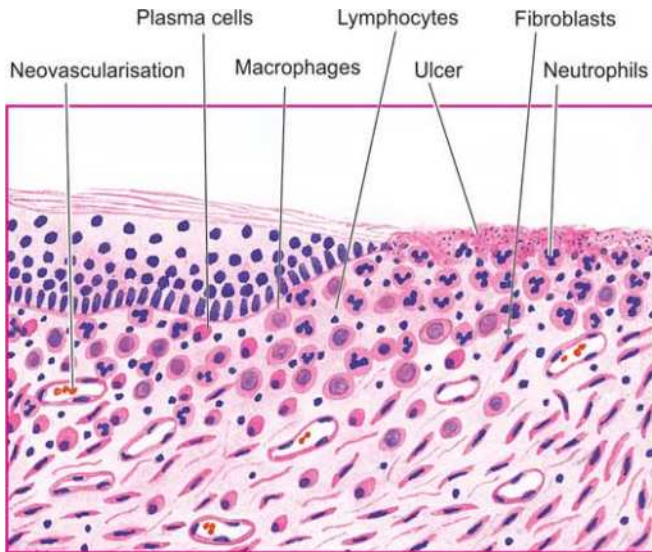

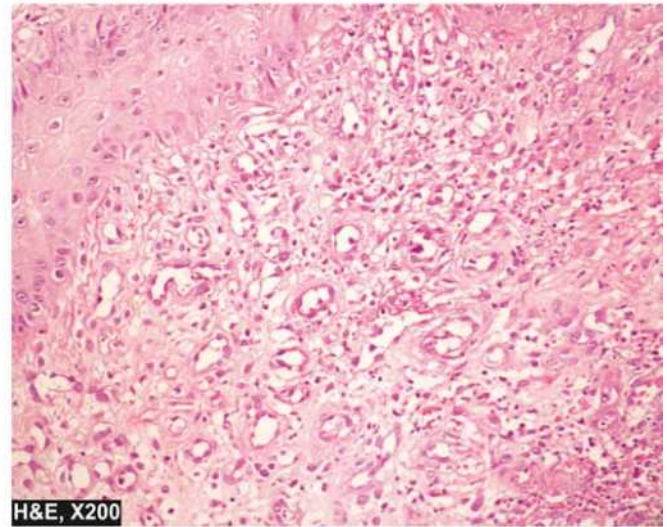

Figure 5.43 Active granulation tissue has inflammatory cell infiltrate, newly formed blood vessels and young fibrous tissue in loose matrix.

Repair response takes place by participation of mesenchymal cells (consisting of connective tissue stem cells, fibrocytes and histiocytes), endothelial cells, macrophages, platelets, and the parenchymal cells of the injured organ.

Granulation Tissue Formation

The term granulation tissue derives its name from slightly granular and pink appearance of the tissue. Each granule corresponds histologically to proliferation of new small blood vessels which are slightly lifted on the surface by thin covering of fibroblasts and young collagen.

The following 3 phases are observed in the formation of granulation tissue (**Fig. 5.43**):

1. PHASE OF INFLAMMATION Following trauma, blood clots at the site of injury. There is acute inflammatory response with exudation of plasma, neutrophils and some monocytes within 24 hours.

2. PHASE OF CLEARANCE Combination of proteolytic enzymes liberated from neutrophils, autolytic enzymes from dead tissues cells, and phagocytic activity of macrophages clear off the necrotic tissue, debris and red blood cells.

3. PHASE OF INGROWTH OF GRANULATION TISSUE This phase consists of 2 main processes: angiogenesis or neovascularisation, and fibrogenesis.

i) Angiogenesis (neovascularisation) Formation of new blood vessels at the site of injury takes place by proliferation of endothelial cells from the margins of severed blood vessels. Initially, the proliferated endothelial cells are solid buds but within a few hours develop a lumen and start carrying blood. The newly formed blood vessels are more leaky, accounting for the oedematous appearance of new granulation tissue. Soon, these blood vessels differentiate into muscular arterioles, thin-walled venules and true capillaries.

The process of angiogenesis is stimulated with proteolytic destruction of basement membrane. Angiogenesis takes place under the influence of following factors:

a) Vascular endothelial growth factor (VEGF) elaborated by

mesenchymal cells while its receptors are present in endothelial cells only.

b) Platelet-derived growth factor (PDGF), transforming growth factor- β (TGF- β), basic fibroblast growth factor (bFGF) and surface integrins are all associated with cellular proliferation.

ii) Fibrogenesis The newly formed blood vessels are present in an amorphous ground substance or matrix. The new fibroblasts have features intermediate between those of fibroblasts and smooth muscle cells (*myofibroblasts*). Collagen fibrils begin to appear by about 6th day. The myofibroblasts have surface receptors for fibronectin molecules which form bridges between collagen fibrils. As maturation proceeds, more and more collagen is formed while the number of active fibroblasts and new blood vessels decreases. This results in formation of inactive looking scar; this process is known as *cicatrization*.

GIST BOX 5.13 Healing: Regeneration and Repair

- ☐ Healing is the body's response to injury in an attempt to restore normal structure and function. It involves 2 processes: regeneration and repair.
- ☐ Regeneration is restoration to original tissue by proliferation of parenchymal cells while repair is healing by proliferation of connective tissue resulting in fibrosis and scarring.
- ☐ Regeneration depends upon the dividing ability of parenchymal cells. Labile cells continue to divide throughout life (e.g. epidermis, mucosa), stable cells decrease or lose their ability to proliferate (e.g. liver, kidneys) while permanent cells cease to regenerate around the time of birth (e.g. neurons, myocardium).
- ☐ Repair is healing by formation of granulation tissue. It involves initial inflammatory reaction by the body, followed by clearance by proteolytic enzymes, and phase of angiogenesis and proliferation of fibroblasts.

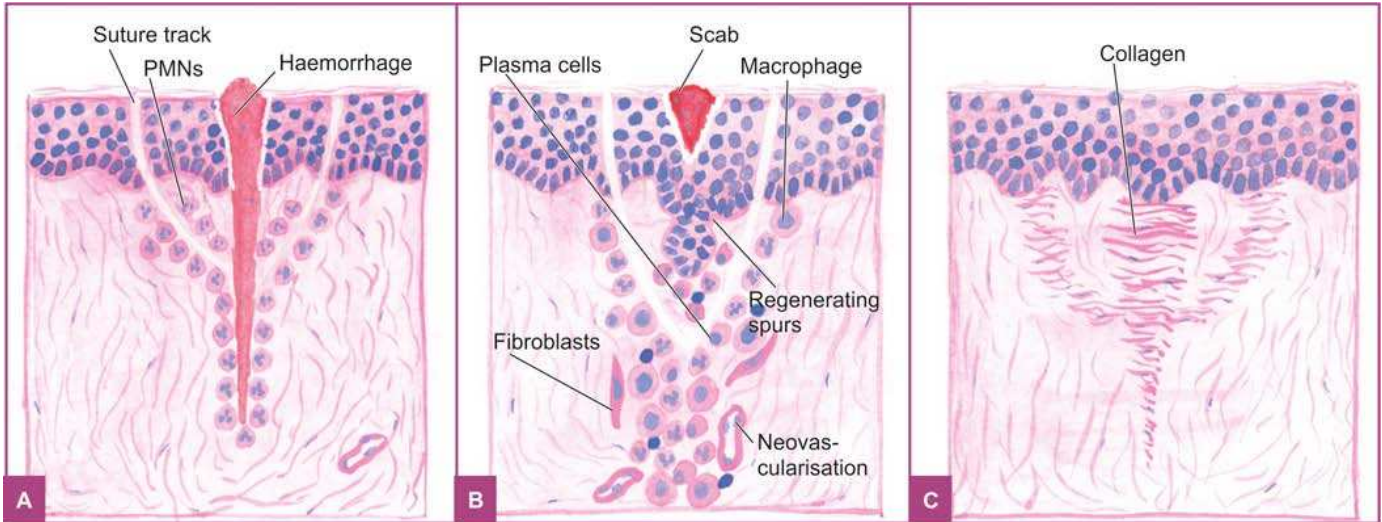

Figure 5.44 Primary union of skin wounds. A, The incised wound as well as suture track on either side are filled with blood clot and there is inflammatory response from the margins. B, Spurs of epidermal cells migrate along the incised margin on either side as well as around the suture track. Formation of granulation tissue also begins from below. C, Removal of suture at around 7th day results in scar tissue at the sites of incision and suture track.

HEALING OF SKIN WOUNDS

Healing of skin wounds provides a classical example of combination of regeneration and repair described above. Wound healing can be accomplished in one of the following two ways:

- ◆ Healing by first intention (*primary union*)
- ◆ Healing by second intention (*secondary union*).

HEALING BY FIRST INTENTION (PRIMARY UNION)

This is defined as healing of a wound which has the following characteristics:

- i) clean and uninfected;
- ii) surgically incised;
- iii) without much loss of cells and tissue; and
- iv) edges of wound are approximated by surgical sutures.

The sequence of events in primary union is illustrated in **Fig. 5.44** and described below:

1. Initial haemorrhage Immediately after injury, the space between the approximated surfaces of incised wound is filled with blood which then clots and seals the wound against dehydration and infection.

2. Acute inflammatory response This occurs within 24 hours with appearance of polymorphs from the margins of incision. By 3rd day, polymorphs are replaced by macrophages.

3. Epithelial changes The basal cells of epidermis from both the cut margins start proliferating and migrating towards incisional space in the form of epithelial spurs. A well-approximated wound is covered by a layer of epithelium in 48 hours. The migrated epidermal cells separate the underlying viable dermis from the overlying necrotic material and clot, forming *scab* which is cast off. The basal cells from the margins continue to divide. By 5th day, a multilayered new epidermis is formed which is differentiated into superficial and deeper layers.

4. Organisation By 3rd day, fibroblasts also invade the wound area. By 5th day, new collagen fibrils start forming which dominate till healing is completed. In 4 weeks, the scar tissue

with scanty cellular and vascular elements, a few inflammatory cells and epithelialised surface is formed.

5. Suture tracks Each suture track is a separate wound and incites the same phenomena as in healing of the primary wound i.e. filling the space with haemorrhage, some inflammatory cell reaction, epithelial cell proliferation along the suture track from both margins, fibroblastic proliferation and formation of young collagen. When sutures are removed around 7th day, much of epithelialised suture track is avulsed and the remaining epithelial tissue in the track is absorbed. However, sometimes the suture track gets infected (*stitch abscess*), or the epithelial cells may persist in the track (*implantation or epidermal cysts*).

Thus, the scar formed in a sutured wound is neat due to close apposition of the margins of wound; the use of adhesive tapes or metal clips avoids removal of stitches and its complications.

HEALING BY SECOND INTENTION (SECONDARY UNION)

This is defined as healing of a wound having the following characteristics:

- i) open with a large tissue defect, at times infected;
- ii) having extensive loss of cells and tissues; and
- iii) the wound is not approximated by surgical sutures but is left open.

The basic events in secondary union are similar to primary union but differ in having a larger tissue defect which has to be bridged. Hence, healing takes place from the base upward and also from the margins inwards. Healing by second intention is slow and results in a large, at times ugly, scar as compared to rapid healing and neat scar of primary union.

The sequence of events in secondary union is illustrated in **Fig. 5.45** and described below:

1. Initial haemorrhage As a result of injury, the wound space is filled with blood and fibrin clot which dries.

2. Inflammatory phase There is an initial acute inflammatory response followed by appearance of macrophages which clear off the debris as in primary union.

3. Epithelial changes As in primary healing, the epidermal cells from both the margins of wound proliferate and migrate

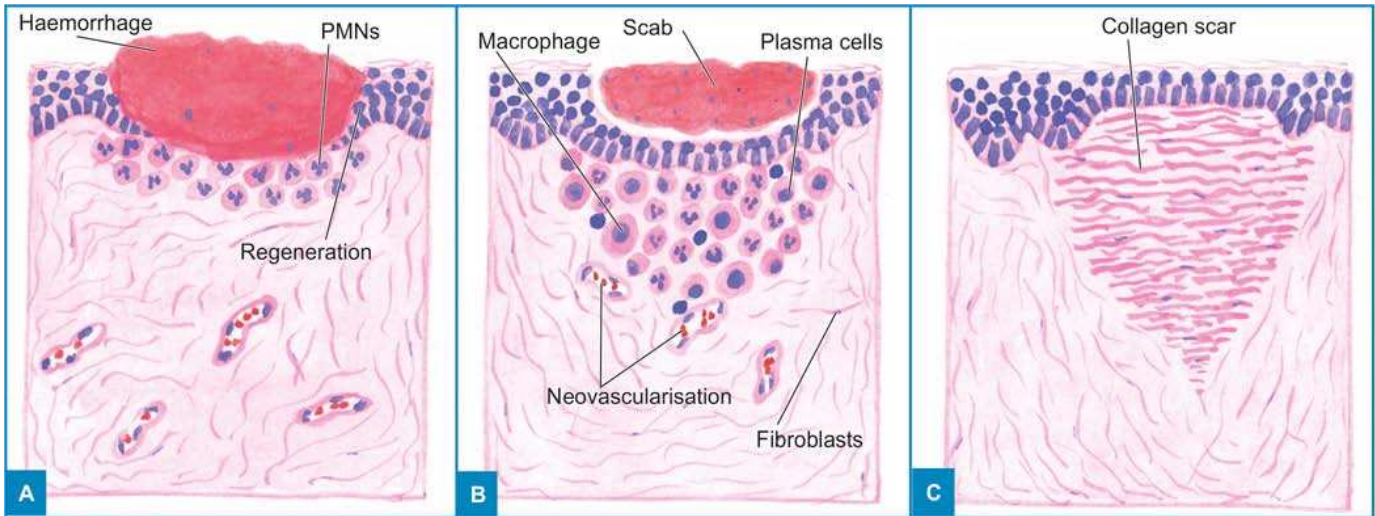

Figure 5.45 Secondary union of skin wounds. A, The open wound is filled with blood clot and there is inflammatory response at the junction of viable tissue. B, Epithelial spurs from the margins of wound meet in the middle to cover the gap and separate the underlying viable tissue from necrotic tissue at the surface forming scab. C, After contraction of the wound, a scar smaller than the original wound is left.

into the wound in the form of epithelial spurs till they meet in the middle and re-epithelialise the gap completely. However, the proliferating epithelial cells do not cover the surface fully until granulation tissue from base has started filling the wound space. In this way, pre-existing viable connective tissue is separated from necrotic material and clot on the surface, forming *scab* which is cast off. In time, the regenerated epidermis becomes stratified and keratinised.

4. Granulation tissue Main bulk of secondary healing is by granulations. Granulation tissue is formed by proliferation of fibroblasts and neovascularisation from the adjoining viable elements. The newly-formed granulation tissue is deep red, granular and very fragile. With time, the scar on maturation becomes pale and white due to increase in collagen and decrease in vascularity. Specialised structures of the skin like hair follicles and sweat glands are not replaced unless their viable residues remain which may regenerate.

5. Wound contraction Contraction of wound is an important feature of secondary healing, not seen in primary healing. Due to the action of myofibroblasts present in granulation tissue, the wound contracts to one-third to one-fourth of its original size.

6. Presence of infection Bacterial contamination of an open wound delays the process of healing due to release of bacterial toxins that provoke necrosis, suppuration and thrombosis.

Surgical removal of dead and necrosed tissue, *debridement*, helps in preventing the bacterial infection of open wounds.

Differences between primary and secondary union of wounds are given in **Table 5.9**.

COMPLICATIONS OF WOUND HEALING

During the course of healing, following complications may occur:

- 1. Infection** The wound may get infected due to entry of bacteria delays the healing.
- 2. Implantation (epidermal) cyst** Formation of implantation epidermoid cyst may occur due to persistence of epithelial cells in the wound after healing.
- 3. Pigmentation** Healed wounds may at times have rust-like colour due to staining with haemosiderin. Some coloured particulate material left in the wound may persist and impart colour to the healed wound.
- 4. Deficient scar formation** This may occur due to inadequate formation of granulation tissue.
- 5. Incisional hernia** A weak scar, especially after a laparotomy, may be the site of bursting open of a wound (wound dehiscence) or an incisional hernia.
- 6. Hypertrophied scars and keloid formation** At times the scar formed is excessive, ugly and painful. Excessive formation of collagen in healing may result in keloid (*claw-like*) formation,

Table 5.9 Differences between primary and secondary union of wounds.

| FEATURE | PRIMARY UNION | SECONDARY UNION |
|-------------------------|--|--|
| 1. Cleanliness of wound | Clean | Unclean |
| 2. Infection | Generally uninfected | May be infected |
| 3. Margins | Surgical clean | Irregular |
| 4. Sutures | Used | Not used |
| 5. Healing | Scanty granulation tissue at the incised gap and along suture tracks | Exuberant granulation tissue to fill the gap |
| 6. Outcome | Neat linear scar | Contracted irregular wound |
| 7. Complications | Infrequent, epidermal inclusion cyst formation | Suppuration, may require debridement |

seen more commonly in Blacks. Hypertrophied scars differ from keloid in that they are confined to the borders of the initial wound while keloids have tumour-like projection of connective tissue.

7. *Excessive contraction* An exaggeration of wound contraction may result in formation of contractures or cicatrization e.g. Dupuytren's (palmar) contracture, plantar contracture and Peyronie's disease (contraction of the cavernous tissues of penis).

8. *Neoplasia* Rarely, scar may be the site for development of carcinoma later e.g. squamous cell carcinoma in Marjolin's ulcer i.e. a scar following burns on the skin.

EXTRACELLULAR MATRIX—WOUND CONTRACTION AND STRENGTH

The wound starts contracting after 2-3 days and the process is completed by the 14th day. During this period, the wound is reduced by approximately 80% of its original size. Contracted wound results in rapid healing since lesser surface area of the injured tissue has to be replaced. The wound is strengthened by proliferation of fibroblasts and myofibroblasts which get structural support from the extracellular matrix (ECM). In addition to providing structural support, ECM can direct cell migration, attachment, differentiation and organisation.

ECM is not a static structure but the matrix proteins comprising it undergo marked remodeling during foetal life which slows down in adult tissues. These matrix proteins are degraded by a family of metalloproteinases which act under regulatory control of inhibitors of metalloproteinases.

ECM has five main components: collagen, adhesive glycoproteins, basement membrane, elastic fibres, and proteoglycans.

1. COLLAGEN The collagens are a family of proteins which provide structural support to the multicellular organism. It is the main component of tissues such as fibrous tissue, bone, cartilage, valves of heart, cornea, basement membrane etc.

Collagen is synthesised and secreted by a complex biochemical mechanism on ribosomes. The collagen synthesis is stimulated by various growth factors and is degraded by collagenase. Regulation of collagen synthesis and degradation take place by various local and systemic factors so that the collagen content of normal organs remains constant. On the other hand, defective regulation of collagen synthesis leads to hypertrophied scar, fibrosis, and organ dysfunction.

Depending upon the biochemical composition, 18 types of collagen have been identified called collagen *type I to XVIII*, many of which are unique for specific tissues. Type I collagen is normally present in the skin, bone and tendons and accounts for 90% of collagen in the body:

◆ Type I, III and V are *true fibrillar collagen* which form the main portion of the connective tissue during healing of wounds in scars.

◆ Other types of collagen are *non-fibrillar* and amorphous material seen as component of the basement membranes.

Morphologically, the smallest units of collagen are *collagen fibrils*, which align together in parallel bundles to form *collagen fibres*, and then *collagen bundles*.

2. ADHESIVE GLYCOPROTEINS Various adhesive glycoproteins act as glue for the ECM and the cells. These consist of

fibronectin, tenascin (cytotactin) and thrombospondin.

i) Fibronectin (*nectere* = to bind) is the best characterised glycoprotein in ECM and has binding properties to other cells and ECM. It is of two types—plasma and tissue fibronectin.

◆ *Plasma fibronectin* is synthesised by the liver cells and is trapped in basement membrane such as during filtration through the renal glomerulus.

◆ *Tissue fibronectin* is formed by fibroblasts, endothelial cells and other mesenchymal cells. It is responsible for the primitive matrix such as in the foetus, and in wound healing.

ii) Tenascin or cytotactin is the glycoprotein associated with fibroblasts and appears in wound about 48 hours after injury. It disappears from mature scar tissue.

iii) Thrombospondin is mainly synthesised by granules of platelets. It functions as adhesive protein for keratinocytes and platelets but is inhibitory to attachment of fibroblasts and endothelial cells.

3. BASEMENT MEMBRANE Basement membranes are periodic acid-Schiff (PAS)-positive amorphous structures that lie underneath epithelia of different organs and endothelial cells. They consist of collagen type IV and laminin.

4. ELASTIC FIBRES While the tensile strength in tissue comes from collagen, the ability to recoil is provided by elastic fibres. Elastic fibres consist of 2 components—elastin glycoprotein and elastic microfibril. Elastases degrade the elastic tissue e.g. in inflammation, emphysema etc.

5. PROTEOGLYCAN These are a group of molecules having 2 components—an essential carbohydrate polymer (called polysaccharide or glycosaminoglycan), and a protein bound to it, and hence the name proteoglycan. Various proteoglycans are distributed in different tissues as under:

i) *Chondroitin sulphate*—abundant in cartilage, dermis

ii) *Heparan sulphate*—in basement membranes

iii) *Dermatan sulphate*—in dermis

iv) *Keratan sulphate*—in cartilage

v) *Hyaluronic acid*—in cartilage, dermis.

In wound healing, the deposition of proteoglycans precedes collagen laying.

The strength of wound also depends upon certain factors such as the site of injury, depth of incision and area of wound. After removal of stitches on around 7th day, the wound strength is approximately 10% which reaches 80% in about 3 months.

FACTORS INFLUENCING HEALING

Two types of factors influence the wound healing: those acting locally, and those acting in general.

A. LOCAL FACTORS:

1. *Infection* is the most important factor acting locally which delays the process of healing.

2. *Poor blood supply* to wound slows healing e.g. injuries to face heal quickly due to rich blood supply while injury to leg with varicose ulcers having poor blood supply heals slowly.

3. *Foreign bodies* including sutures interfere with healing and cause intense inflammatory reaction and infection.

4. *Movement* delays wound healing.

5. Exposure to *ionising radiation* delays granulation tissue formation.
6. Exposure to *ultraviolet light* facilitates healing.
7. *Type, size and location* of injury determines whether healing takes place by resolution or organisation.

B. SYSTEMIC FACTORS:

1. *Age*. Wound healing is rapid in young and somewhat slow in aged and debilitated people due to poor blood supply to the injured area in the latter.
2. *Nutrition*. Deficiency of constituents like protein, vitamin C (scurvy), vitamin A and zinc delays the wound healing.
3. *Systemic infection* delays wound healing.
4. *Administration of glucocorticoids* has anti-inflammatory effect.
5. *Uncontrolled diabetics* are more prone to develop infections and hence delay in healing.
6. *Haematologic abnormalities* like defect of neutrophil functions (chemotaxis and phagocytosis), and neutropenia and bleeding disorders slow the process of wound healing.

GIST BOX 5.14

Healing of Skin Wounds

- ☐ Healing of skin wounds can be accomplished by first intention (*primary union*) and by second intention (*secondary union*).
- ☐ Primary union is healing of a wound which is clean and uninfected, surgically incised, without much loss of cells and tissue. In this, edges of wound are approximated by surgical sutures.
- ☐ Secondary union of a wound is for open with a large tissue defect which are at times infected, having extensive loss of cells and tissues. Here, the wound is not approximated by surgical sutures.
- ☐ The basic events in both primary and secondary union are similar but differ in having a larger tissue defect in secondary union which has to be bridged. Hence, healing takes place from the base upward as well as from the margins inwards.
- ☐ The healing by second intention is slow and results in a large, at times ugly, scar as compared to rapid healing and neat scar of primary union.
- ☐ Complications of wound healing are infection, inclusion cyst formation, pigmentation, incisional hernia, hypertrophied scar and contracture.
- ☐ The wound is strengthened by proliferation of fibroblasts and myofibroblasts which get structural support from the extracellular matrix (ECM).
- ☐ ECM is comprised by collagen, adhesive glycoproteins, basement membrane, elastic tissue and proteoglycans.
- ☐ Various local and systemic factors may influence wound healing.

HEALING IN SPECIALISED TISSUES

Healing of the skin wound provides an example of general process of healing by regeneration and repair. However, in certain specialised tissues, either regeneration or repair may predominate. Some of these examples are described here.

FRACTURE HEALING

Healing of fracture by callus formation depends upon some clinical considerations whether the fracture is:

- ◆ *traumatic* (in previously normal bone), or *pathological* (in previously diseased bone);
- ◆ *complete or incomplete* like green-stick fracture; and
- ◆ *simple* (closed), *comminuted* (splintering of bone), or *compound* (communicating to skin surface).

However, basic events in healing of any type of fracture are similar and resemble healing of skin wound to some extent.

◆ **Primary union of fractures** occurs when the ends of fracture are approximated surgically by application of compression clamps or metal plates. In these cases, bony union takes place with formation of medullary callus without periosteal callus formation. The patient can be made ambulatory early but there is more extensive bone necrosis and slow healing.

◆ **Secondary union** is more common form of fracture healing when the plaster casts are applied for immobilisation of a fracture. Though it is a continuous process, secondary bone union is described under the following 3 headings:

- i) Procallus formation
- ii) Osseous callus formation
- iii) Remodelling

These processes are illustrated in **Fig. 5.46** and described below:

I. PROCALLUS FORMATION Steps involved in the formation of procallus are as follows:

1. Haematoma forms due to bleeding from torn blood vessels, filling the area surrounding the fracture. Loose meshwork is formed by blood and fibrin clot which acts as framework for subsequent granulation tissue formation.

2. Local inflammatory response occurs at the site of injury with exudation of fibrin, polymorphs and macrophages. The macrophages clear away the fibrin, red blood cells, inflammatory exudate and debris. Fragments of necrosed bone are scavenged by macrophages and osteoclasts.

3. Ingrowth of granulation tissue begins with neo-vascularisation and proliferation of mesenchymal cells from periosteum and endosteum. A soft tissue callus is thus formed which joins the ends of fractured bone without much strength.

4. Callus composed of woven bone and cartilage starts within the first few days. The cells of inner layer of the periosteum have osteogenic potential and lay down collagen as well as osteoid matrix in the granulation tissue (**Fig. 5.47**). The osteoid undergoes calcification and is called *woven bone callus*. A much wider zone over the cortex on either side of fractured ends is covered by the woven bone callus and united to bridge the gap between the ends, giving spindle-shaped or fusiform appearance to the union. In poorly immobilised fractures (e.g. fracture ribs), the subperiosteal osteoblasts may form cartilage at the fracture site. At times, callus is composed of woven bone as well as cartilage, temporarily immobilising the bone ends.

This stage is called provisional callus or procallus formation and is arbitrarily divided into *external*, *intermediate* and *internal procallus*.

II. OSSEOUS CALLUS FORMATION The procallus acts as scaffolding on which osseous callus composed of lamellar bone is formed. The woven bone is cleared away by incoming osteoclasts and the calcified cartilage disintegrates. In their

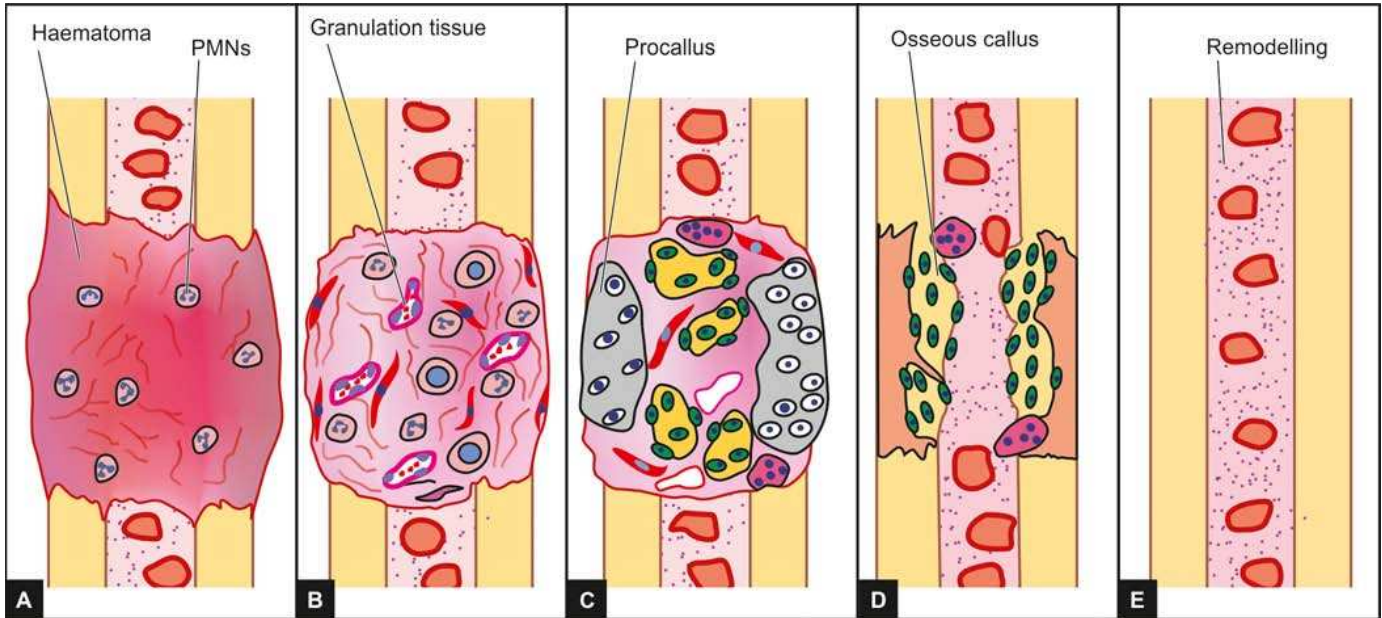

Figure 5.46 Fracture healing. A, Haematoma formation and local inflammatory response at the fracture site. B, Ingrowth of granulation tissue with formation of soft tissue callus. C, Formation of procallus composed of woven bone and cartilage with its characteristic fusiform appearance and having 3 arbitrary components—external, intermediate and internal callus. D, Formation of osseous callus composed of lamellar bone following clearance of woven bone and cartilage. E, Remodelled bone ends; the external callus cleared away. Intermediate callus converted into lamellar bone and internal callus developing bone marrow cavity.

place, newly-formed blood vessels and osteoblasts invade, laying down osteoid which is calcified and lamellar bone is formed by developing Haversian system concentrically around the blood vessels.

III. REMODELLING During the formation of lamellar bone, osteoblastic laying and osteoclastic removal are taking place remodelling the united bone ends, which after sometime, is indistinguishable from normal bone. The external callus is cleared away, compact bone (cortex) is formed in place of intermediate callus and the bone marrow cavity develops in internal callus.

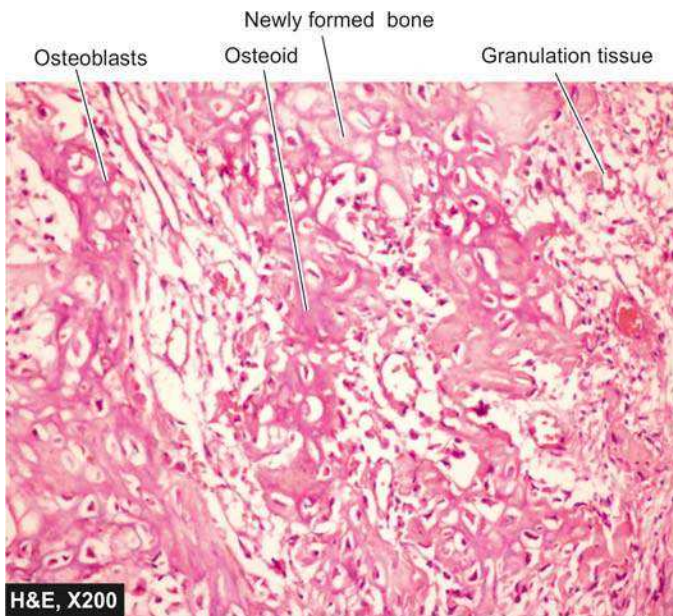

Figure 5.47 Callus formation in fracture healing.

Complications of Fracture Healing

These are as under:

- 1. Fibrous union** may result instead of osseous union if the immobilisation of fractured bone is not done. Occasionally, a false joint may develop at the fracture site (pseudo-arthritis).
- 2. Non-union** may result if some soft tissue is interposed between the fractured ends.
- 3. Delayed union** may occur from causes of delayed wound healing in general such as infection, inadequate blood supply, poor nutrition, movement and old age.

HEALING OF NERVOUS TISSUE

CENTRAL NERVOUS SYSTEM The nerve cells of the brain, spinal cord and ganglia are permanent cells, and therefore once destroyed are not replaced. Axons of CNS also do not show any significant regeneration. The damaged neuroglial cells, however, may show proliferation of astrocytes called gliosis.

PERIPHERAL NERVOUS SYSTEM In contrast to the cells of CNS, the peripheral nerves show limited regeneration, mainly from proliferation of Schwann cells and fibrils from distal end. The process is discussed in Chapter 28. Briefly, it consists of the following:

- Myelin sheath and axon of the intact distal nerve undergo Wallerian degeneration up to the next node of Ranvier towards the proximal end.
- Degenerated debris are cleared away by macrophages.
- Regeneration in the form of sprouting of fibrils takes place from the viable end of axon. These fibrils grow along the track of degenerated nerve so that in about 6-7 weeks, the peripheral stump consists of tube filled with elongated Schwann cells.
- One of the fibrils from the proximal stump enters the old neural tube and develops into new functional axon.

HEALING OF MUSCLE

SKELETAL MUSCLE The regeneration of striated muscle is similar to peripheral nerves. On injury, the cut ends of muscle fibres retract but are held together by stromal connective tissue. The injured site is filled with fibrinous material, polymorphs and macrophages. After clearance of damaged fibres by macrophages, one of the following two types of regeneration of muscle fibres can occur:

◆ If the muscle sheath is intact, sarcolemmal tubes containing histiocytes appear along the endomysial tube which, in about 3 months time, restores properly oriented muscle fibres e.g. in Zenker's degeneration of muscle in typhoid fever.

◆ If the muscle sheath is damaged, it forms a disorganised multinucleate mass and scar composed of fibrovascular tissue e.g. in Volkmann's ischaemic contracture.

SMOOTH MUSCLE Non-striated muscle has limited regenerative capacity e.g. appearance of smooth muscle in the arterioles in granulation tissue. However, in large destructive lesions, the smooth muscle is replaced by permanent scar tissue.

CARDIAC MUSCLE Destruction of heart muscle is replaced by fibrous tissue. However, in situations where the endomysium of individual cardiac fibre is intact (e.g. in diphtheria and coxsackie virus infections), regeneration of cardiac fibres may occur in young patients.

HEALING OF MUCOSAL SURFACES

The cells of mucosal surfaces have very good regeneration and are normally being lost and replaced continuously e.g. mucosa of alimentary tract, respiratory tract, urinary tract, uterine endometrium etc. This occurs by proliferation from margins, migration, multilayering and differentiation of epithelial cells in the same way as in the epidermal cells in healing of skin wounds.

HEALING OF SOLID EPITHELIAL ORGANS

Following gross tissue damage to organs like the kidney, liver and thyroid, the replacement is by fibrous scar e.g. in chronic pyelonephritis and cirrhosis of liver. However, in parenchymal cell damage with intact basement membrane or intact supporting stromal tissue, regeneration may occur. For example:

◆ *In tubular necrosis* of the kidney with intact basement membrane, proliferation and slow migration of tubular epithelial cells may occur to form renal tubules again.

◆ *In viral hepatitis*, if part of the liver lobule is damaged with intact stromal network, proliferation of hepatocytes may result in restoration of liver lobule.

GIST BOX 5.15 Healing in Specialised Tissues

- ▣ Fracture healing may be primary union when the ends of fracture are approximated as is done by application of compression clamps. In these cases, bony union takes place with formation of medullary callus without periosteal callus formation.
- ▣ Secondary union of fractures is more common and includes procallus and osseous callus formation followed by remodeling of the bone.

- ▣ While neurons of the brain and spinal cord lose their ability for regeneration and fail to get replaced, healing of peripheral nerves occurs from limited regeneration, mainly from proliferation of Schwann cells and fibrils from distal end.
- ▣ Regeneration of skeletal muscle is similar to peripheral nerves, while damaged myocardium heals by fibrosis. Smooth muscle, however, has limited regenerative capacity.
- ▣ Healing of mucosal surfaces is by regeneration of the epithelial surface and replaced continuously.
- ▣ Healing of organs such as kidneys, liver and thyroid is by limited regeneration and some healing by fibrosis.

STEM CELL CONCEPT OF HEALING—REGENERATIVE MEDICINE

Currently, the field of stem cell biology has emerged at the forefront of healing of injured tissue, treatment of diseases and holds promise for tissue transplantation in future.

Stem cells are the primitive cells which have 2 main properties:

- i) They have capacity for self renewal.
- ii) They can be coaxed into multilineage differentiation (i.e. into any of about 220 types of cells e.g. red cells, myocardial fibres, neurons etc).

Stem cells exist in both embryos and in adult tissues:

◆ In embryos, they function to generate new organs and tissues; their presence for organogenesis has been an established fact.

◆ In adults, they normally function to replace cells during the natural course of cell turnover. For example, stem cells in the bone marrow which spontaneously differentiate into mature haematopoietic cells has been known for a long time.

However, what is new about stem cells is as follows:

- i) Stem cells exist in almost all adult tissues called somatic stem cells and are less numerous.
- ii) Other sources of stem cells are embryos and umbilical cord blood; these stem cells are more numerous.
- iii) Stem cells can be harvested and grown in the laboratory into a desired cell lineage by transdifferentiation i.e. these cells are pleuropotent.
- iv) Homing of transfused stem cells is their innate ability to travel to the desired site in the body and thus they get engrafted there morphologically and functionally.

Some of the major clinical trials on applications of stem cells underway are in the following directions:

1. Bone marrow stem cells Haematopoietic stem cells, marrow stromal cells and stem cells sourced from umbilical cord blood have been used for treatment of various forms of blood cancers and other blood disorders for about three decades. However, their use for treatment of other diseases by transdifferentiation is relatively new.

2. Neuron stem cells These cells are capable of generating neurons, astrocytes and oligodendroglial cells. It may be possible to use these cells in neurodegenerative diseases such as Parkinsonism and Alzheimer's disease, and in spinal cord injury. Thus, the accepted concept that neurons do not regenerate may not hold true anymore.

3. Islet cell stem cells Clinical trials are under way for use of adult mesenchymal stem cells for islet cells in type 1 diabetes.

4. Cardiac stem cells It is now known that the heart has cardiac stem cells which have capacity to repair myocardium after infarction.

5. Skeletal muscle stem cells Although skeletal muscle cells do not divide when injured, stem cells of muscle have capacity to regenerate.

6. Adult eye stem cells The cornea of the eye contains stem cells in the region of limbus. These limbal stem cells have a potential therapeutic use in corneal opacities and damage to the conjunctiva.

7. Skin stem cells In the skin, the stem cells are located in the region of hair follicle and sebaceous glands. These stem cells contribute to repair of damaged epidermis. While healing in adults normally takes place with formation of scar and loss of hair, stem cells would elicit a response similar to wound healing in foetal tissue where the healing is by regeneration.

8. Liver stem cells In the liver, the stem cells are located in the canal of Hering which connects the bile ductules with hepatocytes. These cells can cause regeneration of fulminant damage to the liver or in chronic hepatitis.

9. Intestinal stem cells Crypts of the intestine contain stem cells which form the villi.

10. Lung tissue stem cells Clinical trials on the repair of injured lung parenchyma in patients of chronic obstructive pulmonary disease (COPD) is going on.

However, it may be mentioned here that except the bone marrow stem cell therapy, all other clinical trials to test the abilities of different types of stem cells to treat certain diseases and replace injured tissues are in experimental stage, costly and controversial, but are anticipated to have vast usefulness in future.

GIST BOX 5.16

Stem Cell Concept of Healing: Regenerative Medicine

- ☐ Stem cell biology is at the forefront of healing of injured tissue, treatment of diseases and holds promise for tissue transplantation in future.
- ☐ Stem cells are the primitive cells having capacity for self-renewal and that they can be modulated into multilineage differentiation.
- ☐ Stem cells exist in embryos where they are more numerous compared to those in adult tissues where they are fewer.
- ☐ Their presence in the bone marrow has been known for long and they have been used for blood cancers and other blood disorders.
- ☐ However, use of bone marrow stem cells for other diseases and sourcing of adult stem cells from other organs and their use for damaged organ is relatively new.

CLINICAL CASE 3

A 35 years old male truck driver reports to hospital emergency with high-grade fever, headache and productive cough and rapid breathing. He gives history of progressive fatigue and weight loss of about 20 kg during the last 6 months.

On examination, he has generalised lymphadenopathy and mild hepatosplenomegaly. The skin shows many warts on neck, hands and genitals. On auscultation, lung fields are clear and CVS examination is normal. CNS examination shows stiffness of neck, positive Kernig's sign. Fundus examination shows papilloedema.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 907 (Appendix II)

INTRODUCTION

Microorganisms, namely bacteria, viruses, fungi and parasites, are present everywhere—in the soil, water, atmosphere and on the body surfaces, and are responsible for a large number of infectious diseases in human beings. Some microorganisms are distributed throughout the world while others are limited to certain geographic regions only. In general, tropical and developing countries are particularly affected more by infectious diseases than the developed countries.

◆ There are several examples of certain *infectious diseases* which are not so common in the developed world now but they continue to be major health problems in the developing countries e.g. tuberculosis, leprosy, typhoid fever, cholera, measles, pertussis, malaria, amoebiasis, pneumonia etc.

◆ *Vaccines* have, however, been successful in controlling or eliminating some diseases all over the world e.g. smallpox, poliomyelitis, measles, pertussis etc. Similarly, insecticides have helped in controlling malaria to an extent.

◆ However, infections still rank very high *as a cause of death* in the world. Reasons for this trend are not difficult to seek:

- i) Development of newer and antibiotic-resistant strains of microorganisms; classic example is that of methicillin-resistant *Staph. aureus* (MRSA).
- ii) Administration of immunosuppressive therapy to patients with malignant tumours and transplanted organs making them susceptible to opportunistic infections
- iii) Increasing number of patients reporting to hospital for different illnesses but instead many developing hospital-acquired infections.
- iv) Lastly, discovery in 1981 of previously unknown deadly disease i.e. acquired immunodeficiency syndrome (AIDS) caused by human immunodeficiency virus (HIV).

While talking of microbial infective diseases, let us not forget the fact that many microorganisms may actually benefit mankind. Following is the range of *host-organism inter-relationship*, which may vary quite widely:

1. *Symbiosis* i.e. cooperative association between two dissimilar organisms beneficial to both.
2. *Commensalism* i.e. two dissimilar organisms living together benefitting one without harming the other.
3. *True parasitism* i.e. two dissimilar organisms living together benefitting the parasite but harming the host.
4. *Saprophytism* i.e. organisms thriving on dead tissues.

Besides microorganisms, a modified infectious host protein present in the mammalian CNS has been identified called *prion protein*. Prions are transmissible agents similar to infectious particles but lack nucleic acid. These agents are implicated in the etiology of spongiform encephalopathy, (including kuru), bovine spongiform encephalopathy (or mad cow disease) and

Creutzfeldt-Jakob disease or CJD (associated with corneal transplantation). (Dr Prusiner who discovered prion protein was awarded Nobel Prize in medicine in 1997).

Transmission of infectious diseases requires a chain of events and is the consequence of inter-relationship between disease-producing properties of microorganisms and host-defense capability against the invading organisms. Briefly, chain in transmission of infections and factors determining this host-microorganism relationship are given below:

CHAIN IN TRANSMISSION OF INFECTIOUS DISEASES

Transmission of infections occurs following a chain of events pertaining to various parameters as under:

i) Reservoir of pathogen Infection occurs from the source of reservoir of pathogen. It may be a human being (e.g. in influenza virus), animal (e.g. dog for rabies), insect (e.g. mosquito for malaria), or soil (e.g. enterobiasis).

ii) Route of infection Infection is transmitted from the reservoir to the human being by different routes, usually from breach in the mucosa or the skin, at the portal of exit from the reservoir as well as the portal of entry in the susceptible host. In general, the organism is transmitted to the site where it would normally flourish e.g. *N. gonorrhoeae* usually inhabits the male and female urethra and, therefore, the route of transmission would be sexual contact.

iii) Mode of transmission The organism may be transmitted directly by physical contact or by faecal contamination (e.g. spread of eggs in hookworm infestation), or indirectly by fomites (e.g. insect bite).

iv) Susceptible host The organism would colonise the host if the host has good immunity but such a host can pass on infection to others. However, if the host is old, debilitated, malnourished, or immunosuppressed due any etiology, he is susceptible to have manifestations of infection.

Key to management of infection lies in breaking or blocking this chain for transmission and spread of infection.

FACTORS RELATING TO INFECTIOUS AGENTS

Microbial factors favouring transmission of infections are as under:

1. Mode of entry Microorganisms causing infectious diseases may gain entry into the body by various routes e.g.

- i) through ingestion (external route);
- ii) inoculation (parenteral method);
- iii) inhalation (respiration);
- iv) perinatally (vertical transmission);
- v) by direct contact (contagious infection); and

vi) by contaminated water, food, soil, environment or from an animal host (zoonotic infections).

2. Spread of infection Microorganisms after entering the body may spread further through the phagocytic cells, blood vessels and lymphatics.

3. Virulence of organisms Many species and strains of organisms may have varying virulence e.g. the three strains of *C. diphtheriae* (*gravis*, *intermedius* and *mitis*) produce the same diphtherial exotoxin but in different amounts.

4. Production of toxins Bacteria liberate toxins which have effects on cell metabolism. *Endotoxins* are liberated on lysis of the bacterial cell while *exotoxins* are secreted by bacteria and have effects at distant sites too.

5. Product of organisms Some organisms produce enzymes that help in spread of infections e.g. hyaluronidase by *Cl. welchii*, streptokinase by streptococci, staphylokinase and coagulase by staphylococci.

FACTORS RELATING TO HOST

Microorganisms invade human body when defenses are not adequate. These factors include the following:

1. Physical barrier A break in the continuity of the skin and mucous membranes allows the microorganisms to enter the body.

2. Chemical barrier Mucus secretions of the oral cavity and the alimentary tract and gastric acidity prevent bacterial colonisation.

3. Effective drainage Natural passages of the hollow organs like respiratory, gastrointestinal, urinary and genital system provide a way to drain the excretions effectively. Similarly, ducts of various glands are the conduits of drainage of secretions. Obstruction in any of these passages promotes infection.

4. Immune defense mechanisms These include the phagocytic leucocytes of blood (polymorphs and monocytes), phagocytes of tissues (mononuclear-phagocyte system) and the immune system as discussed in Chapter 3.

Some of the common diseases produced by pathogenic microorganisms are discussed below. Each group of microorganisms discussed here is accompanied by a Table listing diseases produced by them. These lists of diseases are in no way complete but include only important and common examples. No attempts will be made to give details of organisms as that would mean repeating what is given in the textbooks of Microbiology. Instead, salient clinico-pathologic aspects of these diseases are highlighted.

METHODS OF IDENTIFICATION

The organisms causing infections and parasitic diseases may be identified by routine H & E stained sections in many instances (Table 6.1). However, confirmation in most cases requires either application of special staining techniques or is confirmed by molecular biologic methods (Fig. 6.1). In addition, culture of lesional tissue should be carried out for species identification and drug sensitivity. Generally, the organism is looked for at the advancing edge of the lesion in the tissue section rather than in the necrotic centre.

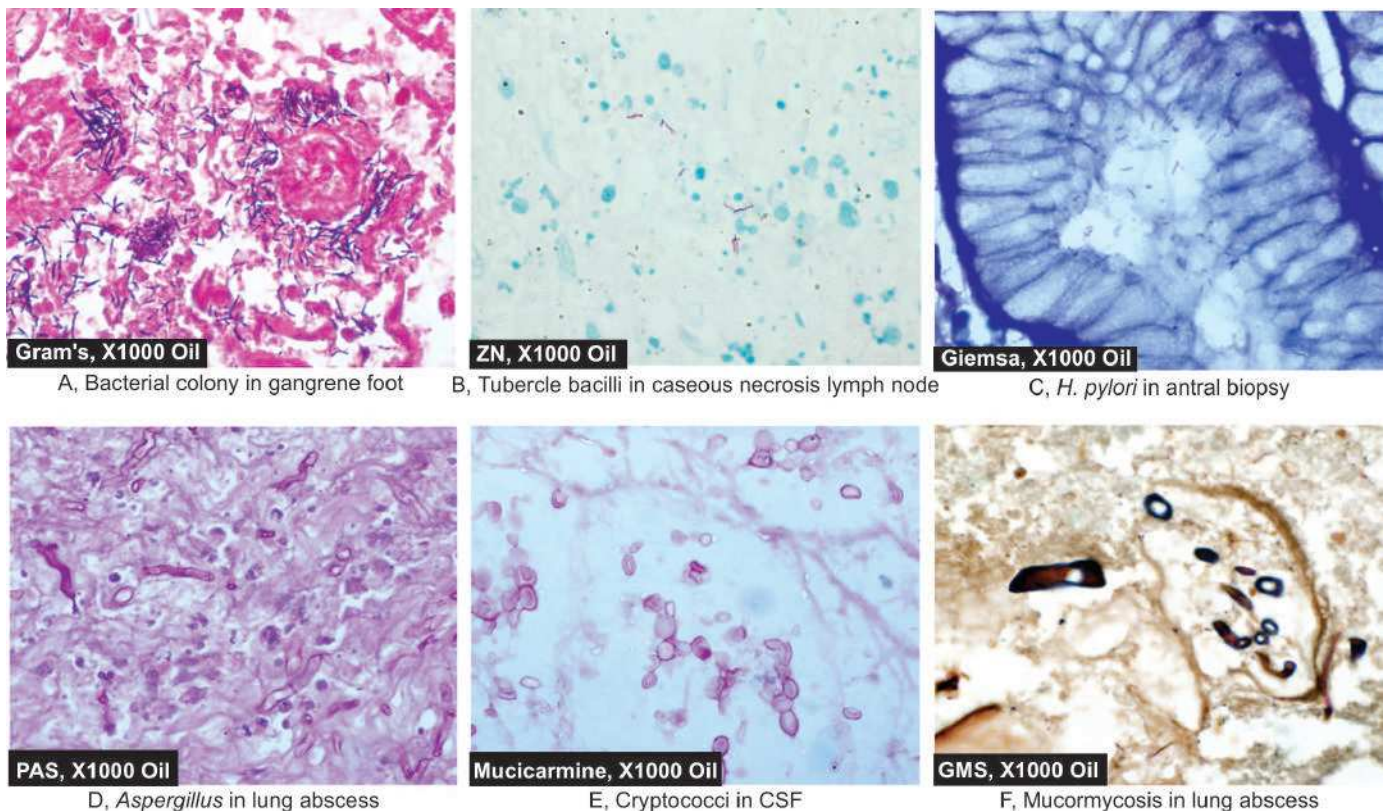

Figure 6.1 Common stains used for demonstration of microbes. A, Gram's stain. B, Ziehl-Neelsen (ZN) or AFB stain. C, Giemsa stain. D, Periodic acid Schiff (PAS) stain. E, Mucicarmine stain. F, Gomori methenamine silver (GMS) stain.

**GIST BOX 6.1****Infections and Infestations: Introduction**

- ▣ Certain infectious diseases continue to be major health problems in the developing countries e.g. tuberculosis, leprosy, typhoid fever, cholera, measles, pertussis, malaria, amoebiasis, pneumonia etc.
- ▣ Factors pertaining to the organism and the host determine the outcome of any microbial infection.
- ▣ Microbial factors favouring transmission of infections are its mode of entry, spread of infection, virulence, production of toxins, and other products.
- ▣ Host factors favouring invasion by microorganisms are breach in physical and chemical barrier, block in drainage, impaired immunity.
- ▣ Identification of organism is done by routine H & E stain, special stains (Gram's, Giemsa, AFB, PAS, GMS), culture and molecular methods.

DISEASES CAUSED BY BACTERIA, SPIROCHAETES AND MYCOBACTERIA

In order to gain an upper hand in human host, bacteria must resist early engulfment by neutrophils. They survive and damage the host in a variety of ways such as by generation of toxins (e.g. gas-forming anaerobes), by forming a slippery capsule that resists attachment to macrophages (e.g. pneumococci), by inhibition of fusion of phagocytic vacuoles with lysosomes (e.g. tubercle bacilli) etc.

Table 6.2 provides an abbreviated classification of bacterial diseases and their etiologic agents. A few common and important examples amongst these are discussed below.

PLAGUE

Plague has been a great killer since 14th century (black death) and is known to have wiped out populations of cities. World over, presently about 1000 to 3000 cases are reported annually.

Plague regularly occurs in Madagascar and Brazil. However, it is not a serious health problem in the modern Europe, Australia and US. In India after about 50 year quiescent period, an outbreak occurred in Surat in Gujarat state in 1994.

ETIOPATHOGENESIS Plague is caused by *Yersinia (Pasteurella) pestis* which is a small Gram-negative coccobacillus that grows rapidly on most culture media. Direct identification of the organism in tissues is possible by fluorescence antisera methods.

Plague is a zoonotic disease and spreads by rodents, primarily by rats, both wild and domestic; others being squirrels and rabbits. Humans are incidental hosts other than rodents.

Infection to humans occurs by rat-flea or by inhalation. After the organisms enter the bloodstream, they reach the draining lymph nodes where, rather than being phagocytosed by phagocytic cells, they proliferate rapidly giving rise to tender lymphadenopathy. This occurs within 24-48 hours of infection and is accompanied by chills, fever, myalgia, nausea, vomiting and marked prostration. If untreated, death occurs from disseminated intravascular coagulation (DIC) within 1 to 2 days with development of widespread petechiae and ecchymoses leading to gangrene, and hence the name *black death*. In other cases, death results from multi-organ failure due to profound toxemia. The patient and his fluids are highly infectious and can be transmitted by arthropods as well as person-to-person contact, giving rise to secondary cases.

Virulence of the organism *Y. pestis* is attributed to the elaboration of plague toxins: pesticin and lipopolysaccharide endotoxin.

MORPHOLOGIC FEATURES Following forms of plague are recognised (**Fig. 6.2**):

1. Bubonic plague, the most common
2. Septicaemic plague
3. Typhoidal plague
4. Pneumonic plague

BUBONIC PLAGUE This form is characterised by rapid appearance of tender, fluctuant and enlarged regional lymph nodes, several centimeters in diameter, and may have discharging sinuses on the skin.

Microscopically, the features are as under:

- i. Effaced architecture of lymph nodes due to necrosis in and around the affected nodes.
- ii. Multiple necrotising granulomas.
- iii. Characteristic mononuclear inflammatory response.
- iv. Masses of proliferating bacilli in sinusoids of lymph nodes.
- v. Cellulitis in the vicinity.

SEPTICAEMIC PLAGUE This is a form of progressive, fulminant bacterial infection associated with profound septicaemia in the absence of apparent regional lymphadenitis.

TYPHOIDAL PLAGUE This form of plague is unassociated with regional lymphadenopathy. The lesions in typhoidal plague are as follows:

- i. Necrotic foci in visceral lymphoid tissue.
- ii. Necrotic areas in parenchymal visceral organs.
- iii. G.I. manifestations with diarrhoea and pain abdomen.

PNEUMONIC PLAGUE This is the most dreaded form of plague that occurs by inhalation of bacilli from air-borne

Table 6.2 Diseases caused by bacteria, spirochaetes and mycobacteria.

| DISEASE | ETIOLOGIC AGENT |
|---|---|
| 1. Typhoid (enteric) fever (page 554) | <i>Salmonella typhi</i> |
| 2. Plague* | <i>Yersinia pestis</i> |
| 3. Anthrax* | <i>Bacillus anthracis</i> |
| 4. Whooping cough* (pertussis) | <i>Bordetella pertussis</i> |
| 5. Chancroid | <i>Haemophilus ducreyi</i> |
| 6. Donovanosis (granuloma inguinale)* | <i>Calymmatobacterium donovani</i> |
| 7. Gonorrhoea | <i>Neisseria gonorrhoeae</i> |
| 8. Cholera | <i>Vibrio cholerae</i> |
| 9. Shigellosis | <i>S. dysenteriae, S. flexneri, S. boydii, S. sonnei</i> |
| 10. Brucellosis | <i>B. melitensis, B. abortus, B. suis, B. canis</i> |
| 11. Diphtheria | <i>Corynebacterium diphtheriae</i> |
| 12. Lobar pneumonia (page 449) | <i>Streptococcus pneumoniae, Staphylococcus aureus, Haemophilus influenzae, Klebsiella pneumoniae</i> |
| 13. Bronchopneumonia (page 452) | <i>Staphylococci, Streptococci, K. pneumoniae, H. influenzae</i> |
| 14. Bacterial meningitis (page 867) | <i>Escherichia coli, H. influenzae, Neisseria meningitidis, Streptococcus pneumoniae</i> |
| 15. Bacterial endocarditis (page 425) | <i>Staphylococcus aureus, Streptococcus viridans</i> |
| 16. Other staphylococcal infections* | <i>S. aureus, S. epidermidis, S. saprophyticus</i> |
| 17. Streptococcal infections* | <i>S. pyogenes, S. faecalis, S. pneumoniae, S. viridans</i> |
| 18. <i>E. coli</i> infections (page 668) (Urinary tract infection) | <i>Escherichia coli</i> |
| 19. Clostridial diseases* | |
| i) Gas gangrene | <i>C. perfringens</i> |
| ii) Tetanus | <i>C. tetani</i> |
| iii) Botulism | <i>C. botulinum</i> |
| iv) Clostridial food poisoning | <i>C. perfringens</i> |
| v) Necrotising enterocolitis | <i>C. perfringens</i> |
| 20. Tuberculosis (page 137) | <i>Mycobacterium tuberculosis</i> |
| 21. Leprosy (page 147) | <i>Mycobacterium leprae</i> |
| 22. Syphilis (page 151) | <i>Treponema pallidum</i> |
| 23. Actinomycosis (page 153) | <i>Actinomyces israelii</i> |
| 24. Nocardiosis | <i>Nocardia asteroides</i> |

*Diseases discussed in this chapter.

particles of carcasses of animals or from affected patient's cough. It is characterised by occurrence of bronchopneumonia, with the following conspicuous microscopic features:

- i. Necrosis of alveolar walls.
- ii. Intense hyperaemia and haemorrhages.
- iii. Numerous bacilli in the alveolar lumina.
- iv. Characteristic mononuclear inflammatory response with very scanty neutrophils.

PROGNOSIS If plague is treated early, death rate is low (1-15%). However, if it is allowed to evolve into septicaemic plague, death rate is high (40%). But pneumonic plague has the worst prognosis and is always fatal with 100% death rate.

ANTHRAX

Anthrax is a bacterial disease of antiquity that spreads from animals to man. The disease is widely prevalent in cattle and sheep but human infection is rare. However, much of knowledge on human anthrax has been gained owing to fear of use of these bacteria for military purpose by rogue countries or for "bio-terrorism" (other microbial diseases in the CDC category A list

in this group include: botulism, pneumonic plague, smallpox, tularaemia, and viral haemorrhagic fevers). In India, anthrax in animals is endemic in most states due to large unprotected and uncontrolled live-stock population.

ETIOPATHOGENESIS The causative organism, *Bacillus anthracis*, is a gram-positive, aerobic bacillus, 4.5 µm long. It is a spore-forming bacillus and the spores so formed outside the body are quite resistant. The disease occurs as an exogenous infection by contact with soil or animal products contaminated with spores.

Depending upon the portal of entry, three types of human anthrax is known to occur:

- i) **Cutaneous form** by direct contact with skin and is most common.
- ii) **Pulmonary form** by inhalation, also called as "wool-sorters' disease" and is most fatal.
- iii) **Gastrointestinal form** by ingestion and is rare.

The mechanism of infection includes spread of bacilli from the portal of entry to the regional lymph nodes through lymphatics where the bacteria proliferate. There is delayed accumulation of polymorphs and macrophages. Macrophages

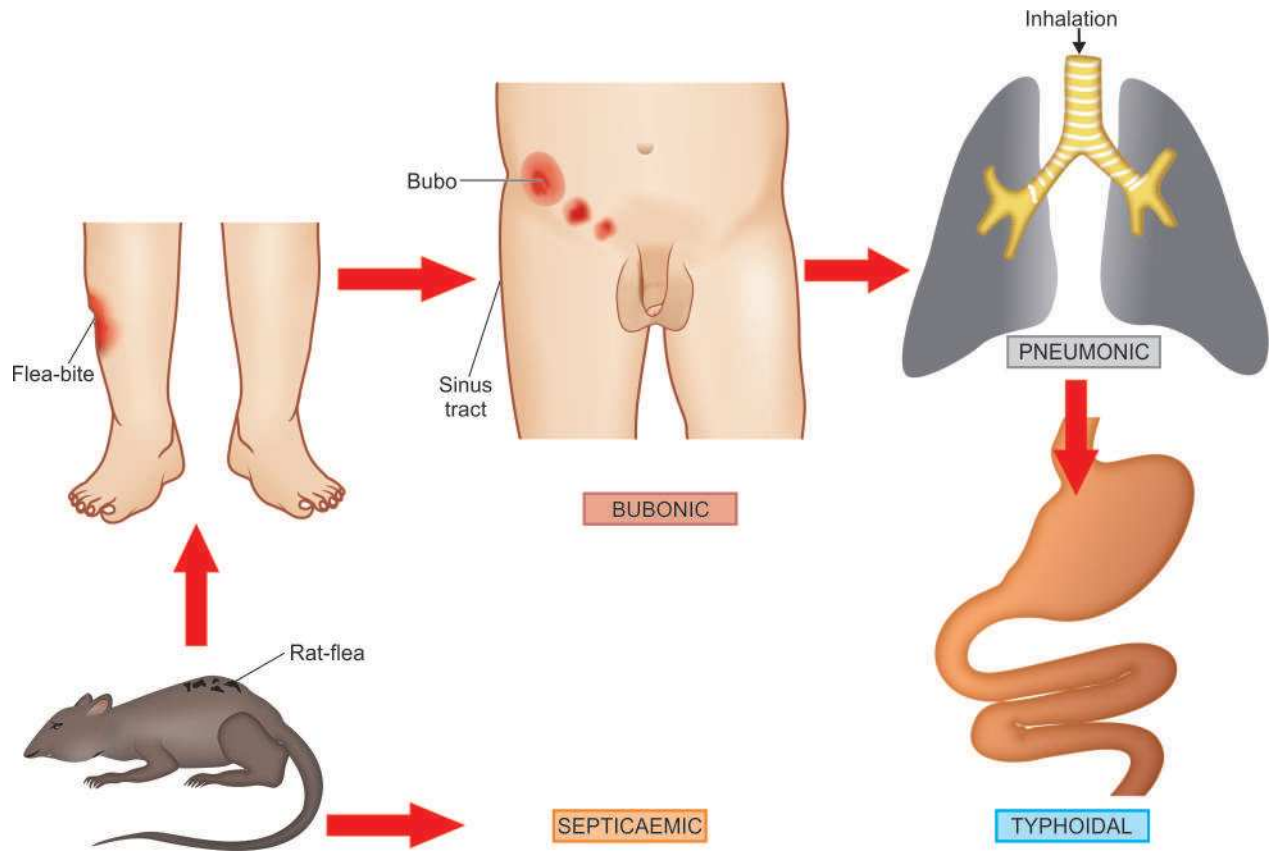

Figure 6.2 Forms of plague.

also play a role in expression of bacterial toxicity; bacterial toxin is quite lethal to macrophages.

MORPHOLOGIC FEATURES The characteristic lesions of anthrax are haemorrhage, oedema and necrosis at the portal of entry.

1. Cutaneous anthrax is the most common and occurs in two forms: one type is characterised by necrotic lesion due to vascular thrombosis, haemorrhage and acellular necrosis, while the other form begins as a pimple at the point of entry of organism into the abraded exposed skin, more often in the region of hands and the head and neck. The initial lesion develops into a vesicle or blister containing clear serous or blood-stained fluid swarming with anthrax bacilli which can be identified readily by smear examination. The bursting of the blister is followed by extensive oedema and black tissue necrosis resulting in formation of severe 'malignant pustule.' Regional lymph nodes are invariably involved along with profound septicaemia.

2. Pulmonary anthrax (wool-sorters' disease) occurring from inhalation of spores of *B. anthracis* in infectious aerosols results in rapid development of malignant pustule in the bronchus. This is followed by development of primary extensive necrotising pneumonia and haemorrhagic mediastinitis which is invariably fatal.

3. Intestinal anthrax is rare in human beings and is quite similar to that seen in cattle. Septicaemia and death often results in this type too. The lesions consist of mucosal

oedema, small necrotic ulcers, massive fluid loss and haemorrhagic mesenteric lymphadenitis.

Besides, anthrax septicaemia results in spread of infection to all other organs.

LABORATORY DIAGNOSIS Anthrax can be diagnosed by a few simple techniques:

i) *Smear examination:* Gram stained smear shows rod-shaped, spore-forming, gram-positive bacilli. Endospores are detectable by presence of unstained defects or holes within the cell.

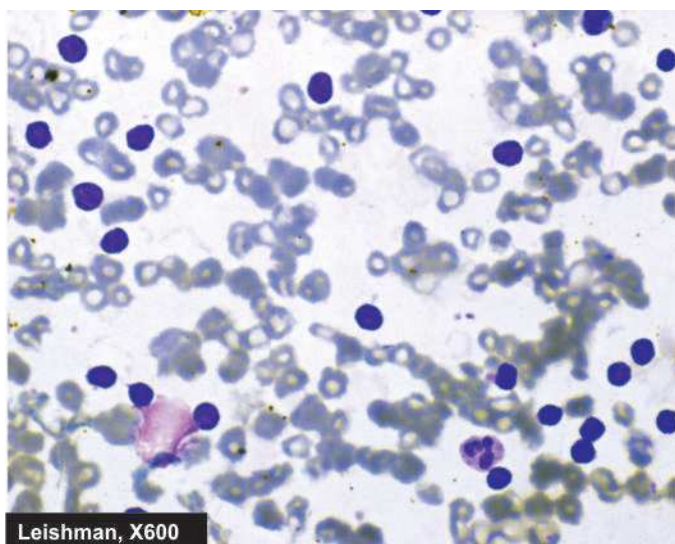

ii) *Culture:* Anthrax bacteria grow on sheep blood agar as flat colonies with an irregular margin (medusa head).

Anthrax contaminated work surfaces, materials and equipment must be decontaminated with 5% hypochlorite or 5% phenol.

WHOOPING COUGH (PERTUSSIS)

Whooping cough is a highly communicable acute bacterial disease of childhood caused by *Bordetella pertussis*. The use of DPT vaccine has reduced the prevalence of whooping cough in different populations.

The causative organism, *B. pertussis*, has strong tropism for the brush border of the bronchial epithelium. The organisms proliferate here and stimulate the bronchial epithelium to produce abundant tenacious mucus. Within 7-10 days after exposure, catarrhal stage begins which is the most infectious stage. There is low grade fever, rhinorrhoea, conjunctivitis and excess tear production. Paroxysms of cough occur with characteristic 'whoop.' The condition is self-limiting but may

Leishman, X600

Figure 6.3 Marked peripheral blood lymphocytosis in whooping cough.

cause death due to asphyxia in infants. *B. pertussis* produces a heat-labile toxin, a heat-stable endotoxin, and a lymphocytosis-producing factor called histamine-sensitising factor.

Microscopically, the lesions in the respiratory tract consist of necrotic bronchial epithelium covered by thick mucopurulent exudate. In severe cases, there is mucosal erosion and hyperaemia. The peripheral blood shows marked lymphocytosis upto 90% (**Fig. 6.3**) and enlargement of lymphoid follicles in the bronchial mucosa and peribronchial lymph nodes.

DONOVANOSIS

Donovanosis also called granuloma inguinale or granuloma venereum is a sexually-transmitted disease affecting the genitalia, inguinal and perianal regions caused by *Calymmatobacterium donovani*. The disease is common in tropical and subtropical countries such as New Guinea, Southern Africa, Australia and India. The organism inhabits the intestinal tract. The infection is transmitted through vaginal or anal intercourse and by autoinoculation. The incubation period varies from 2 to 4 weeks. Initially, the lesion is in the form of a papule, a subcutaneous nodule or an ulcer. Within a few weeks, it develops into a raised, soft, painless, reddish ulcer with exuberant granulation tissue. Genitalia are involved in 90% of cases and inguinal and anal region in 10%. Regional lymphadenopathy generally does not occur.

Microscopically, the margin of the ulcer shows epithelial hyperplasia. The ulcer bed shows neutrophilic abscesses. The dermis and subcutaneous tissues are infiltrated by numerous histiocytes containing many bacteria called *Donovan bodies*, and lymphocytes, plasma cells and neutrophils. These organisms are best demonstrated by silver impregnation techniques.

LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum (LGV) is a sexually-transmitted disease caused by *Chlamydia trachomatis* and is characterised

by mucocutaneous lesions and regional lymphadenopathy. Chlamydia are no more considered as filterable viruses as was previously thought but are instead intracellular gram-negative bacteria. LGV is worldwide in distribution but its prevalence rate is high in tropics and subtropics in Africa, South-East Asia and India.

The condition begins as a painless, herpes-like lesion on the cervix, vagina, or penis. The organisms are carried via lymphatics to regional lymph nodes. The involved lymph nodes are tender, fluctuant and may ulcerate and drain pus.

Microscopically, the lymph nodes have characteristic stellate-shaped abscesses surrounded by a zone of epithelioid cells (granuloma). Healing stage of the acute lesion takes place by fibrosis and permanent destruction of lymphoid structure.

CAT-SCRATCH DISEASE

Another condition related to LGV, cat-scratch disease, is caused by *Bartonella henselae*, an organism linked to rickettsiae but unlike rickettsiae this organism can be grown in culture. The condition occurs more commonly in children (under 18 years of age). There is regional nodal enlargement which appears about 2 weeks after cat-scratch, and sometimes after thorn injury. The lymphadenopathy is self-limited and regresses in 2-4 months.

Microscopically, the changes in lymph node are characteristics:

- i) Initially, there is formation of non-caseating sarcoid-like granulomas.
- ii) Subsequently, there are neutrophilic abscesses surrounded by pallisaded histiocytes and fibroblasts, an appearance simulating LGV discussed above.
- iii) The organism is extracellular and can be identified by silver stains.

STAPHYLOCOCCAL INFECTIONS

Staphylococci are gram-positive cocci which are present everywhere—in the skin, umbilicus, nasal vestibule, stool etc. Three species are pathogenic to human beings: *Staph. aureus*, *Staph. epidermidis* and *Staph. saprophyticus*. Most staphylococcal infections are caused by *Staph. aureus*. Staphylococcal infections are among the commonest antibiotic-resistant hospital-acquired infection in surgical wounds.

A wide variety of suppurative diseases are caused by *Staph. aureus* which includes the following (**Fig. 6.4**):

1. Infections of skin Staphylococcal infections of the skin are quite common. The infection begins from lodgement of cocci in the hair root due to poor hygiene and results in obstruction of sweat or sebaceous gland duct. This is termed *folliculitis*. Involvement of adjacent follicles results in larger lesions called *furuncle*. Further spread of infection horizontally under the skin and subcutaneous tissue causes *carbuncle* or *cellulitis*. *Styes* are staphylococcal infection of the sebaceous glands of Zeis, the glands of Moll and eyelash follicles. *Impetigo* is yet another staphylococcal skin infection common in school children in which there are multiple pustular lesions on face forming honey-yellow crusts. *Breast abscess* may occur

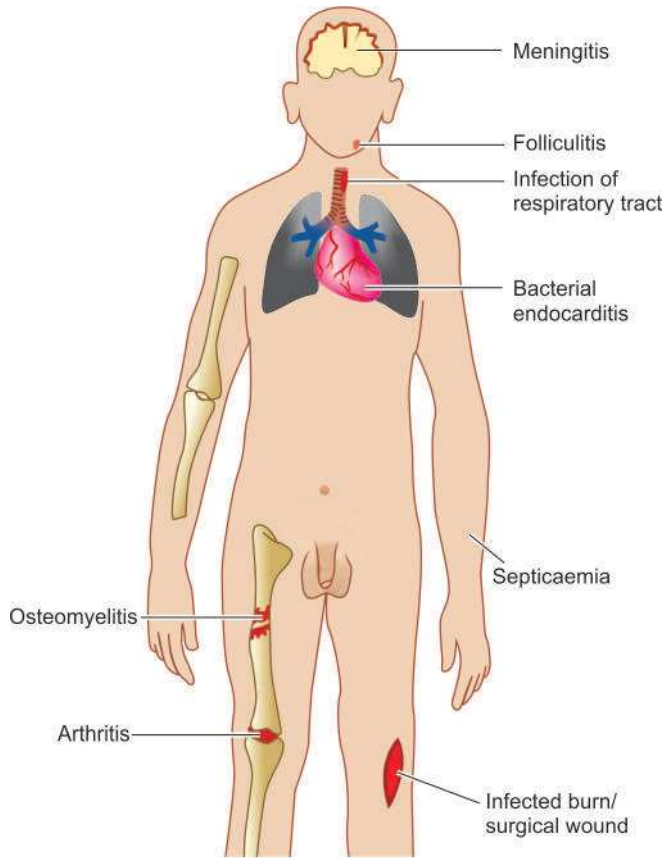

Figure 6.4 Suppurative diseases caused by *Staphylococcus aureus*.

following delivery when staphylococci are transmitted from infant having neonatal sepsis or due to stasis of milk.

2. Infections of burns and surgical wounds These are quite common due to contamination from the patient's own nasal secretions or from hospital staff. Elderly, malnourished, obese patients and neonates have increased susceptibility.

3. Infections of the upper and lower respiratory tract Small children under 2 years of age get staphylococcal infections of the respiratory tract commonly. These include pharyngitis, bronchopneumonia, staphylococcal pneumonia and its complications.

4. Bacterial arthritis Septic arthritis in the elderly is caused by *Staph. aureus*.

5. Infection of bone (Osteomyelitis) Young boys having history of trauma or infection may develop acute staphylococcal osteomyelitis (page 822).

6. Bacterial endocarditis Acute and subacute bacterial endocarditis are complications of infection with *Staph. aureus* and *Staph. epidermidis* (page 425).

7. Bacterial meningitis Surgical procedures on central nervous system may lead to staphylococcal meningitis (page 867).

8. Septicaemia Staphylococcal septicaemia may occur in patients with lowered resistance or in patients having underlying staphylococcal infections. Patients present with features of bacteraemia such as shaking chills and fever (page 133).

9. Toxic shock syndrome Toxic shock syndrome is a serious complication of staphylococcal infection characterised by fever, hypotension and exfoliative skin rash. The condition affected young menstruating women who used tampons of some brands which when kept inside the vagina caused absorption of staphylococcal toxins from the vagina.

STREPTOCOCCAL INFECTIONS

Streptococci are also gram-positive cocci but unlike staphylococci, they are more known for their non-suppurative autoimmune complications than suppurative inflammatory responses. Streptococcal infections occur throughout the world but their problems are greater in underprivileged populations where antibiotics are not instituted readily.

The following groups and subtypes of streptococci have been identified and implicated in different streptococcal diseases (**Fig. 6.5**):

1. *Group A or Streptococcus pyogenes*, also called β -haemolytic streptococci, are involved in causing upper respiratory tract infection and cutaneous infections (erysipelas). In addition, β -haemolytic streptococci are involved in autoimmune reactions in the form of rheumatic heart disease (RHD).
2. *Group B or Streptococcus agalactiae* produces infections in the newborn and is involved in non-suppurative post-streptococcal complications such as RHD and acute glomerulonephritis.
3. *Group C and G streptococci* are responsible for respiratory infections.
4. *Group D or Streptococcus faecalis*, also called enterococci are important in causation of urinary tract infection, bacterial endocarditis, septicaemia etc.

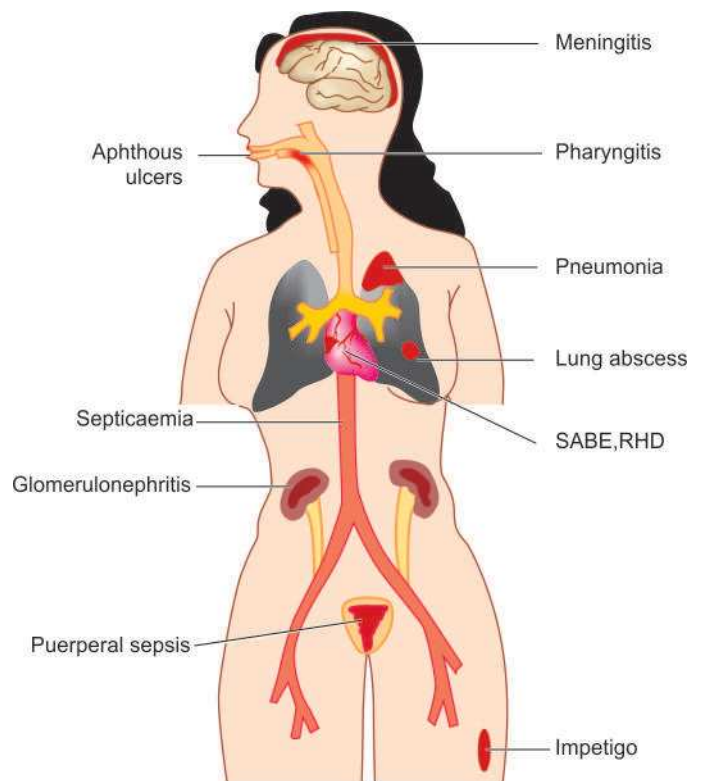

Figure 6.5 Diseases caused by streptococci.

5. *Untypable α -haemolytic streptococci* such as *Streptococcus viridans* constitute the normal flora of the mouth and may cause bacterial endocarditis.

6. *Pneumococci* or *Streptococcus pneumoniae* are etiologic agents for bacterial pneumonias, meningitis and septicaemia.

CLOSTRIDIAL DISEASES

Clostridia are gram-positive spore-forming anaerobic microorganisms found in the gastrointestinal tract of herbivorous animals and man. These organisms may undergo vegetative division under anaerobic conditions, and sporulation under aerobic conditions. These spores are passed in faeces and can survive in unfavourable conditions. On degeneration of these microorganisms, the plasmids are liberated which produce many toxins responsible for the following clostridial diseases depending upon the species (Fig. 6.6):

1. Gas gangrene by *C. perfringens*
2. Tetanus by *C. tetani*
3. Botulism by *C. botulinum*
4. Clostridial food poisoning by *C. perfringens*
5. Necrotising enterocolitis by *C. perfringens*.

GAS GANGRENE Gas gangrene is a rapidly progressive and fatal illness in which there is myonecrosis of previously healthy skeletal muscle due to elaboration of myotoxins by some species of clostridia. In majority of cases (80-90%), the source of myotoxins is *C. perfringens* Type A; others are *C. novyi* and *C. septicum*. Generally, traumatic wounds and surgical procedures are followed by contamination with clostridia and become the site of myonecrosis. The incubation period is 2 to 4 days. The most common myotoxin produced by *C. perfringens* Type A is the alpha toxin which is a lecithinase. The prevention of gas gangrene lies in debridement of damaged tissue in which the clostridia thrive. The lesion has serosanguineous discharge

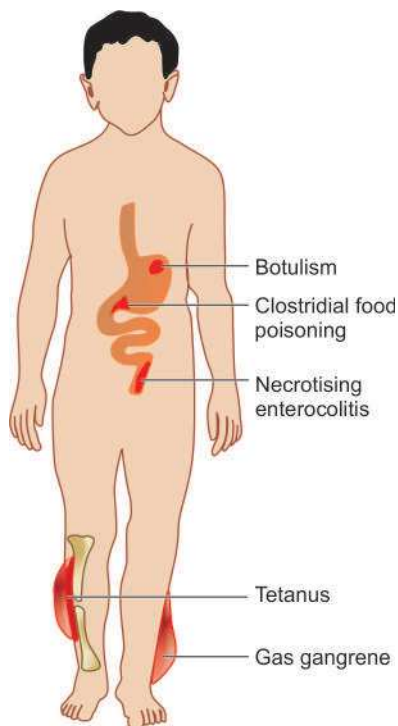

Figure 6.6 Diseases caused by clostridia.

with odour and contains gas bubbles. There is very scanty inflammatory reaction at the site of gas gangrene.

TETANUS Tetanus or 'lock jaw' is a severe acute neurologic syndrome caused by tetanus toxin, tetanospasmin, which is a neurotoxic exotoxin elaborated by *C. tetani*. The spores of the microorganism present in the soil enter the body through a penetrating wound. In underdeveloped countries, tetanus in neonates is seen due to application of soil or dung on the umbilical stump. The degenerated microorganisms liberate the tetanus neurotoxin which causes neuronal stimulation and spasm of muscles. The incubation period of the disease is 1-3 weeks. The earliest manifestation is lock-jaw or trismus. Rigidity of muscles of the back causes backward arching or opisthotonos. Death occurs due to spasm of respiratory and laryngeal muscles.

BOTULISM Botulism is characterised by symmetric paralysis of cranial nerves, limbs and trunk. The condition occurs following ingestion of food contaminated with neurotoxins of *C. botulinum* and less often by contamination of a penetrating wound. The spores of *C. botulinum* are capable of surviving in unfavourable conditions and contaminate vegetables and other foods, especially if improperly stored or canned. The symptoms of botulism begin to appear within 12 to 36 hours of ingestion of food containing the neurotoxins (type A to type G). The toxins resist gastric digestion and are absorbed from the upper portion of small intestine and enter the blood. On reaching the cholinergic nerve endings, the toxin binds to membrane receptors and inhibits release of acetylcholine resulting in paralysis and respiratory failure.

CLOSTRIDIAL FOOD POISONING Clostridial food poisoning is caused by enterotoxin elaborated by *C. perfringens*. Out of five serotypes of *C. perfringens*, type A and C produce alpha-enterotoxin that causes food poisoning. These serotypes of organism are omnipresent in the environment and thus clostridial poisoning occurs throughout the world. Food poisoning from *C. perfringens* is mostly from ingestion of meat and its products which have been allowed to dry resulting in dehydration and anaerobic conditions suitable for growth of *C. perfringens*. The contaminated meat contains vegetative form of the organism and no preformed enterotoxin (unlike botulism where preformed neurotoxin of *C. botulinum* is ingested). On ingestion of the contaminated meat, α -enterotoxin is produced in the intestine. Symptoms of the food poisoning appear within 12 hours of ingestion of contaminated meat and recovery occurs within 2 days.

NECROTISING ENTEROCOLITIS Necrotising enterocolitis or 'pig bel' is caused by beta-enterotoxin produced by *C. perfringens* Type C. The condition occurs especially in undernourished children who suddenly indulge in overeating such as was first reported participation in pig feasts by poor children in New Guinea and hence the name 'pig bel'. Adults do not develop the condition due to good antibody response.

Ingestion of contaminated pork by malnourished children who normally take protein-deficient vegetarian diet causes elaboration of β -enterotoxin. The symptoms appear within 48 hours after ingestion of contaminated meat. These include: severe abdominal pain, distension, vomiting and passage of bloody stools. Milder form of disease runs a course similar to other forms of gastroenteritis while fulminant 'pig bel' may result in death of the child.

Grossly, the disease affects small intestine segmentally. The affected segment of bowel shows green, necrotic pseudomembrane covering the necrotic mucosa and there is associated peritonitis. Advanced cases may show perforation of the bowel wall.

Microscopically, there is transmural infiltration by acute inflammatory cell infiltrate with changes of mucosal infarction, oedema and haemorrhage (page 548). The pseudomembrane consists of necrotic epithelium with entangled bacilli.

GIST BOX 6.2

Diseases caused by Bacteria

- ▣ Plague or black death is caused by *Yersinia (Pasteurella) pestis*, a small Gram-negative coccobacillus. Clinically, bubonic plague is the most common; other forms are septicaemic, typhoidal and pneumonic plague. The last one is invariably fatal.
- ▣ Anthrax is caused by *Bacillus anthracis* and spreads from animals to human beings. Depending upon the portal of entry, there are 3 types: cutaneous form by direct contact with skin and is most common, pulmonary form or wool-sorters' disease by inhalation and is most fatal, and gastrointestinal form by ingestion and is rare.
- ▣ Whooping cough is a highly communicable acute bacterial disease of childhood caused by *Bordetella pertussis* and is characterised by respiratory mucosal erosions and lymphocytosis.
- ▣ Donovanosis (or granuloma inguinale or granuloma venereum) is a sexually-transmitted disease affecting the genitalia and inguinal and perianal regions caused by *Calymmatobacterium donovani*.
- ▣ Lymphogranuloma venereum (LGV) is a sexually-transmitted disease caused by *Chlamydia trachomatis* and is characterised by mucocutaneous lesions and regional lymphadenopathy.
- ▣ Cat-scratch disease is caused by *Bartonella henselae*, an organism linked to rickettsiae.
- ▣ Staphylococci cause wide variety of suppurative infections such as skin, burn wounds, upper and lower respiratory tract, joints, bones and meninges.
- ▣ Streptococci are known for their non-suppurative autoimmune complications such as in rheumatic heart disease and acute glomerulonephritis.
- ▣ Clostridia are spore forming Gram-positive anaerobic bacteria and cause gas gangrene, tetanus, botulism and food poisoning.

DISEASES CAUSED BY FUNGI

Of the large number of known fungi, only a few are infective to human beings. Many of the human fungal infections are opportunistic i.e. they occur in conditions with impaired host immune mechanisms. Such conditions include defective neutrophil function, administration of corticosteroids, immunosuppressive therapy and immunodeficiency states (congenital and acquired). A list of common fungal infections of human beings is given in **Table 6.3**. A few important representative examples are discussed below.

Table 6.3 Diseases caused by fungi.

| DISEASE | ETIOLOGIC AGENT |
|----------------------------------|--|
| 1. Mycetoma* | <i>Madurella mycetomatis</i> |
| 2. Aspergillosis (Chapter 15) | <i>Aspergillus fumigatus</i> , <i>A. flavus</i> , <i>A. niger</i> |
| 3. Blastomycosis | <i>Blastomyces dermatitidis</i> |
| 4. Candidiasis* | <i>Candida albicans</i> |
| 5. Coccidioidomycosis | <i>Coccidioides immitis</i> |
| 6. Cryptococcosis | <i>Cryptococcus neoformans</i> |
| 7. Histoplasmosis | <i>Histoplasma capsulatum</i> |
| 8. Rhinosporidiosis (Chapter 16) | <i>Rhinosporidium seeberi</i> |
| 9. Superficial mycosis* | <i>Microsporium</i> , <i>Trichophyton</i> , <i>Epidermophyton</i> |

*Conditions discussed in this chapter.

MYCETOMA

Mycetoma is a chronic suppurative infection involving a limb, shoulder or other tissues and is characterised by draining sinuses. The material discharged from the sinuses is in the form of grains consisting of colonies of fungi or bacteria. Mycetomas are of 2 main types:

◆ *Mycetoma* caused by actinomyces (higher bacteria) also called actinomycetoma comprises about 60% of cases (page 153).

◆ *Eumycetoma* caused by true fungi, *Madurella mycetomatis* or *Madurella grisea*, comprises the remaining 40% of the cases.

Eumycetomas are particularly common in Northern and tropical Africa, Southern Asia and tropical America. The organisms are inoculated directly from soil into barefeet, from carrying of contaminated sacks on the shoulders, and into the hands from infected vegetation.

MORPHOLOGIC FEATURES After several months of infection, the affected site, most commonly foot, is swollen and hence the name 'madura foot'. The lesions extend deeply into the subcutaneous tissues, along the fascia and eventually invade the bones. They drain through sinus tracts which discharge purulent material and black grains. The surrounding tissue shows granulomatous reaction (**Fig. 6.7**).

CANDIDIASIS

Candidiasis is an opportunistic fungal infection caused most commonly by *Candida albicans* and occasionally by *Candida tropicalis*. In human beings, *Candida* species are present as normal flora of the skin and mucocutaneous areas, intestines and vagina. The organism becomes pathogenic when the balance between the host and the organism is disturbed. Various predisposing factors are: impaired immunity, prolonged use of oral contraceptives, long-term antibiotic therapy, corticosteroid therapy, diabetes mellitus, obesity, pregnancy etc.

MORPHOLOGIC FEATURES *Candida* produces superficial infections of the skin and mucous membranes, or may invade deeper tissues as described under:

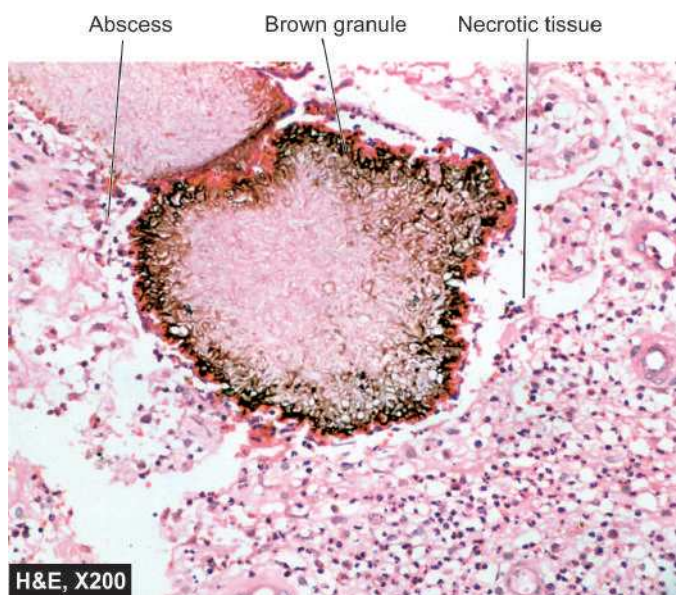

Figure 6.7 Madura foot. Brown granule lying in necrotic tissue in the discharging sinus.

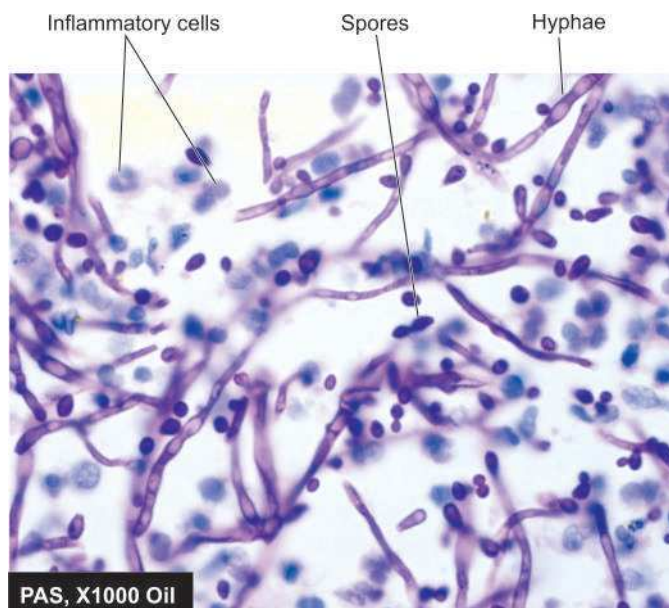

Figure 6.8 Candidiasis of the ulcer in the skin.

1. Oral thrush This is the commonest form of mucocutaneous candidiasis seen especially in early life. Full-fledged lesions consist of creamy white pseudomembrane composed of fungi covering the tongue, soft palate, and buccal mucosa. In severe cases, ulceration may be seen.

2. Candidal vaginitis Vaginal candidiasis or monilial vaginitis is characterised clinically by thick, yellow, curdy discharge. The lesions form pseudomembrane of fungi on the vaginal mucosa. They are quite pruritic and may extend to involve the vulva (vulvovaginitis) and the perineum.

3. Cutaneous candidiasis Candidal involvement of nail folds producing change in the shape of nail plate (paronychia) and colonisation in the intertriginous areas of the skin, axilla, groin, infra- and inter-mammary, intergluteal folds and interdigital spaces are some of the common forms of cutaneous lesions caused by *Candida albicans* (**Fig. 6.8**).

4. Systemic candidiasis Invasive candidiasis is rare and is usually a terminal event of an underlying disorder associated with impaired immune system. The organisms gain entry into the body through an ulcerative lesion on the skin and mucosa or may be introduced by iatrogenic means such as via intravenous infusion, peritoneal dialysis or urinary catheterisation. The lesions of systemic candidiasis are most commonly encountered in kidneys as ascending pyelonephritis and in heart as candidal endocarditis.

CUTANEOUS SUPERFICIAL MYCOSIS

Dermatophytes cause superficial mycosis of the skin, the important examples being *Microsporum*, *Trichophyton* and *Epidermophyton*. These superficial fungi are spread by direct contact or by fomites and infect tissues such as the skin, hair and nails. Examples of diseases pertaining to these tissues are as under:

- ◆ *Tinea capitis* characterised by patchy alopecia affecting the scalp and eyebrows.
- ◆ *Tinea barbae* is acute folliculitis of the beard.

◆ *Tinea corporis* is dermatitis with formation of erythematous papules.

The diagnosis of dermatophytosis is made by light microscopic examination of skin scrapings after addition of sodium or potassium hydroxide solution. Other methods include fungal culture and demonstration of fungus in tissue sections.

GIST BOX 6.3

Diseases caused by Fungi

- ▣ Opportunistic fungi occur in conditions with impaired host immunity.
- ▣ *Mycetoma* is a chronic suppurative infection caused by either actinomyces (higher bacteria) also called actinomycetoma, or *eumycetomas* caused by true fungi (madura foot).
- ▣ Candidiasis is an opportunistic fungal infection caused commonly by *Candida albicans* and produces superficial infections of the skin and mucous membranes e.g. oral thrush, candidal vaginitis, cutaneous candidiasis.
- ▣ Superficial mycosis of the skin are caused by dermatophytes and produce tinea of various tissues.

DISEASES CAUSED BY VIRUSES

Viral diseases are the most common cause of human illness. However, many of the viral infections remain asymptomatic while others produce viral disease. Another peculiar feature of viral infection is that a single etiologic agent may produce different diseases in the same host depending upon host immune response and age at infection e.g. varicella-zoster virus is causative for chickenpox as well as herpes zoster. Viruses are essentially intracellular parasites. Depending upon their nucleic acid genomic composition, they may be single-stranded or double-stranded, RNA or DNA viruses. A list of common viruses and diseases caused by them is given in **Table 6.4**. Oncogenic viruses and their role in neoplasms are discussed

Table 6.4 Diseases caused by viruses.

| DISEASE | ETIOLOGIC AGENT |
|--|---|
| 1. Viral haemorrhagic fevers* | Arthropod-borne (arbo) viruses |
| 2. Influenza [Bird flu, H5N1, Swine flu (H1N1)]* | Influenza virus type A |
| 3. Viral encephalitis | Arthropod-borne (arbo) viruses |
| 4. Rabies* | Rabies virus (arboviruses) |
| 5. Poliomyelitis | Poliovirus |
| 6. Smallpox (Variola) | Variola virus |
| 7. Chickenpox (varicella)* | Varicella-zoster virus |
| 8. Herpes simplex and herpes genitalis* | Herpes simplex virus (HSV-I and HSV-II) |
| 9. Herpes zoster* | Varicella-zoster virus |
| 10. Lymphogranuloma venereum* | <i>Chlamydia trachomatis</i> |
| 11. Cat-scratch disease* | <i>Bartonella henselae</i> |
| 12. Viral hepatitis (page 590) | Hepatotropic viruses |
| 13. Cytomegalovirus inclusion disease | Cytomegalovirus (CMV) |
| 14. Infectious mononucleosis (page 329) | Epstein-Barr virus (EBV) |
| 15. Measles (Rubeola) | Measles virus |
| 16. German measles (Rubella) | Rubella virus |
| 17. Mumps (page 515) | Mumps virus |

*Diseases discussed in this chapter.

in Chapter 7. A few common and important viral diseases are described below.

VIRAL HAEMORRHAGIC FEVERS

Viral haemorrhagic fevers are a group of acute viral infections which have common features of causing haemorrhages, shock and sometimes death. Viruses causing haemorrhagic fevers were earlier called *arthropod-borne* (or *arbo*) viruses since their transmission to humans was considered to be from arthropods. However, now it is known that all such viruses are not transmitted by arthropod vectors alone and hence now such haemorrhagic fevers are classified according to the routes of transmission and other epidemiologic features into 4 groups:

1. Mosquito-borne (e.g. yellow fever, dengue fever, Rift Valley fever)
2. Tick-borne (e.g. Crimean haemorrhagic fever, Kyasanur Forest disease)
3. Zoonotic (e.g. Korean haemorrhagic fever, Lassa fever)
4. Marburg virus disease and Ebola virus disease by unknown route.

Of these, mosquito-borne viral haemorrhagic fevers in which *Aedes aegypti* mosquitoes are vectors, are the most common problem the world over, especially in developing countries. Two important examples of *Aedes* mosquito-borne viral haemorrhagic fevers are yellow fever and dengue fever, which are discussed below.

YELLOW FEVER

Yellow fever is the oldest known viral haemorrhagic fever restricted to some regions of Africa and South America.

Monkeys carry the virus without suffering from illness and the virus is transmitted from them to humans by *Aedes aegypti* as vector.

Yellow fever is characterised by the following clinical features: Sudden onset of high fever, chills, myalgia, headache, jaundice, hepatic failure, renal failure, bleeding disorders and hypotension.

MORPHOLOGIC FEATURES Major pathologic changes are seen in the liver and kidneys.

Liver. The characteristic changes include:

- i) midzonal necrosis;
- ii) Councilman bodies; and
- iii) microvesicular fat.

Kidneys. The kidneys show the following changes:

- i) coagulative necrosis of proximal tubules;
- ii) accumulation of fat in the tubular epithelium; and
- iii) haemorrhages.

Patients tend to recover without sequelae; death rate is less than 5%, death resulting from hepatic or renal failure, and petechial haemorrhages in the brain.

DENGUE HAEMORRHAGIC FEVER (DHF)

The word dengue is derived from African word '*denga*' meaning fever with haemorrhages. Dengue is caused by virus transmitted by bites of mosquito *Aedes aegypti*; the transmission being highest during and after rainy season when mosquitos are numerous. DHF was first described in 1953 when it struck Philippines. Since then, DHF has been regularly reported from tropics and subtropics—South East Asia, Latin America and

Pacific Islands. Since 1996, cases are seen every year in North India in the post-monsoon rain period.

Dengue occurs in two forms:

1. *Dengue fever or break-bone fever* in an uncomplicated way is a self-limited febrile illness affecting muscles and joints with severe back pain due to myalgia (and hence the name 'break-bone' fever).
2. *Dengue haemorrhagic fever (DHF)*, on the other hand, is a severe and potentially fatal form of acute febrile illness characterised by cutaneous and intestinal haemorrhages due to thrombocytopenia, haemoconcentration, hypovolaemic shock and neurologic disturbances. DHF is most common in children under 15 years of age.

There are 4 types of dengue viruses and all of them produce similar clinical syndrome. These viruses infect blood monocytes, lymphocytes and endothelial cells. This initiates complement activation and consumptive coagulopathy including thrombocytopenia. The entire process takes place rapidly and may evolve over a period of a few hours. If patient is treated appropriately at this stage, there is rapid and dramatic recovery. But in untreated cases, *dengue shock syndrome* develops and death occurs.

MORPHOLOGIC FEATURES The predominant *organ changes in DHF* are due to following:

- i) Focal haemorrhages and congestion
- ii) Increased vascular permeability resulting in oedema in different organs
- iii) Coagulopathy with thrombocytopenia
- iv) Haemoconcentration.

Diagnosis of DHF is confirmed by the following tests:

1. Serologic testing for detection of antibodies
2. Detection of virus by immunofluorescence method and monoclonal antibodies
3. Rapid methods such as reverse transcriptase-PCR and fluorogenic-ELISA.

The main abnormalities in **investigations in DHF** are as under:

- i) Leucopenia with relative lymphocytosis, sometimes with atypical lymphocytes
- ii) Thrombocytopenia
- iii) Elevated haematocrit due to haemoconcentration
- iv) X-ray chest showing bilateral pleural effusion
- v) Deranged liver function tests (elevated transaminases, hypoalbuminaemia and reversed A:G ratio)
- vi) Prolonged coagulation tests (prothrombin time, activated partial thromboplastin time and thrombin time)

At autopsy, the predominant organ changes observed are as follows:

- i) *Brain*: Intracranial haemorrhages, cerebral oedema, dengue encephalitis.
- ii) *Liver*: Enlarged; necrosis of hepatocytes and Kupffer cells, Reye's syndrome in children.
- iii) *Kidneys*: Petechial haemorrhages and features of renal failure.
- iv) *Muscles and joints*: Perivascular mononuclear cell infiltrate.

CHIKUNGUNYA VIRUS INFECTION

The word chikungunya means "that which bends up" and is derived from the language in Africa where this viral disease

was first found in human beings. Chikungunya virus infection is primarily a disease in nonhuman primates but the infection is transmitted to humans by *A. aegypti* mosquito. The disease is endemic in parts of Africa and Asia and occurs sporadically elsewhere.

❖ *Clinically*, the disease is characterised by abrupt onset of fever, severe arthralgia (producing bending posture of patient due to pain and hence the name), migratory polyarthritis affecting small joints, chills, headache, anorexia, nausea, abdominal pain, rash, petechiae and ocular symptoms such as photophobia.

❖ *Major laboratory findings* include leucopenia, mild thrombocytopenia, elevated transaminases and raised CRP.

INFLUENZA VIRUS INFECTIONS

Influenza virus infection is an important and common form of communicable disease, especially prevalent as a seasonal infection in the developed countries. Its general clinical features range from a mild afebrile illness similar to common cold by appearance of sudden fever, headache, myalgia, malaise, chills and respiratory tract manifestations such as cough, soar throat to a more severe form of acute respiratory illness and lymphadenopathy. Various forms of influenza virus infections have occurred as an outbreak at different times, sometimes with alarming morbidity and mortality in the world. Seasonal flu vaccine is administered to population at high risk in developed countries.

ETIOLOGIC AGENT Influenza virus is a single-stranded RNA virus belonging to coronaviruses. Depending upon its antigenic characteristics of the nucleoprotein and matrix, 3 distinct types are known: A, B and C. Out of these, influenza type A is responsible for most serious and severe forms of outbreaks in human beings while types B and C cause a milder form of illness. Type A influenza virus is further subtyped based on its 2 viral surface features:

Haemagglutinin (H) H antigen elicits host immune response by antibodies and determines the future protection against influenza A viruses. There are 16 distinct H subtypes of type A influenza viruses.

Neuraminidase (N) Antibody response against N antigen limits the spread of viral infection and is responsible for reduction of infection. N antigen of influenza A exists in 9 subtypes.

Thus, the subtypes of influenza A viruses are designated by denoting serial subtype numbers of H and N antigens as H1N1, H2N2 etc.

Influenza A viruses infect human beings, birds, pigs and horses. In view of a high antigenic variation in H and N components, influenza A viruses are responsible for many known epidemics and pandemics in history and in present times. Major antigenic variation in H or N antigens is called *antigenic shift* while minor variation is termed *antigenic drift*. In general, population at high risk are immunosuppressed patients, elderly individuals and infants.

Two of the known subtypes of influenza A viruses which have affected the human beings in recent times are as under:

- ❖ Avian influenza virus A/H5N1 commonly called "bird flu".
- ❖ Swine influenza virus A/H1N1 commonly called "swine flu".

These two entities are briefly discussed below.

BIRD FLU ((INFLUENZA A/H5N1)

H5N1 subtype of the influenza type A virus infection causes severe acute respiratory syndrome (SARS) which is the human form of bird flu or avian influenza with having similar symptomatology. Every year, there have been outbreaks in poultry birds in different parts of the world resulting in slaughtering of millions of infected chickens every year. Human outbreak of the disease called SARS reemerged in December 2003 in southern China, Hong Kong and Vietnam and then spread to other countries in Asia, Europe and America. Since then, every year there have been seasonal outbreaks in the human form of the disease in high winter and has so far affected 15 countries and taken a toll of over 250 lives. Its rapidly downhill and fatal clinical course and an apprehension of pandemic has sent alarm bells all over world for quarantine.

PATHOGENESIS SARS is caused by influenza type A/H5N1 respiratory virus, also called SARS-associated coronaviruses (SARS-CoV). Though it is not fatal for wild birds, it can kill poultry birds and people. Humans acquire infection through contaminated nasal, respiratory and faecal material from infected birds. An individual who has human flu and also gets infected with bird flu, then the hybrid virus so produced is highly contagious and causes lethal disease. No person-to-person transmission has been reported so far but epidemiologists fear that if it did occur it will be a global epidemic. Humans do not have immune protection against avian viruses.

LABORATORY DIAGNOSIS Following abnormalities in laboratory tests are noted:

1. Almost normal-to-low TLC with lymphopaenia in about half the cases, mostly due to fall in CD4+ T cells.
2. Thrombocytopenia.
3. Elevated liver enzymes: aminotransferases, creatine kinase and LDH.
4. Virus isolation by reverse transcriptase-PCR on respiratory sample, plasma, urine or stool.
5. Tissue culture.
6. Detection of serum antibodies by ELISA or immunofluorescence.

CLINICOPATHOLOGICAL FEATURES Typically, the disease begins with influenza-like features such as fever, cough, dyspnoea, sore throat, muscle aches and eye infection. Soon, the patient develops viral pneumonia evident on X-ray chest and acute respiratory distress (hence the term SARS), and terminally kidney failure.

There is apprehension of an epidemic of SARS, if the avian virus mutates and gains the ability to cause person-to-person infection. Since currently vaccine is yet being developed, the available measures are directed at prevention of infection such as by culling (killing of the infected poultry birds) and isolation of infected case.

SWINE FLU (INFLUENZA A/H1N1)

H1N1 influenza type A flu which appeared last in 1977-78 as a mild form of pandemic reappeared in April 2009 as an outbreak in Mexico but is rapidly spreading elsewhere. Presently, the disease has already spread to 39 countries including US. In view of rising number of cases, with about 10,000 confirmed cases and about 100 deaths by end-May 2009 attributed to

swine flu from all over the world, the WHO has alerted that it may become a worldwide flu pandemic.

PATHOGENESIS H1N1 influenza type A virus is primarily an infection in pigs with low mortality in them. Human beings acquire infection by direct contact with infected pigs. However, further transmission of H1N1 flu occurs by person-to-person contact such as by coughing, sneezing etc but it is not known to occur from eating pork.

CLINICAL FEATURES The disease has the usual flu-like clinical features, but additionally one-third of cases have been found to have diarrhoea and vomiting.

Since human beings do not have immune protection by antibody response against H1N1 influenza type A and the usual seasonal flu vaccine does not provide protection against H1N1, personal hygiene and prophylaxis remain the mainstay of further spread of disease.

VARICELLA ZOSTER VIRUS INFECTION

Varicella zoster virus is a member of herpes virus family and causes chickenpox (varicella) in non-immune individuals and herpes zoster (shingles) in those who had chickenpox in the past.

Varicella or chickenpox It is an acute vesicular exanthem occurring in non-immune persons, especially children. The condition begins as an infection of the nasopharynx. On entering the blood stream, viraemia is accompanied by onset of fever, malaise and anorexia. Maculopapular skin rash, usually on the upper trunk and face, develops in a day or two. This is followed by formation of vesicles which rupture and heal with formation of scabs. A few cases may develop complications which include pneumonia, hepatitis, encephalitis, carditis, orchitis, arthritis, and haemorrhages.

Herpes zoster or shingles It is a recurrent, painful, vesicular eruption caused by reactivation of dormant varicella zoster virus in an individual who had chickenpox in the earlier years. The condition is infectious and spreads to children. The virus during the latent period resides in the dorsal root spinal ganglia or in the cranial nerve ganglia. On reactivation, the virus spreads from the ganglia to the sensory nerves and to peripheral nerves. Unlike chickenpox, the vesicles in shingles are seen in one or more of the sensory dermatomes and along the peripheral nerves. The lesions are particularly painful as compared with painless eruptions in chickenpox.

HERPES SIMPLEX VIRUS INFECTION

Two of the herpes simplex viruses (HSV)—type 1 and 2, cause 'fever blisters' and herpes genitalis respectively.

HSV-1 causes vesicular lesions on the skin, lips and mucous membranes. The infection spreads by close contact. The condition is particularly severe in immunodeficient patients and neonates while milder attacks of infection cause fever-blisters on lips, oral mucosa and skin. Severe cases may develop complications such as meningoencephalitis and keratoconjunctivitis. Various stimuli such as fever, stress and respiratory infection reactivate latent virus lying in the ganglia and result in recurrent attacks of blisters.

HSV-2 causes herpes genitalis characterised by vesicular and necrotising lesions on the cervix, vagina and vulva. Like

HSV-1 infection, lesions caused by HSV-2 are also recurrent and develop in non-immune individuals. Latency of HSV-2 infection is similar to HSV-1 and the organisms are reactivated by stimuli such as menstruation and sexual intercourse.

RABIES

Rabies is a fatal form of encephalitis in humans caused by rabies virus. The virus is transmitted into the human body by the bite of infected carnivores e.g. dog, wolf, fox and bats. The virus spreads from the contaminated saliva of these animals. The organism enters a peripheral nerve and then travels to the spinal cord and brain. A latent period of 10 days to 3 months may elapse between the bite and onset of symptoms. Since the virus localises at the brainstem, it produces classical symptoms of difficulty in swallowing and painful spasm of the throat termed hydrophobia. Other clinical features such as irritability, seizure and delirium point towards viral encephalopathy. Death occurs within a period of a few weeks.

Microscopically, neurons of the brainstem show characteristic Negri bodies which are intracytoplasmic, deeply eosinophilic inclusions.

GIST BOX 6.4 Diseases caused by Viruses

- ☐ Mosquito-borne viral haemorrhagic fevers in which *Aedes aegypti* mosquitoes are vectors, are the most common problem the world over, especially in developing countries, and include yellow fever and dengue fever.
- ☐ Chikungunya is primarily a disease in nonhuman primates but the infection is transmitted to humans by *A. aegypti* mosquito.

- ☐ Influenza virus infection is an important and common form of communicable disease, especially prevalent as a seasonal infection in the developed countries.
- ☐ Two of the known subtypes of influenza A viruses which have affected the mankind in recent times are avian influenza virus A/H5N1 commonly called "bird flu" and swine influenza virus A/H1N1 commonly called "swine flu".
- ☐ Varicella zoster virus is a member of herpes virus family and causes chickenpox (varicella) in non-immune individuals and herpes zoster (shingles) in those who had chickenpox in the past.
- ☐ Two of the herpes simplex viruses (HSV)—type 1 and 2, cause 'fever blisters' and herpes genitalis.
- ☐ Rabies is a fatal form of encephalitis in humans caused by rabies virus.

DISEASES CAUSED BY PARASITES

Diseases caused by parasites (protozoa and helminths) are quite common and comprise a very large group of infestations and infections in human beings. Parasites may cause disease due to their presence in the lumen of the intestine, due to infiltration into the blood stream, or due to their presence inside the cells. A short list of parasitic diseases is given in **Table 6.5**. These diseases form a distinct subject of study called Parasitology; only a few conditions are briefly considered below.

AMOEBIASIS

Amoebiasis is caused by *Entamoeba histolytica*, named for its lytic action on tissues. It is the most important intestinal infection of man. The condition is particularly more common in tropical and subtropical areas with poor sanitation.

Table 6.5 Diseases caused by parasites.

| DISEASE | ETIOLOGIC AGENT |
|---|---|
| A. PROTOZOAL DISEASES | |
| 1. Chagas' disease (Trypanosomiasis) | <i>Trypanosoma cruzi</i> |
| 2. Leishmaniasis (Kala-azar) | <i>L. tropica</i> , <i>L. braziliensis</i> , <i>L. donovani</i> |
| 3. Malaria* | <i>Plasmodium vivax</i> , <i>P. falciparum</i> , <i>P. ovale</i> , <i>P. malariae</i> |
| 4. Toxoplasmosis | <i>Toxoplasma gondii</i> |
| 5. Pneumocystosis | <i>Pneumocystis carinii</i> |
| 6. Amoebiasis* | <i>Entamoeba histolytica</i> |
| 7. Giardiasis | <i>Giardia lamblia</i> |
| B. HELMINTHIC DISEASES | |
| 1. Ascariasis | <i>Ascaris lumbricoides</i> |
| 2. Enterobiasis (oxyuriasis) | <i>Enterobius vermicularis</i> |
| 3. Hookworm disease | <i>Ancylostoma duodenale</i> |
| 4. Trichinosis | <i>Trichinella spiralis</i> |
| 5. Filariasis* | <i>Wuchereria bancrofti</i> |
| 6. Visceral larva migrans | <i>Toxocara canis</i> |
| 7. Cutaneous larva migrans | <i>Strongyloides stercoralis</i> |
| 8. Schistosomiasis (Bilharziasis) | <i>Schistosoma haematobium</i> |
| 9. Clonorchiasis | <i>Clonorchis sinensis</i> |
| 10. Fascioliasis | <i>Fasciola hepatica</i> |
| 11. Echinococcosis (Hydatid disease) (page 601) | <i>Echinococcus granulosus</i> |
| 12. Cysticercosis* | <i>Taenia solium</i> |

*Diseases discussed in this chapter

The parasite occurs in 2 forms:

- ◆ a *trophozoite form* which is active adult form seen in the tissues and diarrhoeal stools; and
- ◆ a *cystic form* seen in formed stools but not in the tissues.

The trophozoite form can be stained positively with PAS stain in tissue sections while amoebic cysts having four nuclei can be identified in stools. The cysts are the infective stage of the parasite and are found in contaminated water or food. The trophozoites are formed from the cyst stage in the intestine and colonise in the caecum and large bowel (page 555). The trophozoites as well as cysts are passed in stools but the trophozoites fail to survive outside or are destroyed by gastric secretions.

MORPHOLOGIC FEATURES The lesions of amoebiasis include amoebic colitis, amoeboma, amoebic liver abscess and spread of lesions to other sites (Fig. 6.9).

Amoebic colitis, the most common type of amoebic infection begins as a small area of necrosis of mucosa which may ulcerate. These ulcerative lesions may enlarge, develop undermining of margins of the ulcer due to lytic action of the trophozoite and have necrotic bed. Such chronic amoebic ulcers are described as flask-shaped ulcers due to their shape. The margin of the ulcer shows inflammatory response consisting of admixture of polymorphonuclear as well as mononuclear cells besides the presence of trophozoites of *Entamoeba histolytica* (Fig. 6.10).

Amoeboma is the inflammatory thickening of the wall of large bowel resembling carcinoma of the colon.

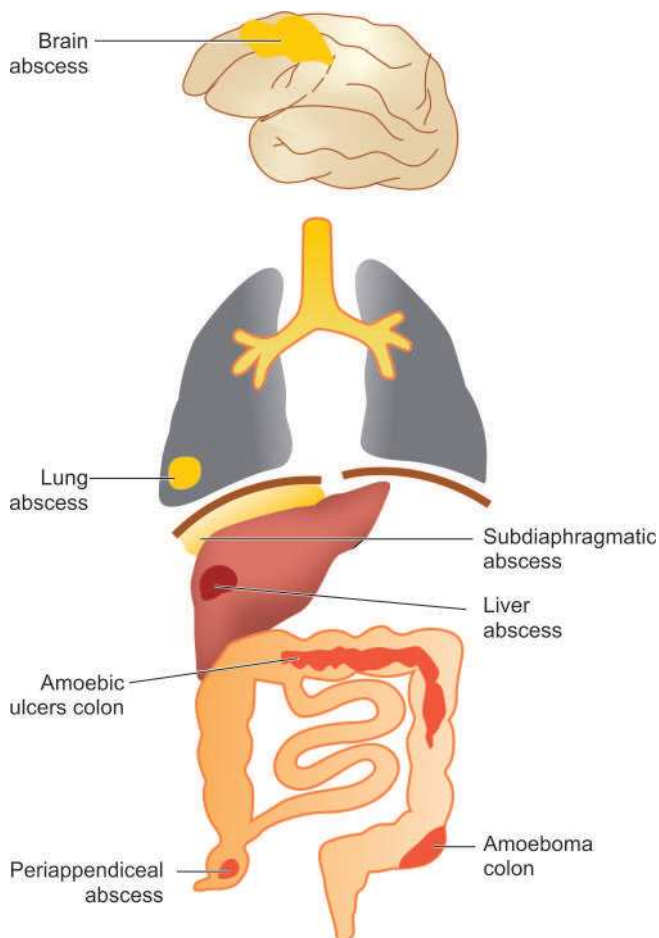

Figure 6.9 Lesions of amoebiasis.

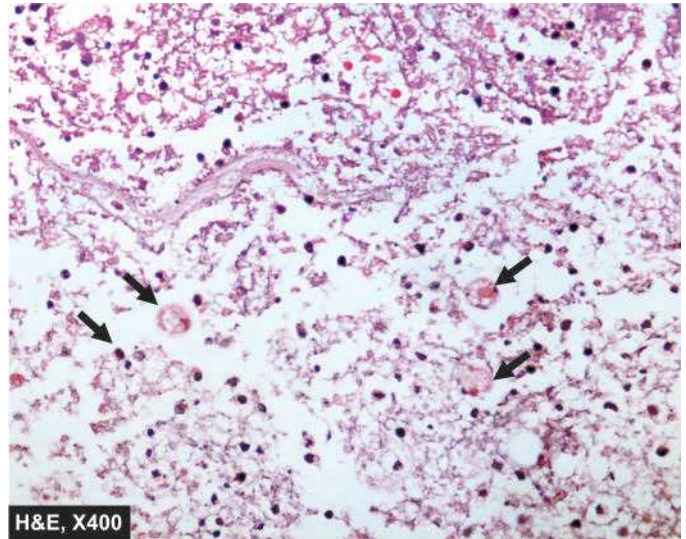

Figure 6.10 Amoebic colitis. Section from margin of amoebic ulcer shows necrotic debris, acute inflammatory infiltrate and a few trophozoites of *Entamoeba histolytica* (arrow).

Microscopically, the lesion consists of inflammatory granulation tissue, fibrosis and clusters of trophozoites at the margin of necrotic with viable tissue.

Amoebic liver abscess may be formed by invasion of the radicle of the portal vein by trophozoites. Amoebic liver abscess may be single or multiple (page 600). The amoebic abscess contains yellowish-grey amorphous liquid material in which trophozoites are identified at the junction of the viable and necrotic tissue.

Other sites where spread of amoebic infection may occur are peritonitis by perforation of amoebic ulcer of colon, extension to the lungs and pleura by rupture of amoebic liver abscess, haematogenous spread to cause amoebic carditis and cerebral lesions, cutaneous amoebiasis via spread of rectal amoebiasis or from anal intercourse.

MALARIA

Malaria is a protozoal disease caused by any one or combination of four species of plasmodia: *Plasmodium vivax*, *Plasmodium falciparum*, *Plasmodium ovale* and *Plasmodium malariae*. While *Plasmodium falciparum* causes malignant malaria, the other three species produce benign form of illness. These parasites are transmitted by bite of female *Anopheles* mosquito. The disease is endemic in several parts of the world, especially in tropical Africa, parts of South and Central America, India and South-East Asia.

The life cycle of plasmodia is complex and is diagrammatically depicted in Fig. 6.11, A. *P. falciparum* differs from other forms of plasmodial species in 4 respects:

- i) It does not have exo-erythrocytic stage.
- ii) Erythrocytes of any age are parasitised while other plasmodia parasitise juvenile red cells.
- iii) One red cell may contain more than one parasite.
- iv) The parasitised red cells are sticky causing obstruction of small blood vessels by thrombi, a feature which is responsible for extraordinary virulence of *P. falciparum*.

The main clinical features of malaria are cyclic peaks of high fever accompanied by chills, anaemia and splenomegaly.

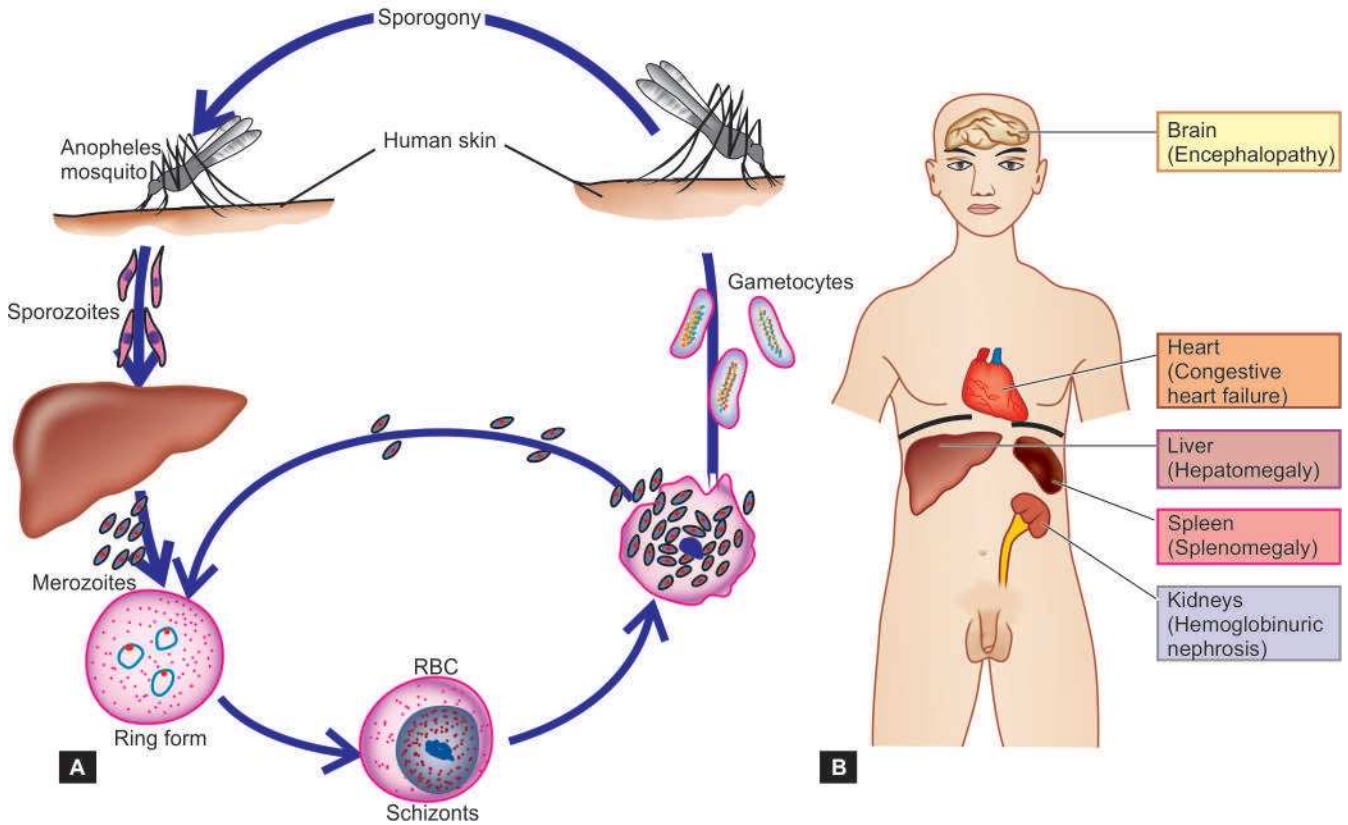

Figure 6.11 Life cycle of malaria (A) and major pathological changes in organs (B).

MORPHOLOGIC FEATURES Parasitisation and destruction of erythrocytes are responsible for major pathologic changes as under (Fig. 6.11,B):

1. Malarial pigment liberated by destroyed red cells accumulates in the phagocytic cells of the reticulo-endothelial system resulting in enlargement of the spleen and liver (*hepatosplenomegaly*).
2. In falciparum malaria, there is massive absorption of haemoglobin by the renal tubules producing *blackwater fever* (*haemoglobinuric nephrosis*).
3. At autopsy, *cerebral malaria* is characterised by congestion and petechiae on the white matter.
4. Parasitised erythrocytes in falciparum malaria are sticky and get attached to endothelial cells resulting in obstruction of capillaries of deep organs such as of the brain leading to hypoxia and death. If the patient lives, *microhaemorrhages* and *microinfarcts* may be seen in the brain.

The diagnosis of malaria is made by demonstration of malarial parasite in thin or thick blood films or sometimes in histologic sections (Fig. 6.12).

Major complications occur in severe falciparum malaria which may have manifestations of cerebral malaria (coma), hypoglycaemia, renal impairment, severe anaemia, haemoglobinuria, jaundice, pulmonary oedema, and acidosis followed by congestive heart failure and hypotensive shock.

FILARIASIS

Wuchereria bancrofti and *Brugia malayi* are responsible for causing Bancroftian and Malayan filariasis in different geographic regions. The lymphatic vessels inhabit the adult worm, especially in the lymph nodes, testis and epididymis. Microfilariae seen in the circulation are produced by the female worm (Fig. 6.13). Majority of infected patients remain asymptomatic. Symptomatic cases may have two forms of disease—an acute form and a chronic form.

◆ *Acute form* of filariasis presents with fever, lymphangitis, lymphadenitis, epididymo-orchitis, urticaria, eosinophilia and microfilariaemia.

◆ *Chronic form* of filariasis is characterised by lymphadenopathy, lymphoedema, hydrocele and elephantiasis.

MORPHOLOGIC FEATURES The most significant histologic changes are due to the presence of adult worms in the lymphatic vessels causing lymphatic obstruction and lymphoedema. The regional lymph nodes are enlarged and their sinuses are distended with lymph. The tissues surrounding the blocked lymphatics are infiltrated by chronic inflammatory cell infiltrate consisting of lymphocytes, histiocytes, plasma cells and eosinophils. Chronicity of the process causes enormous thickening and induration of the skin of legs and scrotum resembling the hide of an elephant and hence the name *elephantiasis*. *Chylous ascites* and *chyluria* may occur due to rupture of the abdominal lymphatics.

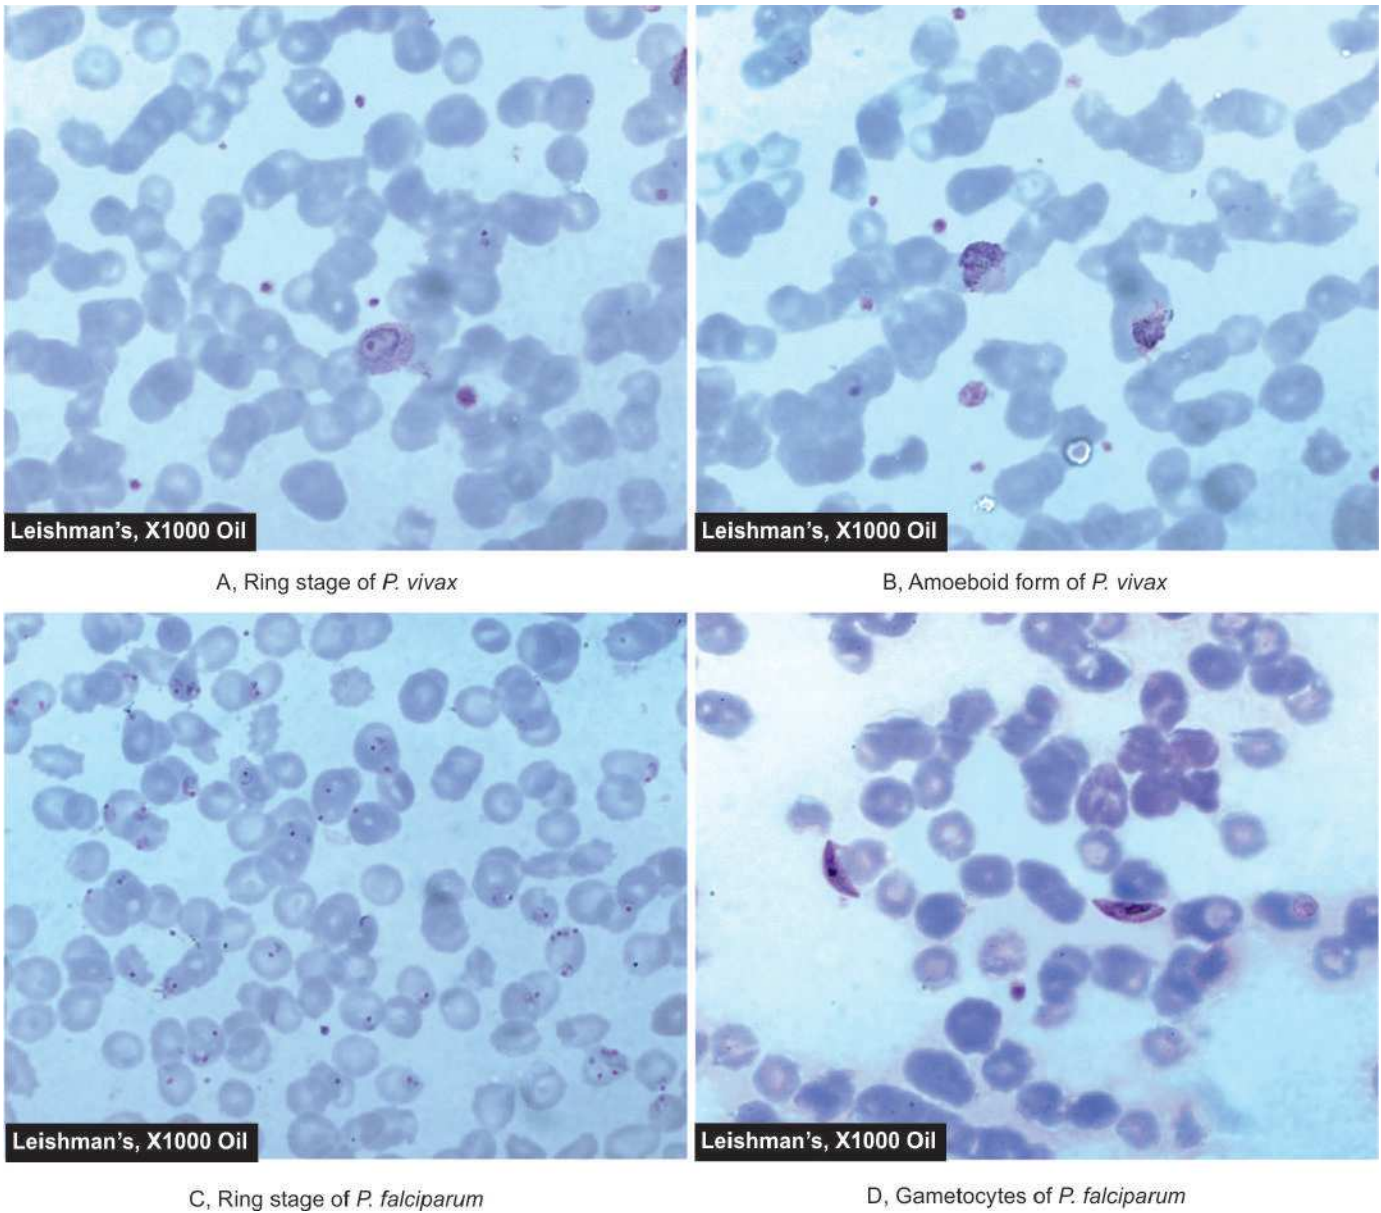

Figure 6.12 Malarial parasite in blood film—various stages of two main species, *P. vivax* and *P. falciparum*.

Figure 6.13 Microfilariae in blood film.

CYSTICERCOSIS

Cysticercosis is an infection by the larval stage of *Taenia solium*, the pork tapeworm. The adult tapeworm resides in the human intestines. The eggs are passed in human faeces which are ingested by pigs or they infect vegetables. These eggs then develop into larval stages in the host, spread by blood to any site in the body and form cystic larvae termed *cysticercus cellulosae*. Human beings may acquire infection by the larval stage by eating undercooked pork ('measly pork'), by ingesting uncooked contaminated vegetables, and sometimes, by autoinfection.

MORPHOLOGIC FEATURES The cysticercus may be single or there may be multiple cysticerci in the different tissues of the body. The cysts may occur virtually anywhere in body and accordingly produce symptoms; most common sites are the brain, skeletal muscle and skin (**Fig. 6.14**). Cysticercus consists of a round to oval white cyst, about

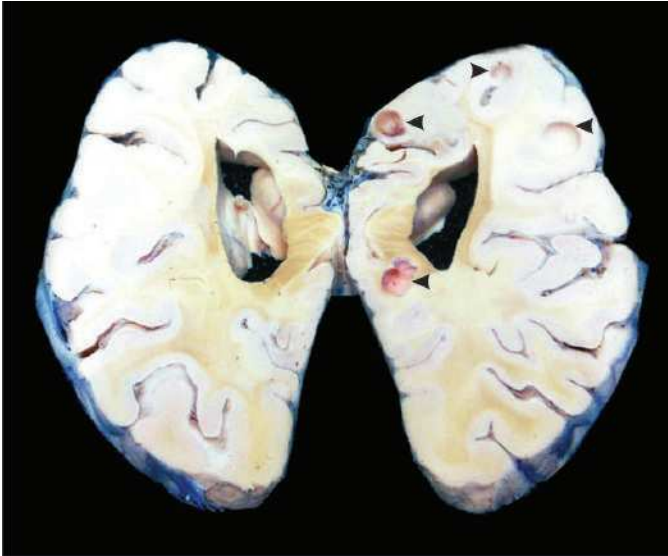

Figure 6.14 Numerous cysticerci in the base of the brain.

1 cm in diameter, contains milky fluid and invaginated scolex with birefringent hooklets. The cysticercus may remain viable for a long time and incite no inflammation. But when the embryo dies, it produces granulomatous reaction with eosinophils. Later, the lesion may become scarred and calcified (**Fig. 6.15**).

TORCH COMPLEX

Acronym 'TORCH' complex refers to development of common complex of symptoms in infants due to infection with different microorganisms that include: *Toxoplasma*, Others, Rubella, Cytomegalovirus, and Herpes simplex virus; category of 'Others' refers to infections such as hepatitis B, coxsackievirus B, mumps and poliovirus. The infection may be acquired by the foetus during intrauterine life, or perinatally and damage the foetus or infant. Since the symptoms produced by TORCH group of organisms are indistinguishable from each other, it is a common practice to test for all the four main TORCH agents in a suspected pregnant mother or infant.

It has been estimated that TORCH complex infections have an overall incidence of 1-5% of all live born children. All the microorganisms in the TORCH complex are transmitted transplacentally and, therefore, infect the foetus from the mother. Herpes and cytomegalovirus infections are common intrapartum infections acquired venereally.

- ◆ Toxoplasmosis is a protozoal infection acquired by contact with cat's faeces or by ingestion of raw uncooked meat.
- ◆ Rubella or German measles is teratogenic in pregnant mothers.
- ◆ Cytomegalovirus and herpesvirus infections are generally transmitted to foetus by chronic carrier mothers.

An infectious mononucleosis-like disease is present in about 10% of mothers whose infants have *Toxoplasma* infection. Genital herpes infection is present in 20% of mothers whose newborn babies suffer from herpes infection. Rubella infection during acute stage in the first 10 weeks of pregnancy

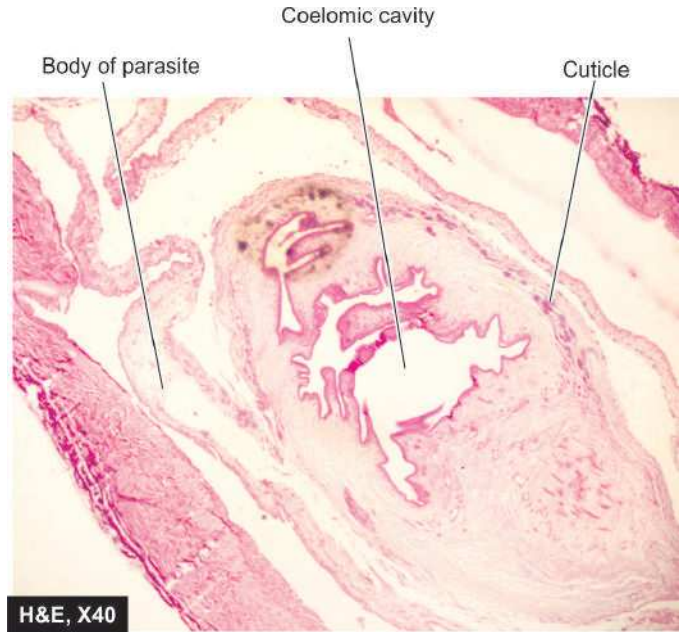

Figure 6.15 Cysticercus in skeletal muscle. The worm is seen in the cyst while the cyst wall shows palisade layer of histiocytes.

is more harmful to the foetus than at later stage of gestation. Symptoms of cytomegalovirus infection are present in less than 1% of mothers who display antibodies to it.

The classic features of syndrome produced by TORCH complex are seen in congenital rubella. The features include: ocular defects, cardiac defects, CNS manifestations, sensori-neural deafness, thrombocytopenia and hepatosplenomegaly (**Fig. 6.16**).

The foetal damage caused by TORCH complex infection is irreparable and, therefore, prevention and immunisation are the best modes of therapy.

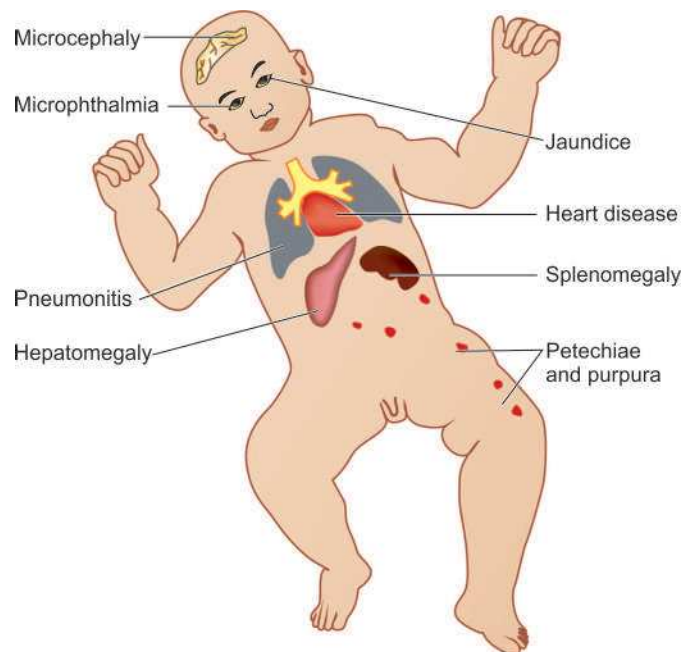

Figure 6.16 Lesions produced by TORCH complex infection in foetus *in utero*.

GIST BOX 6.5

Diseases caused by Parasites and TORCH

- Amoebiasis is caused by *Entamoeba histolytica* and the lesions produced are amoebic colitis, amoeboma, amoebic liver abscess.
- Malaria is a protozoal disease caused by any one or combination of four species of plasmodia: *Plasmodium vivax*, *Plasmodium falciparum*, *Plasmodium ovale* and *Plasmodium malariae*.
- Wuchereria bancrofti* and *Brugia malayi* cause Bancroftian and Malayan filariasis. The lymphatic vessels inhabit the adult worm, especially in the lymph nodes, testis and epididymis, while microfilariae are seen in the circulation.

- Cysticercosis is infection by the larval stage of *Taenia solium*, the pork tapeworm, and produces cystic larvae in different tissues called cysticercosis cellulosae.
- TORCH complex refers to development of symptoms in infants due to infection with *Toxoplasma*, Others, Rubella, Cytomegalovirus, and Herpes simplex virus; category of 'Others' refers to infections such as hepatitis B, coxsackievirus B, mumps and poliovirus.

7

Neoplasia

NOMENCLATURE AND CLASSIFICATION

INTRODUCTION The term 'neoplasia' means new growth; the new growth produced is called 'neoplasm' or 'tumour'. However, all 'new growths' are not neoplasms since examples of new growth of tissues and cells also exist in the processes of embryogenesis, regeneration and repair, hyperplasia and hormonal stimulation. The proliferation and maturation of cells in normal adults is controlled. Thus, normally some cells proliferate throughout life (labile cells), some have limited proliferation (stable cells), while others do not replicate (permanent cells). On the other hand, neoplastic cells lose control and regulation of replication and form an abnormal mass of tissue.

Therefore, satisfactory definition of a neoplasm or tumour is 'a mass of tissue formed as a result of abnormal, excessive, uncoordinated, autonomous and purposeless proliferation of cells even after cessation of stimulus for growth which caused it.' The branch of science dealing with the study of neoplasms or tumours is called oncology (*oncos*=tumour, *logos*=study). Neoplasms may be 'benign' when they are slow-growing and localised without causing much difficulty to the host, or 'malignant' when they proliferate rapidly, spread throughout the body and may eventually cause death of the host. The common term used for all malignant tumours is cancer. Hippocrates (460-370 BC) coined the term *karkinos* for cancer of the breast. The word 'cancer' means crab, thus reflecting the true character of cancer since 'it sticks to the part stubbornly like a crab'.

All tumours, benign as well as malignant, have 2 basic components:

◆ '*Parenchyma*' comprised by proliferating tumour cells; parenchyma determines the nature and evolution of the tumour.

◆ '*Supportive stroma*' composed of fibrous connective tissue and blood vessels; it provides the framework on which the parenchymal tumour cells grow.

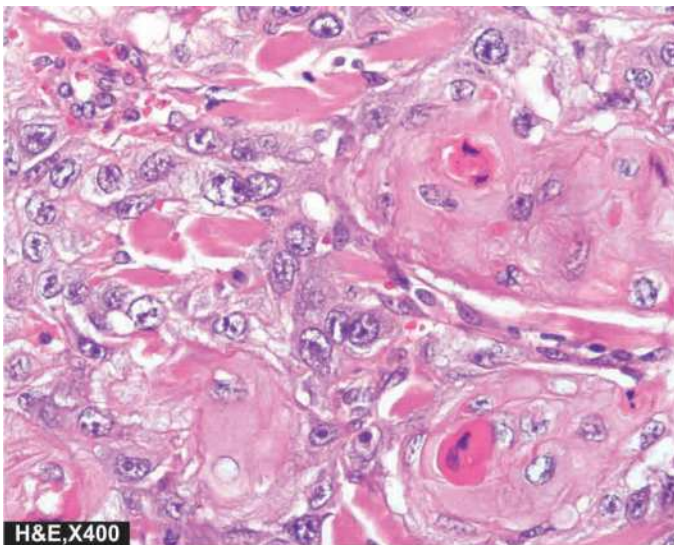

The tumours derive their nomenclature on the basis of the parenchymal component comprising them. The suffix '*-oma*' is added to denote benign tumours. Malignant tumours of epithelial origin are called *carcinomas*, while malignant mesenchymal tumours are named *sarcomas* (*sarcos* = fleshy) (Fig. 7.1). However, some cancers are composed of highly undifferentiated cells and are referred to as *undifferentiated malignant tumours*.

Although, this broad generalisation regarding nomenclature of tumours usually holds true in majority of instances, some examples contrary to this concept are: *melanoma* for carcinoma of the melanocytes, *hepatoma* for carcinoma of the hepatocytes, *lymphoma* for malignant tumour of the lymphoid tissue, and *seminoma* for malignant tumour of the testis. *Leukaemia* is the term used for cancer of blood forming cells.

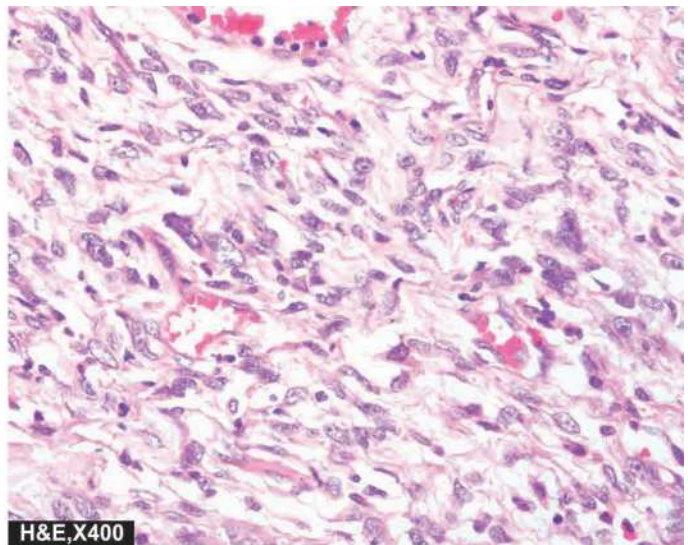

SPECIAL CATEGORIES OF TUMOURS Following categories of tumours are examples which defy the generalisation in nomenclature given above:

1. Mixed tumours When two types of tumours are combined in the same tumour, it is called a mixed tumour. For example:

i) *Adenosquamous carcinoma* is the combination of adenocarcinoma and squamous cell carcinoma in the endometrium.

A, SQUAMOUS CELL CARCINOMA

B, FIBROSARCOMA

Figure 7.1 Examples of carcinoma (epithelial malignant tumour) (A) and sarcoma (mesenchymal malignant tumour) (B).

ii) *Adenoacanthoma* is the mixture of adenocarcinoma and benign squamous elements in the endometrium.

iii) *Carcinosarcoma* is the rare combination of malignant tumour of the epithelium (carcinoma) and of mesenchymal tissue (sarcoma) such as in thyroid.

iv) *Collision tumour* is the term used for morphologically two different cancers in the same organ which do not mix with each other.

v) *Mixed tumour of the salivary gland* (or pleomorphic adenoma) is the term used for benign tumour having combination of both epithelial and mesenchymal tissue elements.

2. Teratomas These tumours are made up of a mixture of various tissue types arising from totipotent cells derived from the three germ cell layers—ectoderm, mesoderm and endoderm. Most common sites for teratomas are ovaries and testis (*gonadal teratomas*). But they occur at *extra-gonadal sites* as well, mainly in the midline of the body such as in the head and neck region, mediastinum, retroperitoneum, sacrococcygeal region etc. Teratomas may be *benign or mature* (most of the ovarian teratomas) or *malignant or immature* (most of the testicular teratomas).

3. Blastomas (Embryomas) Blastomas or embryomas are a group of malignant tumours which arise from embryonal or partially differentiated cells which would normally form blastema of the organs and tissue during embryogenesis. These tumours occur more frequently in infants and children (under 5 years of age). Some examples of such tumours in this age group are: neuroblastoma, nephroblastoma (Wilms' tumour), hepatoblastoma, retinoblastoma, medulloblastoma, pulmonary blastoma.

4. Hamartoma Hamartoma is benign tumour which is made of mature but disorganised cells of tissues indigenous to the particular organ e.g. hamartoma of the lung consists of mature cartilage, mature smooth muscle and epithelium. Thus, all mature differentiated tissue elements which comprise the bronchus are present in it but are jumbled up as a mass.

5. Choristoma Choristoma is the name given to the ectopic islands of normal tissue. Thus, choristoma is heterotopia but is not a true tumour, though it sounds like one.

CLASSIFICATION Currently, classification of tumours is based on the histogenesis (i.e. cell of origin) and on the anticipated behaviour (**Table 7.1**). However, it must be mentioned

Table 7.1 Classification of tumours.

| TISSUE OF ORIGIN | BENIGN | MALIGNANT |
|--|---|--------------------------------------|
| I. TUMOURS OF ONE PARENCHYMAL CELL TYPE | | |
| A. Epithelial Tumours | | |
| 1. Squamous epithelium | Squamous cell papilloma | Squamous cell (Epidermoid) carcinoma |
| 2. Transitional epithelium | Transitional cell papilloma | Transitional cell carcinoma |
| 3. Glandular epithelium | Adenoma | Adenocarcinoma |
| 4. Basal cell layer skin | — | Basal cell carcinoma |
| 5. Neuroectoderm | Naevus | Melanoma (Melanocarcinoma) |
| 6. Hepatocytes | Liver cell adenoma | Hepatoma (Hepatocellular carcinoma) |
| 7. Placenta (Chorionic epithelium) | Hydatidiform mole | Choriocarcinoma |
| B. Non-epithelial (Mesenchymal) Tumours | | |
| 1. Adipose tissue | Lipoma | Liposarcoma |
| 2. Adult fibrous tissue | Fibroma | Fibrosarcoma |
| 3. Embryonic fibrous tissue | Myxoma | Myxosarcoma |
| 4. Cartilage | Chondroma | Chondrosarcoma |
| 5. Bone | Osteoma | Osteosarcoma |
| 6. Synovium | Benign synovioma | Synovial sarcoma |
| 7. Smooth muscle | Leiomyoma | Leiomyosarcoma |
| 8. Skeletal muscle | Rhabdomyoma | Rhabdomyosarcoma |
| 9. Mesothelium | — | Mesothelioma |
| 10. Blood vessels | Haemangioma | Angiosarcoma |
| 11. Lymph vessels | Lymphangioma | Lymphangiosarcoma |
| 12. Glomus | Glomus tumour | — |
| 13. Meninges | Meningioma | Invasive meningioma |
| 14. Haematopoietic cells | — | Leukaemias |
| 15. Lymphoid tissue | Pseudolymphoma | Malignant lymphomas |
| 16. Nerve sheath | Neurilemmoma, Neurofibroma | Neurogenic sarcoma |
| 17. Nerve cells | Ganglioneuroma | Neuroblastoma |
| II. MIXED TUMOURS | | |
| Salivary glands | Pleomorphic adenoma (mixed salivary tumour) | Malignant mixed salivary tumour |
| III. TUMOURS OF MORE THAN ONE GERM CELL LAYER | | |
| Totipotent cells in gonads or in embryonal rests | Mature teratoma | Immature teratoma |

here that the classification described here is only a summary. Detailed classifications of benign and malignant tumours pertaining to different tissues and body systems along with morphologic features of specific tumours appear in the specific chapters of Systemic Pathology later.

**GIST BOX 7.1****Nomenclature and Classification of Tumours**

- ▣ A neoplasm or tumour is a mass of tissue formed as a result of abnormal, excessive, uncoordinated, autonomous and purposeless proliferation of cells even after removal of stimulus for growth which caused it.
- ▣ Neoplasms may be 'benign' when they are slow-growing and localised without causing much difficulty to the host, or 'malignant' when they proliferate rapidly, spread throughout the body and may eventually cause death of the host.
- ▣ All tumours have 2 basic components: parenchyma comprised by proliferating tumour cells, and supportive stroma composed of fibrous connective tissue and blood vessels.
- ▣ The tumours are named with suffix '-oma' to denote benign tumours. Malignant tumours of epithelial origin are called *carcinomas*, while malignant mesenchymal tumours are named *sarcomas*.
- ▣ A few examples of combination of tumours are mixed tumours, teratoma, blastoma, hamartoma, and choristoma.

CHARACTERISTICS OF TUMOURS

Majority of neoplasms can be categorised into benign and malignant on the basis of certain clinical features, biologic behaviour and morphological characteristics. However, there are exceptions—a small proportion of tumours have some features suggesting innocent growth while other features point towards a more ominous behaviour. Therefore, it must be borne in mind that based characteristics of neoplasms, there is a wide variation in the degree of deviation from the normal in all the tumours.

The characteristics of tumours are described under the following headings:

- I. Rate of growth
- II. Cancer phenotype and stem cells
- III. Clinical and gross features
- IV. Microscopic features
- V. Spread of tumours
 - a. Local invasion or direct spread
 - b. Metastasis or distant spread

Based on these characteristics, contrasting features of benign and malignant tumours are summarised in **Table 7.2** and illustrated in **Fig. 7.2**.

I. RATE OF GROWTH

The tumour cells generally proliferate more rapidly than the normal cells. In general, benign tumours grow slowly and malignant tumours rapidly. However, there are exceptions

Table 7.2 Contrasting features of benign and malignant tumours.

| FEATURE | BENIGN | MALIGNANT |
|---------------------------------------|--|---|
| I. CLINICAL AND GROSS FEATURES | | |
| 1. <i>Boundaries</i> | Encapsulated or well-circumscribed | Poorly-circumscribed and irregular |
| 2. <i>Surrounding tissue</i> | Often compressed | Usually invaded |
| 3. <i>Size</i> | Usually small | Often larger |
| 4. <i>Secondary changes</i> | Occur less often | Occur more often |
| II. MICROSCOPIC FEATURES | | |
| 1. <i>Pattern</i> | Usually resembles the tissue of origin closely | Often poor resemblance to tissue of origin |
| 2. <i>Basal polarity</i> | Retained | Often lost |
| 3. <i>Pleomorphism</i> | Usually not present | Often present |
| 4. <i>Nucleo-cytoplasmic ratio</i> | Normal | Increased |
| 5. <i>Anisonucleosis</i> | Absent | Generally present |
| 6. <i>Hyperchromatism</i> | Absent | Often present |
| 7. <i>Mitoses</i> | May be present but are always typical mitoses | Mitotic figures increased and are generally atypical and abnormal |
| 8. <i>Tumour giant cells</i> | May be present but without nuclear atypia | Present with nuclear atypia |
| 9. <i>Chromosomal abnormalities</i> | Infrequent | Invariably present |
| 10. <i>Function</i> | Usually well maintained | May be retained, lost or become abnormal |
| III. GROWTH RATE | Usually slow | Usually rapid |
| IV. LOCAL INVASION | Often compresses the surrounding tissues without invading or infiltrating them | Usually infiltrates and invades the adjacent tissues |
| V. METASTASIS | Absent | Frequently present |
| VI. PROGNOSIS | Local complications | Death by local and metastatic complications |

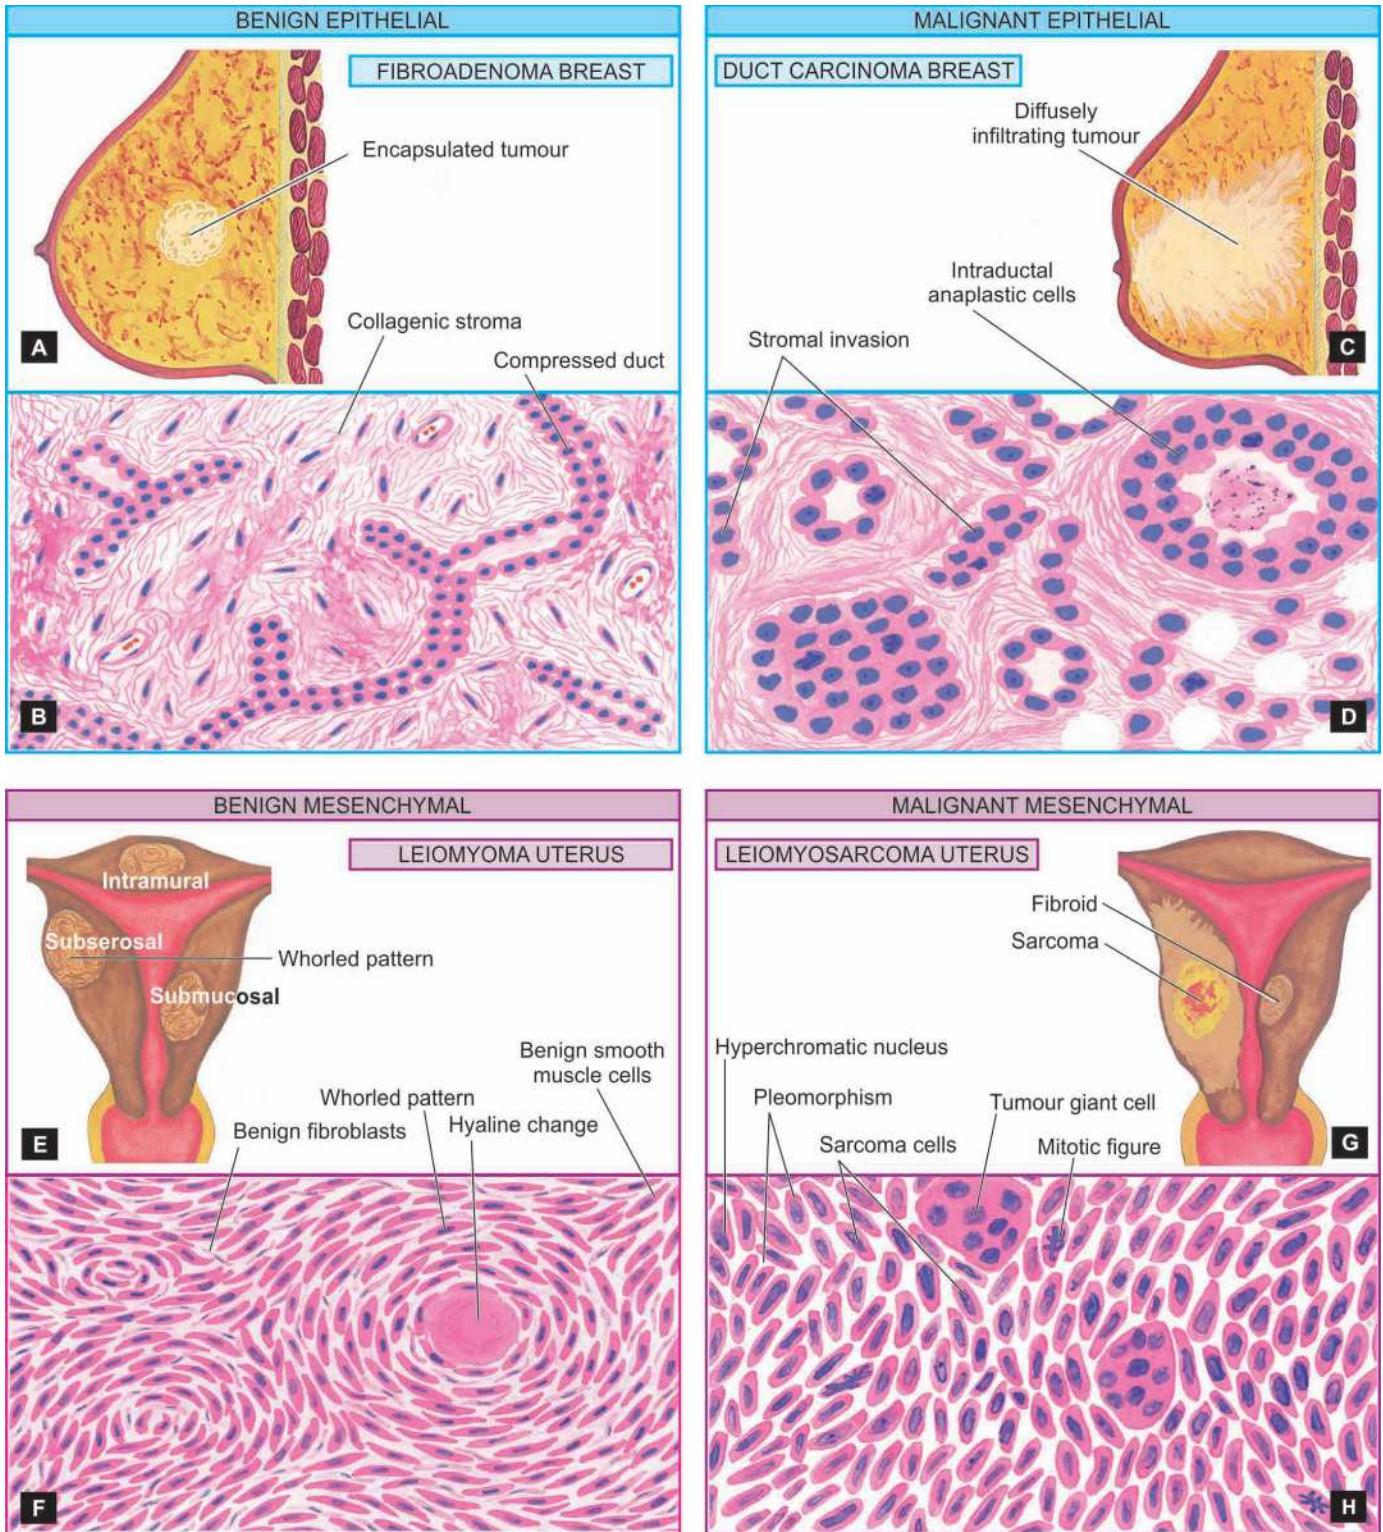

Figure 7.2 Salient gross and microscopic features of prototypes of benign (*left*) and malignant (*right*) tumours.

to this generalisation. The rate at which the tumour enlarges depends upon 2 main factors:

1. Rate of cell production, growth fraction and rate of cell loss
2. Degree of differentiation of the tumour.

1. Rate of cell production, growth fraction and rate of cell loss Rate of growth of a tumour depends upon 3 important parameters:

i) doubling time of tumour cells,

ii) number of cells remaining in proliferative pool (growth fraction), and

iii) rate of loss of tumour cells by cell shedding.

In general, malignant tumour cells have increased mitotic rate (doubling time) and slower death rate i.e. the cancer cells do not follow normal controls in cell cycle and are immortal. If the rate of cell division is high, it is likely that tumour cells in the centre of the tumour do not receive adequate nourishment and undergo ischaemic necrosis. At a stage when malignant

tumours grow relentlessly, they do so because a larger proportion of tumour cells remain in replicative pool but due to lack of availability of adequate nourishment, these tumour cells are either lost by shedding or leave the cell cycle to enter into G_0 (resting phase) or G_1 phase. While dead tumour cells appear as 'apoptotic figures' (page 30), the dividing cells of tumours are seen as normal and abnormal 'mitotic figures' (discussed later). Ultimately, malignant tumours grow in size because the cell production exceeds the cell loss.

2. Degree of differentiation Secondly, the rate of growth of malignant tumour is directly proportionate to the degree of differentiation. Poorly differentiated tumours show aggressive growth pattern as compared to better differentiated tumours. Some tumours, after a period of slow growth, may suddenly show spurt in their growth due to development of an aggressive clone of malignant cells. On the other hand, some tumours may cease to grow after sometime. Rarely, a malignant tumour may disappear spontaneously from the primary site, possibly due to necrosis caused by good host immune attack, only to reappear as secondaries elsewhere in the body e.g. choriocarcinoma, malignant melanoma.

The regulation of tumour growth is under the control of growth factors secreted by the tumour cells. Out of various growth factors, important ones modulating tumour biology are listed below and discussed later:

- i) Epidermal growth factor (EGF)
- ii) Fibroblast growth factor (FGF)
- iii) Platelet-derived growth factor (PDGF)
- iv) Colony stimulating factor (CSF)
- v) Transforming growth factors- β (TGF- β)
- vi) Interleukins 1 and 6 (IL-1, IL-6)
- vii) Vascular endothelial growth factor (VEGF)
- viii) Hepatocyte growth factor (HGF)

II. CANCER PHENOTYPE AND STEM CELLS

Normally growing cells in an organ are related to the neighbouring cells—they grow under normal growth controls, perform their assigned function and there is a balance between the rate of cell proliferation and the rate of cell death including cell suicide (i.e. apoptosis). Thus, normal cells are socially desirable. However, cancer cells exhibit anti-social behaviour as under:

- i) Cancer cells disobey the growth controlling signals in the body and thus *proliferate rapidly*.
- ii) Cancer cells escape death signals and achieve *immortality*.
- iii) Imbalance between cell proliferation and cell death in cancer causes *excessive growth*.
- iv) Cancer cells lose properties of differentiation and thus perform *little or no function*.
- v) Due to loss of growth controls, cancer cells are genetically unstable and develop *newer mutations*.
- vi) Cancer cells overrun their neighbouring tissue and *invade locally*.
- vii) Cancer cells have the ability to travel from the site of origin to other sites in the body where they colonise and establish *distant metastasis*.

Cancer cells originate by clonal proliferation of a single progeny of a cell (monoclonality). There is evidence to suggest that cancer cells arise from stem cells normally present in the tissues in small number and are not readily identifiable. These stem cells have the properties of prolonged self-renewal,

asymmetric replication and transdifferentiation (i.e. plasticity). These cancer stem cells are called tumour-initiating cells. Their definite existence in acute leukaemias has been known for a few decades and have now been found to be present in some other malignant tumours.

III. CLINICAL AND GROSS FEATURES

Clinically, benign tumours are generally slow growing, and depending upon the location, may remain asymptomatic (e.g. subcutaneous lipoma), or may produce serious symptoms (e.g. meningioma in the nervous system). On the other hand, malignant tumours grow rapidly, may ulcerate on the surface, invade locally into deeper tissues, may spread to distant sites (metastasis), and also produce systemic features such as weight loss, anorexia and anaemia. In fact, three cardinal clinical features of malignant tumours are: *anaplasia, invasiveness and metastasis* (discussed later).

Gross appearance of benign and malignant tumours may be quite variable and the features may not be diagnostic on the basis of gross appearance alone. However, certain distinctive features characterise almost all tumours compared to neighbouring normal tissue of origin—they have a different colour, texture and consistency. Gross terms such as papillary, fungating, infiltrating, haemorrhagic, ulcerative and cystic are used to describe the macroscopic appearance of the tumours. General gross features of benign and malignant tumours are as under (**Figs. 7.2 and 7.3**):

- ◆ *Benign tumours* are generally spherical or ovoid in shape. They are encapsulated or well-circumscribed, freely movable, more often firm and uniform, unless secondary changes like haemorrhage or infarction supervene (**Fig. 7.2, A, E**).
- ◆ *Malignant tumours*, on the other hand, are usually irregular in shape, poorly-circumscribed and extend into the adjacent tissues. Secondary changes like haemorrhage, infarction and ulceration are seen more often. Sarcomas typically have fish-flesh like consistency while carcinomas are generally firm (**Fig. 7.2, C, G**).

IV. MICROSCOPIC FEATURES

For recognising and classifying the tumours, the microscopic characteristics of tumour cells are of greatest importance. These features appreciated in histologic sections are as under:

1. Microscopic pattern
2. Histomorphology of neoplastic cells (differentiation and anaplasia)
3. Tumour angiogenesis and stroma
4. Inflammatory reaction.

1. MICROSCOPIC PATTERN

The patterns or arrangements of tumour cells are best appreciated under *low power* microscopic examination of the tissue section. Some of the common patterns in tumours are as under:

- i) The *epithelial tumours* generally consist of acini, sheets, columns or cords of epithelial tumour cells that may be arranged in solid or papillary pattern (**Fig. 7.2, B, D**).
- ii) The *mesenchymal tumours* have mesenchymal tumour cells arranged as interlacing bundles, fascicles or whorls, lying separated from each other usually by the intercellular matrix substance such as hyaline material in leiomyoma (**Fig. 7.2, E**),

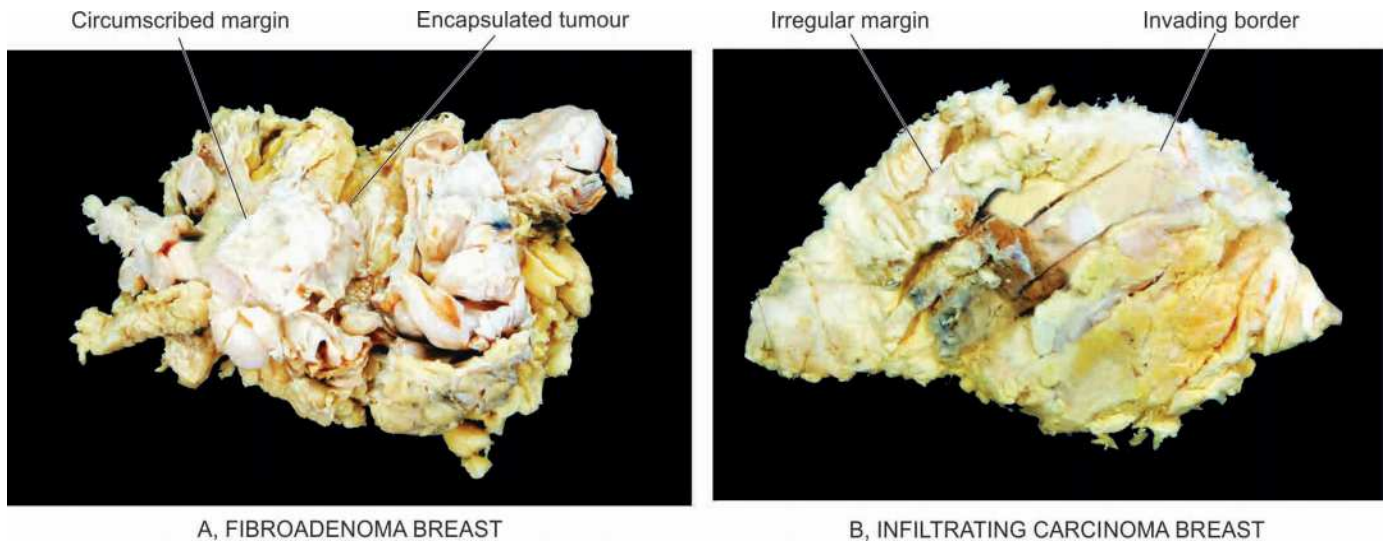

Figure 7.3 Gross appearance of a prototype of benign and malignant tumour.

cartilaginous matrix in chondroma, osteoid in osteosarcoma, reticulin network in soft tissue sarcomas etc (Fig. 7.2,H).

iii) Certain tumours have *mixed patterns* e.g. teratoma arising from totipotent cells, pleomorphic adenoma of salivary gland (mixed salivary tumour), fibroadenoma of the breast, carcinosarcoma of the uterus and various other combinations of tumour types.

iv) *Haematopoietic tumours* such as leukaemias and lymphomas often have none or little stromal support.

v) Generally, most benign tumours and low grade malignant tumours *reduplicate* the normal structure of origin more closely so that there is little difficulty in identifying and classifying such tumours (Fig. 7.2, B, F). However, anaplastic tumours differ greatly from the arrangement in normal tissue of origin of the tumour and may occasionally pose problems in classifying the tumour.

2. CYTOMORPHOLOGY OF NEOPLASTIC CELLS (DIFFERENTIATION AND ANAPLASIA)

The neoplastic cell is characterised by morphologic and functional alterations, the most significant of which are '*differentiation*' and '*anaplasia*'.

◆ **Differentiation** is defined as the extent of morphological and functional resemblance of parenchymal tumour cells

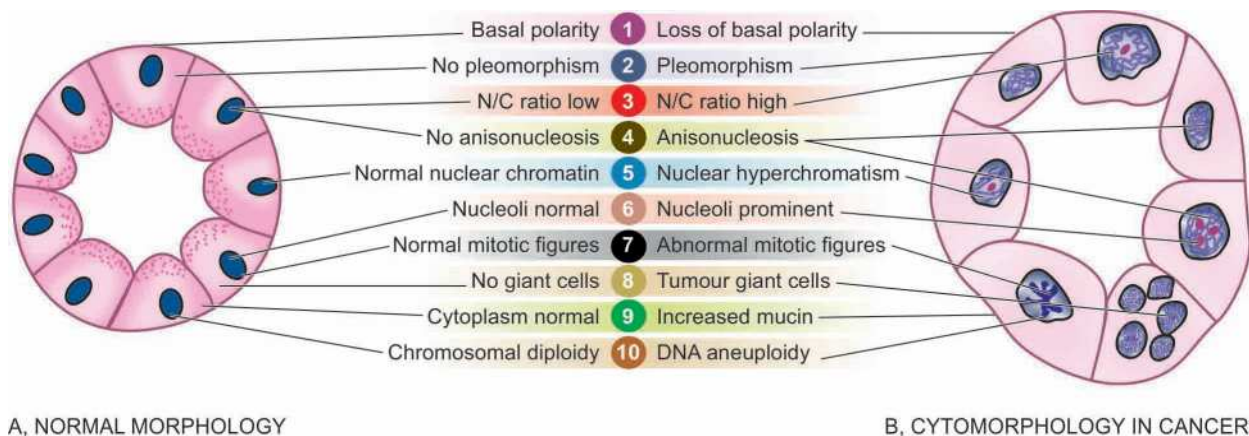

to corresponding normal cells. If the deviation of neoplastic cell in structure and function is minimal as compared to normal cell, the tumour is described as '*well-differentiated*' such as most benign and low-grade malignant tumours. '*Poorly differentiated*', '*undifferentiated*' or '*dedifferentiated*' are synonymous terms for poor structural and functional resemblance to corresponding normal cell.

◆ **Anaplasia** is lack of differentiation and is a characteristic feature of most malignant tumours. Depending upon the degree of differentiation, the extent of anaplasia is also variable i.e. poorly differentiated malignant tumours have high degree of anaplasia.

As a result of anaplasia, noticeable morphological and functional alterations in the neoplastic cells are observed which are best appreciated under *higher magnification* of the microscope. These features are as follows and are diagrammatically illustrated in Fig. 7.4:

i) **Loss of polarity** Normally, the nuclei of epithelial cells are oriented along the basement membrane which is termed as basal polarity. This property is based on cell adhesion molecules, particularly selectins. Early in malignancy, tumour cells lose their basal polarity so that the nuclei tend to lie away from the basement membrane (Fig. 7.5).

ii) **Pleomorphism** The term pleomorphism means variation in size and shape of the tumour cells. The extent of cellular

A, NORMAL MORPHOLOGY

B, CYTOMORPHOLOGY IN CANCER

Figure 7.4 Diagrammatic representation of cytomorphologic features of neoplastic cells. Characteristics of cancer (B) are contrasted with the normal appearance of an acinus (A).

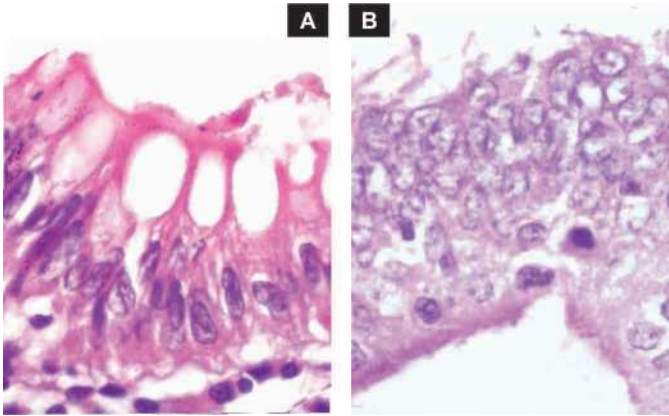

Figure 7.5 Microscopic appearance of loss of nuclear polarity (B) contrasted with normal basal polarity in columnar epithelium (A). The basement membrane is intact in both.

pleomorphism generally correlates with the degree of anaplasia. Tumour cells are often bigger than normal but in some tumours they can be of normal size or smaller than normal (**Fig. 7.6**).

iii) *N:C ratio* Generally, the nuclei of malignant tumour cells show more conspicuous changes. Nuclei are enlarged disproportionate to the cell size so that the nucleocytoplasmic ratio is increased from normal 1:5 to 1:1 (**Fig. 7.6**).

iv) *Anisonucleosis* Just like cellular pleomorphism, the nuclei too, show variation in size and shape in malignant tumour cells (**Fig. 7.6**).

v) *Hyperchromatism* Characteristically, the nuclear chromatin of malignant cell is increased and coarsely clumped. This is due to increase in the amount of nucleoprotein resulting in dark-staining nuclei, referred to as hyperchromatism (**Fig. 7.6**). Nuclear shape may vary, nuclear membrane may be irregular and nuclear chromatin is clumped along the nuclear membrane.

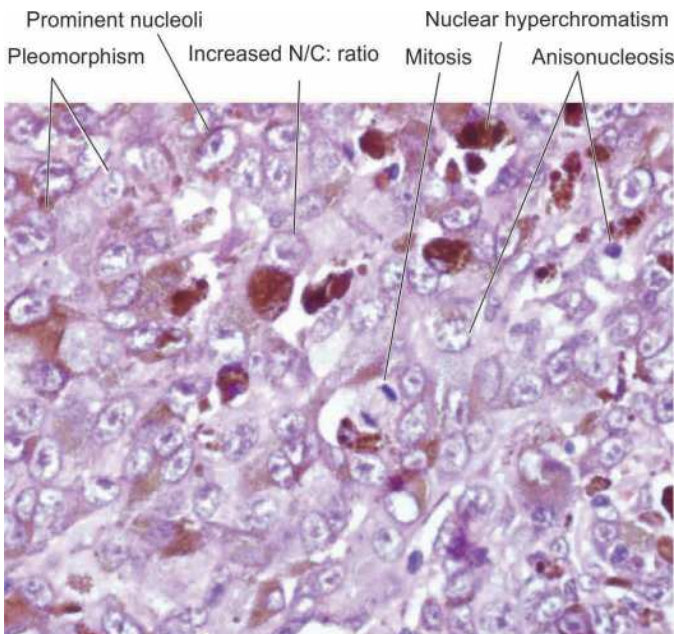

Figure 7.6 Nuclear features of malignant cells in malignant melanoma—pleomorphism, anisonucleosis, increased N/C: ratio, nuclear hyperchromatism and prominent nucleoli.

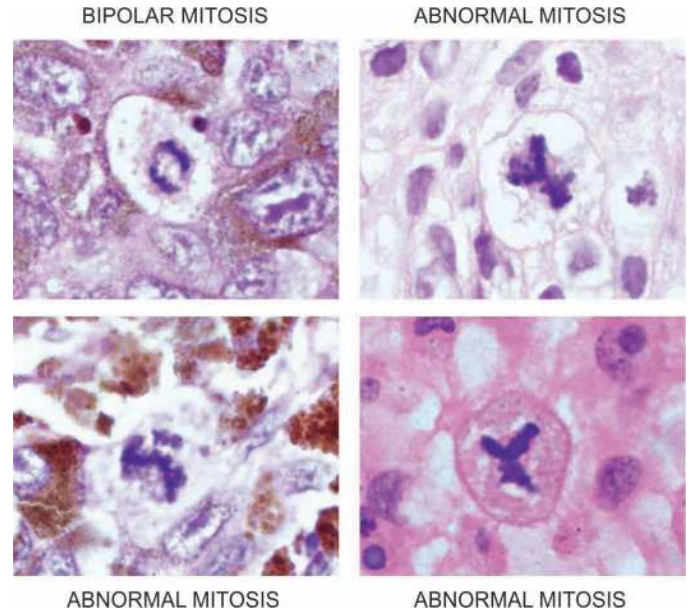

Figure 7.7 Normal and abnormal (atypical) mitotic figures.

vi) *Nucleolar changes* Malignant cells frequently have a prominent nucleolus or nucleoli in the nucleus reflecting increased nucleoprotein synthesis (**Fig. 7.6**). This may be demonstrated as Nucleolar Organiser Region (NOR) by silver (Ag) staining called AgNOR material.

vii) *Mitotic figures* The parenchymal cells of poorly-differentiated tumours often show large number of mitoses as compared with benign tumours and well-differentiated malignant tumours. As stated above, these appear as either normal or abnormal mitotic figures (**Fig. 7.7**):

◆ *Normal mitotic figures* may be seen in some non-neoplastic proliferating cells (e.g. haematopoietic cells of the bone marrow, intestinal epithelium, hepatocytes etc), in certain benign tumours and some low grade malignant tumours; in sections they are seen as a dark band of dividing chromatin at two poles of the nuclear spindle.

◆ *Abnormal or atypical mitotic figures* are more important in malignant tumours and are identified as tripolar, quadripolar and multipolar spindles in malignant tumour cells.

viii) *Tumour giant cells* Multinucleate tumour giant cells or giant cells containing a single large and bizarre nucleus, possessing nuclear characters of the adjacent tumour cells, are another important feature of anaplasia in malignant tumours (**Fig. 7.8**).

ix) *Functional (Cytoplasmic) changes* Structural anaplasia in tumours is accompanied with functional anaplasia as appreciated from the cytoplasmic constituents of the tumour cells. The functional abnormality in neoplasms may be quantitative, qualitative, or both.

◆ Generally, benign tumours and better-differentiated malignant tumours continue to function well qualitatively, though there may be *quantitative* abnormality in the product e.g. large or small amount of collagen produced by benign tumours of fibrous tissue, keratin formation in well-differentiated squamous cell carcinoma. In more anaplastic tumours, there is usually quantitative fall in the product made by the tumour cells e.g. absence of keratin in anaplastic squamous cell carcinoma.

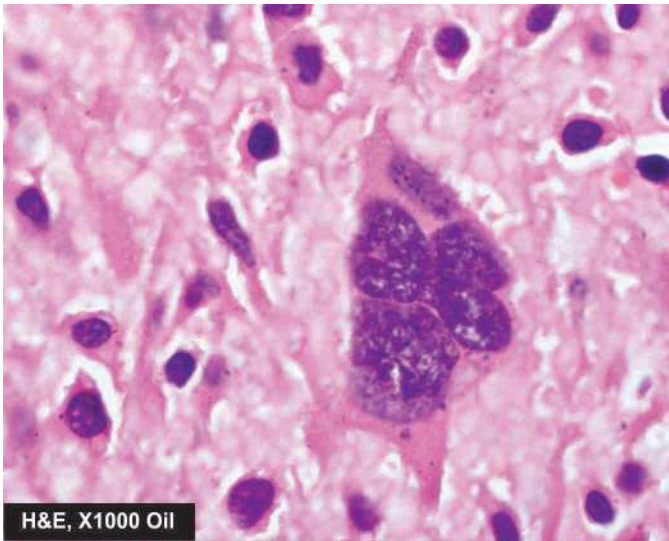

Figure 7.8 A multinucleate tumour giant cell in osteosarcoma.

◆ There may be both *qualitative and quantitative* abnormality of the cellular function in some anaplastic tumours e.g. multiple myeloma producing abnormal immunoglobulin in large quantities.

◆ Endocrine tumours may cause excessive hormone production leading to characteristic clinical syndromes. Besides the production of hormones by endocrine tumours, hormones or hormone-like substances may be produced by certain tumours quite unrelated to the endocrine glands. This property of tumours is called *ectopic hormone production* e.g. oat cell carcinoma of the lung can secrete ACTH and ADH; less often it may produce gonadotropin, thyrotropin, parathormone, calcitonin and growth hormone. Ectopic erythropoietin may be produced by carcinoma of kidneys, hepatocellular carcinoma and cerebellar haemangioblastoma.

x) *Chromosomal abnormalities* All tumour cells have abnormal genetic composition and on division they transmit the genetic abnormality to their progeny. The chromosomal abnormalities are more marked in more malignant tumours which include deviations in both morphology and number of chromosomes. Most malignant tumours show *DNA aneuploidy*, often in the form of an increase in the number of chromosomes, reflected morphologically by the increase in the size of nuclei.

One of the most important examples of a consistent chromosomal abnormality in human malignancy is the presence of Philadelphia chromosome (named after the city in which it was first described) in 95% cases of chronic myeloid leukaemia. In this, part of the long arm of chromosome 9 is translocated to part of the long arm of chromosome 22 (t 9; 22). Other examples of neoplasms showing chromosomal abnormalities are Burkitt's lymphoma, acute lymphoid leukaemia, multiple myeloma, retinoblastoma, oat cell carcinoma, Wilms' tumour etc.

3. TUMOUR ANGIOGENESIS AND STROMA

The connective tissue alongwith its vascular network forms the supportive framework on which the parenchymal tumour cells grow and receive nourishment. In addition to variable amount of connective tissue and vascularity, the stroma may have nerves and metaplastic bone or cartilage but no lymphatics.

TUMOUR ANGIOGENESIS In order to provide nourishment to growing tumour, new blood vessels are formed from pre-existing ones (angiogenesis). Its mechanism and the role of angiogenic factors elaborated by tumour cells (e.g. vascular endothelium growth factor or VEGF) is discussed later under molecular pathogenesis of cancer. However, related morphologic features are as under:

i) *Microvascular density* The new capillaries add to the vascular density of the tumour which has been used as a marker to assess the rate of growth of tumours and hence grade the tumours. This is done by counting microvascular density in the section of the tumour.

ii) *Central necrosis* However, if the tumour outgrows its blood supply as occurs in rapidly growing tumours or tumour angiogenesis fails, its core undergoes ischaemic necrosis.

TUMOUR STROMA The collagenous tissue in the stroma may be scanty or excessive. In the former case, the tumour is soft and fleshy (e.g. in sarcomas, lymphomas), while in the latter case the tumour is hard and gritty (e.g. infiltrating duct carcinoma breast). Growth of fibrous tissue in tumour is stimulated by basic fibroblast growth factor (bFGF) elaborated by tumour cells.

◆ If the epithelial tumour is almost entirely composed of parenchymal cells, it is called *medullary* e.g. medullary carcinoma of the breast (**Fig. 7.9, A**), medullary carcinoma of the thyroid.

◆ If there is excessive connective tissue stroma in the epithelial tumour, it is referred to as *desmoplasia* and the tumour is hard or *scirrhous* e.g. infiltrating duct carcinoma breast (**Fig. 7.9, B**), linitis plastica of the stomach.

4. INFLAMMATORY REACTION

At times, prominent inflammatory reaction is present in and around the tumours. It could be the result of ulceration in the cancer when there is secondary infection. The inflammatory reaction in such instances may be acute or chronic. However, some tumours show chronic inflammatory reaction, chiefly of lymphocytes, plasma cells and macrophages, and in some

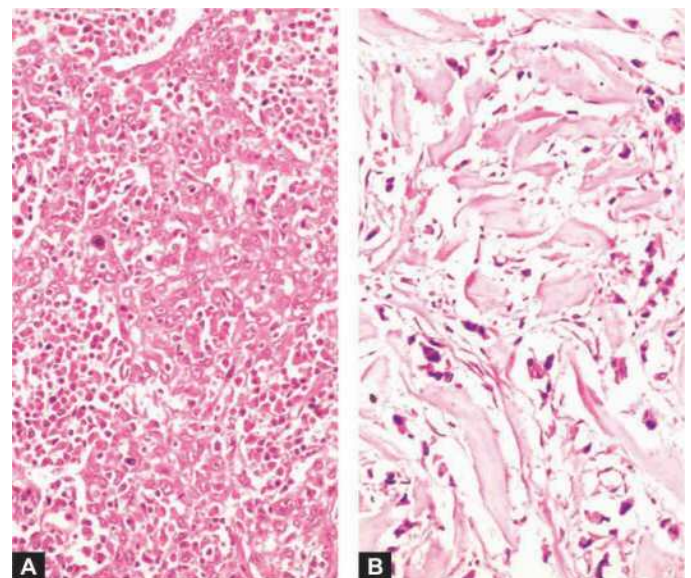

Figure 7.9 Tumour stroma. A, Medullary carcinoma of breast is rich in parenchymal cells. B, Scirrhous carcinoma of breast having abundant collagenised (desmoplastic) stroma.

instances granulomatous reaction, as a part of the morphologic features of the tumour, in the absence of ulceration. This is due to cell-mediated immunologic response by the host in an attempt to destroy the tumour. In some cases, such an immune response improves the prognosis.

The *examples* of such reaction are: seminoma testis (Fig. 7.10), malignant melanoma of the skin, lympho-epithelioma of the throat, medullary carcinoma of the breast, choriocarcinoma, Warthin's tumour of salivary glands etc.

GIST BOX 7.2

Characteristics of Tumours

- ▣ Neoplasms are categorised into benign and malignant on the basis of certain clinical and morphologic features.
- ▣ The tumour cells generally proliferate more rapidly than the normal cells; benign tumours grow slowly and malignant tumours rapidly. Tumour enlargement depends upon rate of cell production, growth fraction and rate of cell loss and degree of differentiation of the tumour.
- ▣ Evidence suggests that cancer cells originate by clonal proliferation of a single progeny of stem cells (monoclonality).
- ▣ Clinically, benign tumours are generally slow growing and may remain asymptomatic while malignant tumours grow rapidly and may spread locally or to distant sites.
- ▣ Grossly, benign tumours are generally encapsulated or well-circumscribed, while malignant tumours are usually irregular in shape, poorly-circumscribed and extend into the adjacent tissues.
- ▣ Microscopic features of tumours are more important for recognising and classifying the tumours. These include microscopic pattern of tumour cells, histomorphology of neoplastic cells, tumour angiogenesis, and stromal reaction.
- ▣ The neoplastic cells are characterised by morphologic and functional alterations, the most significant of which are 'differentiation' and 'anaplasia'. *Differentiation* is defined as the extent of morphological and functional resemblance of parenchymal tumour cells to corresponding normal cells. *Anaplasia* is lack of differentiation and is a characteristic feature of most malignant tumours.
- ▣ Important features of anaplasia are: loss of polarity, pleomorphism, increased N:C ratio, hyperchromatism, prominent nucleoli, abnormal mitotic figures, qualitative or quantitative cytoplasmic changes, and chromosomal abnormalities.
- ▣ Stromal features of significance in tumours are angiogenesis, collagenous stroma (desmoplasia) and inflammatory stromal reaction by the host.

V. SPREAD OF TUMOURS

One of the cardinal features of malignant tumours is its ability to invade and destroy adjoining tissues (local invasion or direct spread) and disseminate to distant sites (metastasis or distant spread).

LOCAL INVASION (DIRECT SPREAD)

BENIGN TUMOURS Most benign tumours form encapsulated or circumscribed masses that *expand and push aside*

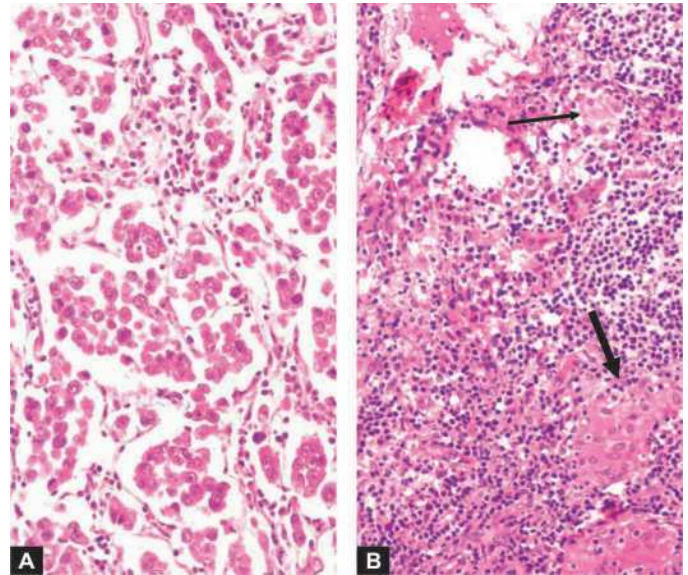

Figure 7.10 Inflammatory reaction in the stroma of the tumour. A, Lymphocytic reaction in seminoma testis. B, Granulomatous reaction (thick arrow) in Hodgkin's lymphoma (thin arrow for RS cell).

the surrounding normal tissues without actually invading, infiltrating or metastasising.

MALIGNANT TUMOURS Malignant tumours also enlarge by expansion and some well-differentiated tumours may be partially encapsulated as well e.g. follicular carcinoma thyroid. But characteristically, they are distinguished from benign tumours by *invasion, infiltration and destruction* of the surrounding tissue, besides spread to distant sites or metastasis (described below). In general, tumours invade via the route of least resistance, though eventually most cancers recognise no anatomic boundaries. Often, cancers extend through tissue spaces, permeate lymphatics, blood vessels, perineural spaces and may penetrate a bone by growing through nutrient foramina. More commonly, the tumours invade thin-walled capillaries and veins than thick-walled arteries. Dense compact collagen, elastic tissue and cartilage are some of the tissues which are sufficiently resistant to invasion by tumours.

Mechanism of direct invasion of malignant tumours is discussed together with that of metastasis below.

METASTASIS (DISTANT SPREAD)

Metastasis (*meta* = transformation, *stasis* = residence) is defined as spread of tumour by invasion in such a way that discontinuous secondary tumour mass/masses are formed at the site of lodgement. *Besides anaplasia, invasiveness and metastasis are the two other most important features to distinguish malignant from benign tumours.* Benign tumours do not metastasise while all the malignant tumours can metastasise, barring a few exceptions like gliomas of the central nervous system and basal cell carcinoma of the skin. Generally, larger, more aggressive and rapidly-growing tumours are more likely to metastasise but there are some exceptions. About one-third of malignant tumours at presentation have evident metastatic deposits while another 20% have occult metastasis.

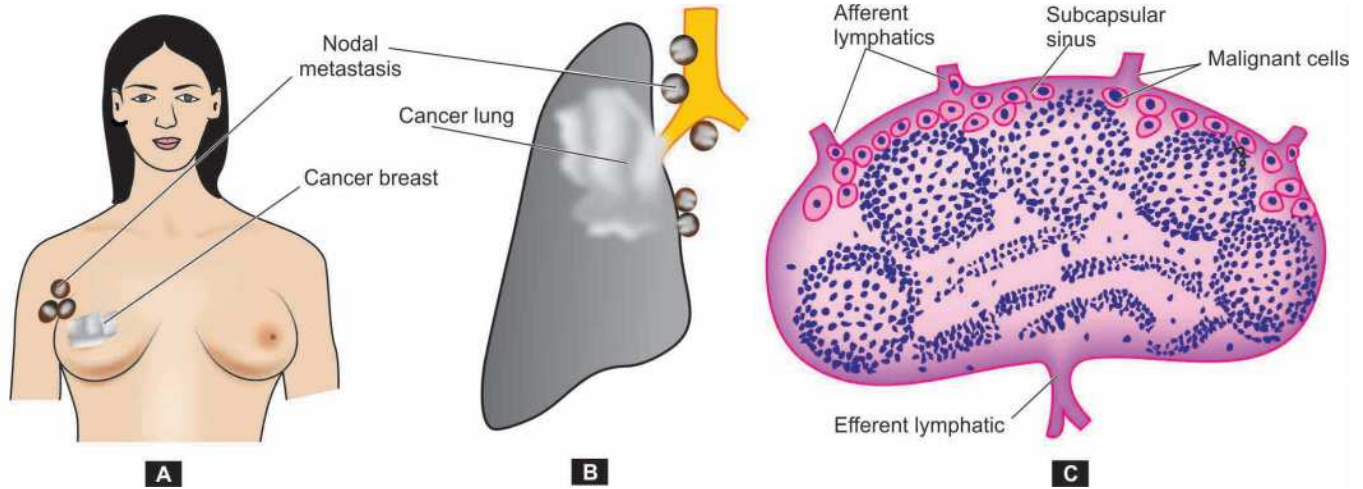

Figure 7.11 Regional nodal metastasis. A, Axillary nodes involved by carcinoma breast. B, Hilar and para-tracheal lymph nodes involved by bronchogenic carcinoma. C, Lymphatic spread begins by lodgement of tumour cells in subcapsular sinus via afferent lymphatics entering at the convex surface of the lymph node.

Routes of Metastasis

Cancers may spread to distant sites by following pathways:

1. Lymphatic spread
2. Haematogenous spread
3. Spread along body cavities and natural passages (Trans-coelomic spread, along epithelium-lined surfaces, spread via cerebrospinal fluid, implantation).

1. LYMPHATIC SPREAD *In general, carcinomas metastasise by lymphatic route while sarcomas favour haematogenous route.* However, some sarcomas may also spread by lymphatic pathway. The involvement of lymph nodes by malignant cells may be of two forms:

i) *Lymphatic permeation* The walls of lymphatics are readily invaded by cancer cells and may form a continuous growth in the lymphatic channels called lymphatic permeation.

ii) *Lymphatic emboli* Alternatively, the malignant cells may detach to form tumour emboli so as to be carried along the

lymph to the next draining lymph node. The tumour emboli enter the lymph node at its convex surface and are lodged in the subcapsular sinus where they start growing (**Fig. 7.11**). Later, of course, the whole lymph node may be replaced and enlarged by the metastatic tumour (**Fig. 7.12**). A few characteristics of lymphatic spread of malignant tumors are as follows:

◆ Generally, regional lymph nodes draining the tumour are invariably involved producing *regional nodal metastasis* e.g. from carcinoma breast to axillary lymph nodes, from cancer of the thyroid to lateral cervical lymph nodes, bronchogenic carcinoma to hilar and para-tracheal lymph nodes etc.

◆ However, all regional nodal enlargements are not due to nodal metastasis because necrotic products of tumour and antigens may also incite regional lymphadenitis of *sinus histiocytosis*.

◆ Sometimes lymphatic metastases do not develop first in the lymph node nearest to the tumour because of venous-lymphatic anastomoses or due to obliteration of lymphatics by inflammation or radiation, so called *skip metastasis*.

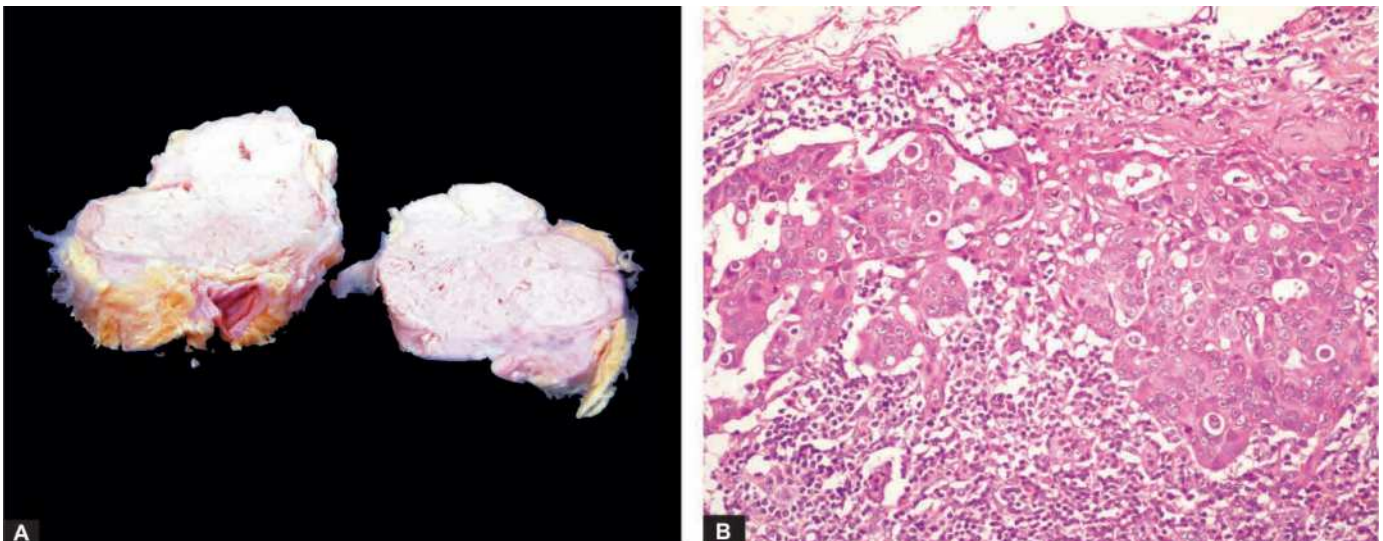

Figure 7.12 Metastatic carcinoma in lymph nodes. A, Matted mass of lymph nodes is surrounded by increased fat. Sectioned surface shows merging capsules of lymph nodes and replacement of grey brown tissue of nodes by large grey white areas of tumour. B, Masses of malignant cells are seen in the subcapsular sinus and extending into the underlying nodal tissue.

◆ Other times, due to obstruction of the lymphatics by tumour cells, the lymph flow is disturbed and tumour cells spread against the flow of lymph causing *retrograde metastases* at unusual sites e.g. metastasis of carcinoma prostate to the supraclavicular lymph nodes, metastatic deposits from bronchogenic carcinoma to the axillary lymph nodes.

◆ *Virchow's lymph node* is nodal metastasis preferentially to supraclavicular lymph node from cancers of abdominal organs e.g. cancer stomach, colon, and gallbladder.

It is believed that lymph nodes in the vicinity of tumour perform multiple roles—as initial barrier filter, and in destruction of tumour cells, while later provide fertile soil for growth of tumour cells.

Mechanism of lymphatic route of metastasis is discussed later under biology of invasion and metastasis.

2. HAEMATogenous SPREAD *Blood-borne metastasis is the common route for sarcomas but certain carcinomas also frequently metastasise by this mode*, especially those of the lung, breast, thyroid, kidney, liver, prostate and ovary. The sites where blood-borne metastasis commonly occurs are: the liver, lungs, brain, bones, kidney and adrenals, all of which provide 'good soil' for the growth of 'good seeds', i.e. *seed-soil theory* postulated by Ewing and Paget a century ago. However, a few organs such as the spleen, heart, and skeletal muscle generally do not allow tumour metastasis to grow. Spleen is unfavourable site due to open sinusoidal pattern which does not permit tumour cells to stay there long enough to produce metastasis. In general, only a proportion of cancer cells are capable of clonal proliferation in the proper environment; others die without establishing a metastasis. A few features of haemogenous metastasis are as under:

- i) *Systemic veins* drain blood into vena cavae from limbs, head and neck and pelvis. Therefore, cancers of these sites more often metastasise to the lungs.
- ii) *Portal veins* drain blood from the bowel, spleen and pancreas into the liver. Thus, tumours of these organs frequently have secondaries in the liver.
- iii) *Pulmonary veins* provide another route of spread of not only primary lung cancer but also metastatic growths in the lungs. Blood in the pulmonary veins carrying cancer cells from

the lungs reaches left side of the heart and then into systemic circulation and thus may form secondary masses elsewhere in the body.

iv) *Arterial spread* of tumours is less likely because they are thick-walled and contain elastic tissue which is resistant to invasion. Nevertheless, arterial spread may occur when tumour cells pass through pulmonary capillary bed or through pulmonary arterial branches which have thin walls. However, cancers of the kidneys, adrenals, bones, limbs and uterus, which are drained by systemic veins, spread to the lungs via pulmonary artery.

v) *Retrograde spread* by blood route may occur at unusual sites due to retrograde spread after venous obstruction, just as with lymphatic metastases. Important examples are vertebral metastases in cancers of the thyroid and prostate.

Grossly, blood-borne metastases in an organ appear as multiple, rounded nodules of varying size, scattered throughout the organ (**Fig. 7.13**). Sometimes, the metastasis may grow bigger than the primary tumour. At times, metastatic deposits may come to attention first without an evident primary tumour. In such cases search for primary tumour may be rewarding, but rarely the primary tumour may remain undetected or occult. Metastatic deposits just like primary tumour may cause further dissemination via lymphatics and blood vessels (**Fig. 7.14, A**).

Microscopically, the secondary deposits generally reproduce the structure of primary tumour (**Fig. 7.14, B**). However, the same primary tumour on metastasis at different sites may show varying grades of differentiation, apparently due to the influence of local environment surrounding the tumour for its growth.

3. SPREAD ALONG BODY CAVITIES AND NATURAL PASSAGES Uncommon routes of spread of some cancers are by *seeding* across body cavities and *natural passages* as under:

i) **Transcoelomic spread** Certain cancers invade through the serosal wall of the coelomic cavity so that tumour fragments or clusters of tumour cells break off to be carried in the coelomic fluid and are implanted elsewhere in the body cavity.

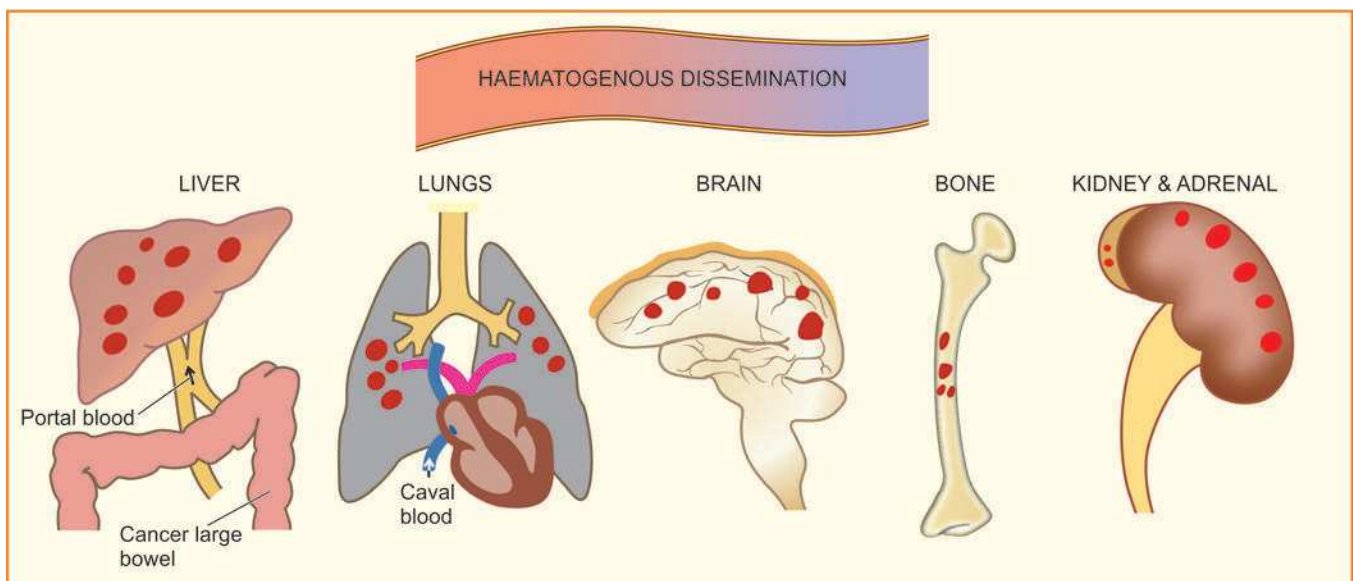

Figure 7.13 Gross appearance of haematogenous metastases at common sites.

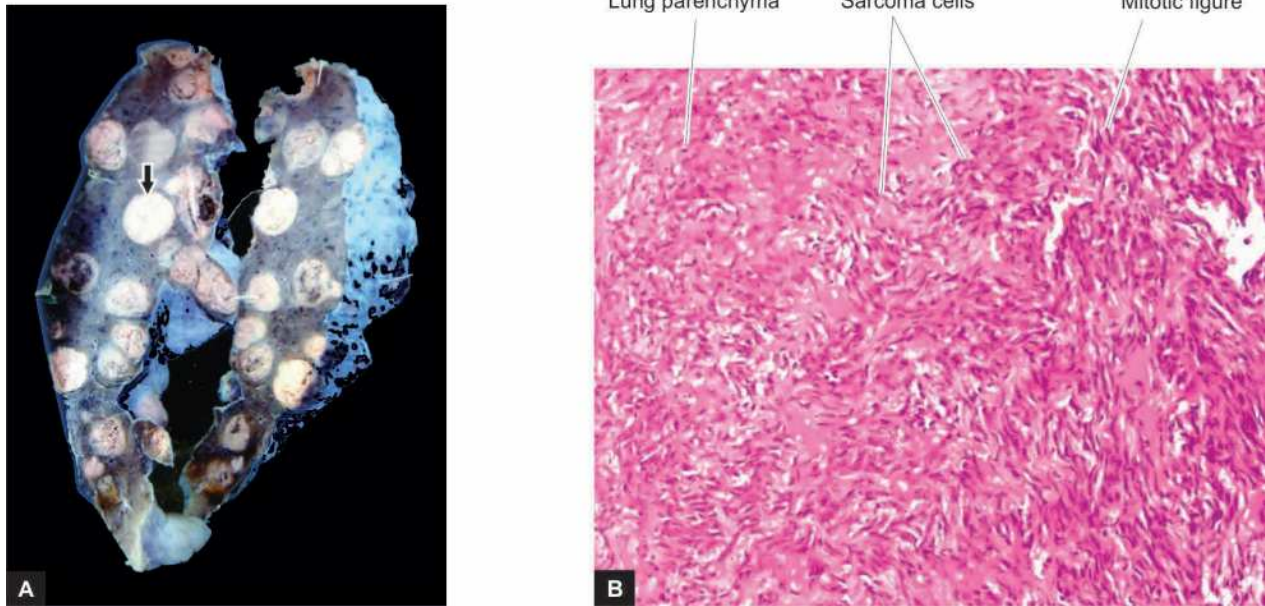

Figure 7.14 Metastatic sarcoma lung. A, Sectioned surface of the lung shows replacement of slaty-grey spongy parenchyma with multiple, firm, grey-white nodular masses, some having areas of haemorrhages and necrosis. B, Microscopic appearance of pulmonary metastatic deposits from sarcoma.

Peritoneal cavity is involved most often, but occasionally pleural and pericardial cavities are also affected. A few examples of transcoelomic spread are as follows:

- a) *Carcinoma of the stomach* seeding to both ovaries (Krukenberg tumour).
- b) *Carcinoma of the ovary* spreading to the entire peritoneal cavity without infiltrating the underlying organs.
- c) *Pseudomyxoma peritonei* is the gelatinous coating of the peritoneum from mucin-secreting carcinoma of the ovary or appendix.
- d) *Carcinoma of the bronchus and breast* seeding to the pleura and pericardium.

ii) Spread along epithelium-lined surfaces It is unusual for a malignant tumour to spread along the epithelium-lined surfaces because intact epithelium and mucus coat are quite resistant to penetration by tumour cells. However, exceptionally a malignant tumour may spread through:

- a) the fallopian tube from the endometrium to the ovaries or *vice-versa*;
- b) through the bronchus into alveoli; and
- c) through the ureters from the kidneys into lower urinary tract.

iii) Spread via cerebrospinal fluid Malignant tumour of the ependyma and leptomeninges may spread by release of tumour fragments and tumour cells into the CSF and produce metastases at other sites in the central nervous system.

iv) Implantation There are isolated and rare case reports of spread of some cancers by implantation by surgeon's scalpel, needles, sutures, and direct prolonged contact of cancer of the lower lip causing its implantation to the apposing upper lip.

MECHANISM AND BIOLOGY OF INVASION AND METASTASIS

The process of local invasion and distant spread by lymphatic and haematogenous routes (together called lymphovascular spread) discussed above involves passage through barriers before gaining access to the vascular lumen. This includes

making the passage by the cancer cells by dissolution of extracellular matrix (ECM) at three levels—at the basement membrane of tumour itself, at the level of interstitial connective tissue, and at the basement membrane of microvasculature. The following sequential steps are involved which are schematically illustrated in **Fig. 7.15**.

1. Aggressive clonal proliferation and angiogenesis The first step in the spread of cancer cells is the development of rapidly proliferating clone of cancer cells. This is explained on the basis of *tumour heterogeneity*, i.e. in the population of monoclonal tumour cells, a subpopulation or clone of tumour cells has the right biologic characteristics to complete the steps involved in the development of metastasis. Tumour angiogenesis plays a very significant role in metastasis since the new vessels formed as part of growing tumour are more vulnerable to invasion because these evolving vessels are directly in contact with cancer cells.

2. Tumour cell loosening Normal cells remain glued to each other due to presence of cell adhesion molecules (CAMs) i.e. E (epithelial)-cadherin. In epithelial cancers, there is either loss or inactivation of E-cadherin and also other CAMs of immunoglobulin superfamily, all of which results in loosening of cancer cells.

3. Tumour cell-ECM interaction Loosened cancer cells are now attached to ECM proteins, mainly *laminin* and *fibronectin*. This attachment is facilitated due to profoundness of receptors on the cancer cells for both these proteins. There is also loss of *integrins*, the transmembrane receptors, further favouring invasion.

4. Degradation of ECM Tumour cells overexpress *proteases* and matrix-degrading enzymes, *metalloproteinases* (e.g. collagenases and gelatinase), while the inhibitors of metalloproteinases are decreased. Another protease, cathepsin D, is also increased in certain cancers. These enzymes bring

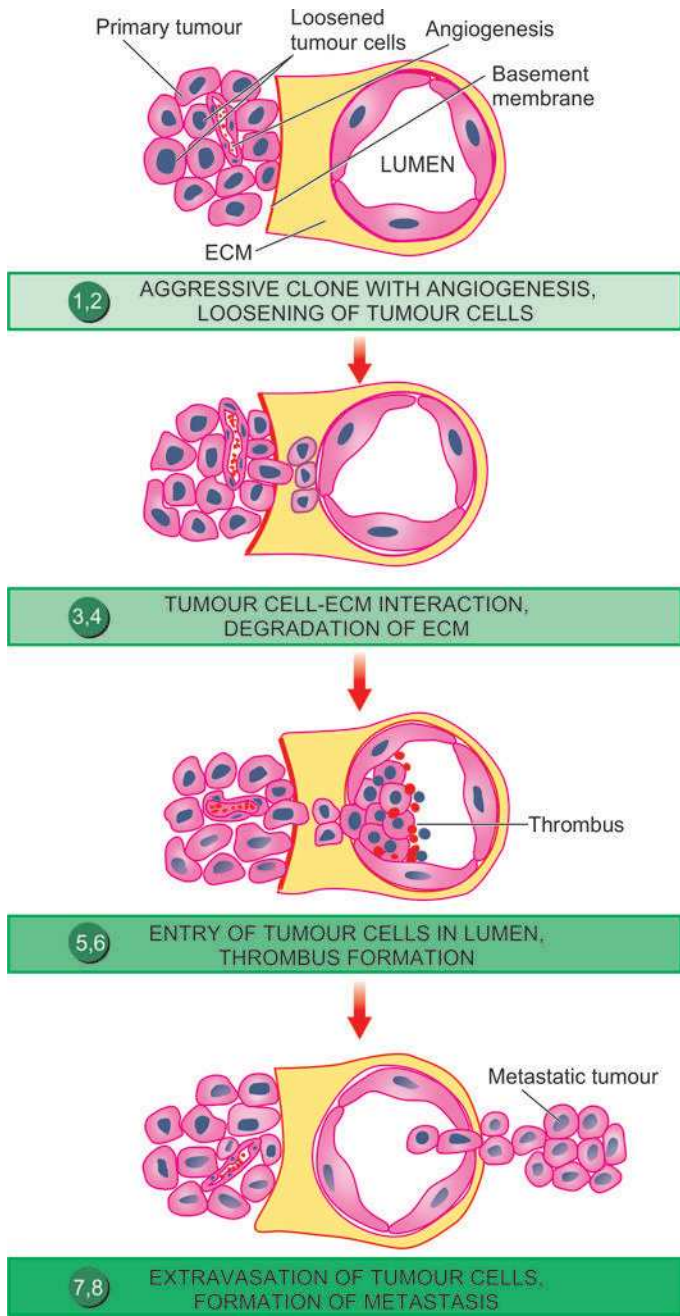

Figure 7.15 Mechanism and biology of local invasion and metastasis. The serial numbers in the figure correspond to their description in the text.

about dissolution of ECM—firstly basement membrane of tumour itself, then make way for tumour cells through the interstitial matrix, and finally dissolve the basement membrane of the vessel wall.

5. Entry of tumour cells into capillary lumen The tumour cells after degrading the basement membrane are ready to migrate into lumen of capillaries or venules for which the following mechanisms play a role:

- Autocrine motility factor (AMF)*, a cytokine derived from tumour cells which stimulates receptor-mediated motility of tumour cells.
- Cleavage products of matrix components* which are formed following degradation of ECM have properties of tumour

cell chemotaxis, growth promotion and angiogenesis in the cancer.

After the malignant cells have migrated through the breached basement membrane, these cells enter the lumen of lymphatic and capillary channels.

6. Thrombus formation The tumour cells protruding in the lumen of the capillary are now covered with constituents of the circulating blood and form the thrombus. Thrombus provides nourishment to the tumour cells and also protects them from the immune attack by the circulating host cells. In fact, normally a large number of tumour cells are released into circulation but they are attacked by the host immune cells. Actually a very small proportion of malignant cells (less than 0.1%) in the blood stream survive to develop into metastasis.

7. Extravasation of tumour cells Tumour cells in the circulation (capillaries, venules, lymphatics) may mechanically block these vascular channels and attach to vascular endothelium and then extravasate to the extravascular space. In this way, the sequence similar to local invasion is repeated and the basement membrane is exposed.

8. Survival and growth of metastatic deposit The extravasated malignant cells on lodgement in the right environment grow further under the influence of growth factors produced by host tissues, tumour cells and by cleavage products of matrix components. Some of the growth promoting factors are: PDGF, FGF, TGF- β and VEGF. The metastatic deposits grow further if the host immune defense mechanism fails to eliminate it. Metastatic deposits may further metastasise to the same organ or to other sites by forming emboli.

PROGNOSTIC INDICATORS

Metastasis is a common event in malignant tumours which greatly reduces the survival of the patient. In the biology of tumour, metastasis is a form of unusual cell differentiation in which the tumour cells form disorderly masses at ectopic sites and start growing there. This random phenomenon takes place in a stepwise manner involving only a subpopulation of tumour cells selectively. The process is governed by *inappropriate expression of genes which normally partake in physiologic processes* i.e. it is a genetically programmed phenomenon.

Recent evidence has shown that in metastatic tumours, survival of host is correlated with some clinical and molecular features of tumours which act as *prognostic markers*. These are as under:

- Clinical prognostic markers:** Size, histologic grade, nodal involvement and vascular invasion by the tumour.
- Molecular prognostic markers:** Molecular markers indicative of poor prognosis in certain specific tumours are as follows:
 - expression of an oncogene by tumour cells (*C-met*)
 - CD 44 molecule
 - Oestrogen receptors
 - Epidermal growth factor receptor
 - Angiogenesis factors and degree of neovascularisation
 - Expression of *metastasis associated gene* or *nucleic acid (MAGNA)* in the DNA fragment in metastasising tumour.

GRADING AND STAGING OF CANCER

'Grading' and 'staging' are the two systems to predict tumour behaviour and guide therapy after a malignant tumour is detected. *Grading is defined as the gross appearance and microscopic degree of differentiation of the tumour, while staging means extent of spread of the tumour within the patient.* Thus, grading is done on pathologic basis while staging is on clinical grounds.

GRADING

Cancers may be graded grossly and microscopically. Gross features like exophytic or fungating appearance are indicative of less malignant growth than diffusely infiltrating tumours. However, grading is largely based on 2 important histologic features: *the degree of anaplasia, and the rate of growth.* Based on these features, cancers are categorised from grade I as the most differentiated, to grade III or IV as the most undifferentiated or anaplastic. Many systems of grading have been proposed but the one described by Broders for dividing squamous cell carcinoma into 4 grades depending upon the degree of differentiation is followed for other malignant tumours as well. *Broders' grading* is as under:

Grade I: Well-differentiated (less than 25% anaplastic cells)

Grade II: Moderately-differentiated (25-50% anaplastic cells)

Grade III: Moderately-differentiated (50-75% anaplastic cells)

Grade IV: Poorly-differentiated or anaplastic (more than 75% anaplastic cells)

However, grading of tumours has several shortcomings. It is subjective and the degree of differentiation may vary from one area of tumour to the other. Therefore, it is common practice with pathologists to grade cancers in descriptive terms (e.g. well-differentiated, undifferentiated, keratinising, non-keratinising etc) rather than giving the tumours grade numbers.

More objective criteria for histologic grading include use of flow cytometry for mitotic cell counts, cell proliferation markers by immunohistochemistry, and by applying image morphometry for cancer cell and nuclear parameters.

STAGING

The extent of spread of cancers can be assessed by 3 ways—by clinical examination, by investigations, and by pathologic examination of the tissue removed. Two important staging systems currently followed are: TNM staging and AJC staging.

TNM staging TNM staging (T for primary tumour, N for regional nodal involvement, and M for distant metastases) was developed by the UICC (Union Internationale Contre Cancer, Geneva). For each of the 3 components namely T, N and M, numbers are added to indicate the extent of involvement, as under:

T0 to T4: In situ lesion to largest and most extensive primary tumour.

N0 to N3: No nodal involvement to widespread lymph node involvement.

M0 to M2: No metastasis to disseminated haematogenous metastases.

AJC staging American Joint Committee staging divides all cancers into stage 0 to IV, and takes into account all the 3

components of the preceding system (primary tumour, nodal involvement and distant metastases) in each stage.

TNM and AJC staging systems can be applied for staging of most malignant tumours.

Currently, clinical staging of tumours does not rest on routine radiography (X-ray, ultrasound) and exploratory surgery but more modern techniques are available by which it is possible to 'stage' a malignant tumour by non-invasive techniques. These include use of modern imaging techniques such as *computed tomography (CT)* and *magnetic resonance imaging (MRI)* scan based on tissue density for locating the local extent of tumour and its spread to other organs. Availability of *positron emission tomography (PET)* scan has further overcome the limitation of CT and MRI scan because PET scan facilitates distinction of benign and malignant tumour on the basis of biochemical and molecular processes in tumours. *Radioactive tracer studies* in vivo such as use of iodine isotope 125 bound to specific tumour antibodies is another method by which small number of tumour cells in the body can be detected by imaging of tracer substance bound to specific tumour antigen.

GIST BOX 7.3

Spread, Grading, Staging of Cancer

- ☐ Malignant tumours invade and destroy adjoining tissues (local invasion or direct spread) and disseminate to distant sites (metastasis or distant spread).
- ☐ Cancers spread to distant sites commonly by lymphatic or haematogenous route, and less commonly along body cavities (transcoelomic spread) and via natural passages (e.g. along bronchus, fallopian tubes, ureters, CSF etc).
- ☐ Carcinomas metastasise more commonly by lymphatic route while sarcomas favour haematogenous route.
- ☐ Common sites of lymphatic metastasis are the regional nodes, while blood borne metastases are common in the liver, lungs, bones, brain, kidneys and adrenals.
- ☐ Mechanism of direct invasion and metastasis involves passage of cancer cells through the extracellular matrix in the interstitial tissue, basement membranes of the tumour and of the vessel wall.
- ☐ Grading of tumours is done on pathologic examination and includes the gross appearance and microscopic degree of differentiation of the tumour (e.g. well differentiated, poorly-differentiated).
- ☐ Staging of the cancer is clinical and it means the extent of spread of tumour within the patient (e.g. TNM staging, AJC staging).

EPIDEMIOLOGY AND MOLECULAR PATHOGENESIS OF CANCER

CANCER INCIDENCE

The overall incidence of cancer in a population or a country is known by registration of all cancer cases (cancer registry) and by rate of death from cancer. Worldwide, it is estimated that about 20% of all deaths are cancer-related; in US, cancer is the second most common cause of deaths, next to heart disease. There have been changing patterns in incidence of cancers in both the sexes and in different geographic locations as outlined here. **Table 7.3** shows worldwide incidence (in descending

Table 7.3 Five most common primary cancers in the world.

| | MEN | WOMEN | CHILDREN (UNDER 20) |
|----|------------------------------------|-----------------------------|---------------------|
| 1. | Prostate (oral cavity in India) | Breast (cervix in India) | Acute leukaemia |
| 2. | Lung | Lung | Gliomas |
| 3. | Colorectal | Colorectal | Bone sarcoma |
| 4. | Urinary bladder | Endometrial | Endocrine |
| 5. | Lymphoma | Lymphoma | Soft tissue sarcoma |

order) of 5 most common cancers in men, women, and children. Due to varying etiologic factors, cancers of the cervix and oral cavity are more common in India while cancers of the breast and lung are commoner in the Western populations.

In general, most common cancers in the developed and developing countries are as under:

- ◆ *Developed countries:* lung, breast, prostate and colorectal.
- ◆ *Developing countries:* liver, cervix, oral cavity and oesophagus.

About one-third of all cancers worldwide are attributed to 9 *modifiable life-style factors*: tobacco use, alcohol consumption, obesity, physical inactivity, low fiber diet, unprotected sex, polluted air, indoor household smoke, and contaminated injections. Overall, there has been a declining trend in incidence of some of the cancers due to cancer screening programmes e.g. for cancers of the cervix, breast, colorectal region and prostate.

EPIDEMIOLOGIC FACTORS

A lot of clinical and experimental research and epidemiological studies have been carried out in the field of oncology so as to know the possible causes of cancer and mechanisms involved in transformation of a normal cell into a neoplastic cell. It is widely known that no single factor is responsible for development of tumours. The role of some factors in causation of neoplasia is established while that of others is epidemiological and many others are still unknown.

Besides the etiologic role of some agents discussed later, the pattern and incidence of cancer depends upon the following:

- A) *Predisposing epidemiologic factors or cofactors* which include a number of endogenous host factors and exogenous environmental factors
- B) *Chronic non-neoplastic (pre-malignant) conditions*
- C) *Role of hormones in cancer*

The role of these aspects in cancer epidemiology is briefly discussed below.

A. PREDISPOSING FACTORS

1. FAMILIAL AND GENETIC FACTORS It has long been suspected that familial predisposition and heredity play a role in the development of cancers. In general, the risk of developing cancer in relatives of a known cancer patient is almost three times higher as compared to control subjects. Some of the cancers with familial occurrence are colon, breast, ovary, brain and melanoma. Familial cancers occur at a relatively early age, appear at multiple sites and occur in 2 or more first-degree blood relatives. The overall estimates suggest that genetic cancers comprise about 5% of all cancers. Some of the common examples are as under:

i) Retinoblastoma About 40% of retinoblastomas are familial and show an autosomal dominant inheritance. Carriers of such genetic composition have 10,000 times higher risk of developing retinoblastoma which is often bilateral. Such patients are further predisposed to develop another primary malignant tumour, notably osteogenic sarcoma.

Familial form of retinoblastoma is due to missing of a portion of chromosome 13 where *RB* gene is normally located. In fact, genetic absence of *RB* gene was the first ever tumour suppressor gene identified. Absence of a single copy of *RB* gene predisposes an individual to retinoblastoma and the tumour develops when other copy of *RB* gene from the second parent is also defective.

ii) Familial polyposis coli This condition has autosomal dominant inheritance. The polypoid adenomas may be seen at birth or in early age. By the age of 50 years, almost 100% cases of familial polyposis coli develop cancer of the colon.

iii) Multiple endocrine neoplasia (MEN) A combination of adenomas of pituitary, parathyroid and pancreatic islets (MEN-I) or syndrome of medullary carcinoma thyroid, pheochromocytoma and parathyroid tumour (MEN-II) are encountered in families.

iv) Neurofibromatosis or von Recklinghausen's disease This condition is characterised by multiple neurofibromas and pigmented skin spots (*cafe au lait spots*). These patients have family history consistent with autosomal dominant inheritance in 50% of patients.

v) Cancer of the breast Female relatives of breast cancer patients have 2 to 6 times higher risk of developing breast cancer. Inherited breast cancer comprises about 5-10% of all breast cancers. As discussed later, there are two breast cancer susceptibility genes, *BRCA-1* and *BRCA-2*. Mutations in these genes appear in about 3% cases and these patients have about 85% risk of development of breast cancer.

vi) Congenital chromosomal syndromes For example,

a) *Down's syndrome or mongolism* has trisomy 21; these cases have increased risk of development of acute leukaemia.

b) *Klinefelter syndrome* associated with an extra X chromosome (47, XXY) has high risk of developing cancer of male breast and extra-gonadal germ cell tumours.

vii) DNA-chromosomal instability syndromes These are a group of pre-neoplastic conditions having defect in DNA repair mechanism. A classical example is xeroderma pigmentosum, an autosomal recessive disorder, characterised by extreme sensitivity to ultraviolet radiation. The patients may develop various types of skin cancers such as basal cell carcinoma, squamous cell carcinoma and malignant melanoma.

2. RACIAL AND GEOGRAPHIC FACTORS Differences in racial incidence of some cancers may be partly attributed to the role of genetic composition but are largely due to influence of the environment and geographic differences affecting the whole population such as climate, soil, water, diet, habits, customs etc. Some of the examples of racial and geographic variations in various cancers are as under:

i) White Europeans and Americans develop most commonly malignancies of the prostate, lung, breast and colorectal region. Liver cancer is uncommon in these races.

ii) Black Africans, on the other hand, have more commonly cancers of the skin, penis, cervix and liver.

iii) **Japanese** have five times higher incidence of carcinoma of the stomach than the Americans. Breast cancer is uncommon in Japanese women than American women.

iv) **South-East Asians**, especially of Chinese origin, develop nasopharyngeal cancer more commonly.

v) **Indians** of both sexes have higher incidence of carcinoma of the oral cavity and upper aerodigestive tract, while in females carcinoma of uterine cervix and of the breast run parallel in incidence. Etiologic factor responsible for liver cancer in India is more often viral hepatitis (HBV and HCV) and subsequent cirrhosis, while in western populations it is more often due to alcoholic cirrhosis.

3. ENVIRONMENTAL AND CULTURAL FACTORS It may seem rather surprising that through out our life we are surrounded by an environment of carcinogens which we eat, drink, inhale and touch. Some of the examples are given below:

i) **Cigarette smoking** (as well as passive inhalation) is the single most important environmental factor implicated in the etiology of cancer of the lung, oral cavity, pharynx, larynx, nasal cavity and paranasal sinuses, oesophagus, stomach, pancreas, liver, kidney, urinary bladder, uterine cervix and myeloid leukaemia.

ii) **Alcohol abuse** predisposes to the development of cancer of oropharynx, larynx, oesophagus and liver.

iii) **Synergistic interaction of alcohol and tobacco** further accentuates the risk of developing cancer of the upper aerodigestive tract and lung.

iv) **Cancer of the cervix** is linked to a number of factors such as age at first coitus, frequency of coitus, multiplicity of partners, parity etc. Sexual partners of circumcised males have lower incidence of cervical cancer than the partners of uncircumcised males.

v) **Penile cancer** is rare in the Jews and Muslims as they are customarily circumcised. Carcinogenic component of smegma appears to play a role in the etiology of penile cancer.

vi) **Betel nut cancer** of the cheek and tongue is quite common in some parts of India due to habitual practice of keeping the bolus of *paan* in a particular place in mouth for a long time.

vii) A large number of **industrial and environmental substances** are carcinogenic and are occupational hazard for some populations. These include exposure to substances like arsenic, asbestos, benzene, vinyl chloride, naphthylamine etc.

viii) **Certain constituents of diet** have also been implicated in the causation of cancer. Overweight individuals, deficiency of vitamin A and people consuming diet rich in animal fats and low in fibre content are more at risk of developing certain cancers such as colonic cancer. Diet rich in vitamin E, on the other hand, possibly has some protective influence by its antioxidant action.

4. AGE The most significant risk factor for cancer is age. Generally, cancers occur in older individuals past 5th decade of life (two-third of all cancers occur above 65 years of age), though there are variations in age incidence in different forms of cancers. Higher incidence of cancer in advanced age could be due to alteration in the cells of the host, longer exposure to the effect of carcinogen, or decreased ability of the host immune response. Some tumours have two peaks of incidence e.g. acute leukaemias occur in children and in older age group.

The biologic behaviour of tumours in children does not always correlate with histologic features. Besides acute leukaemias, *other tumours in infancy and childhood* are: neuroblastoma, nephroblastoma (Wilms' tumour), retinoblastoma, hepatoblastoma, rhabdomyosarcoma, Ewing's sarcoma, teratoma and CNS tumours.

5. SEX Apart from the malignant tumours of organs peculiar to each sex, most tumours are generally more common in men than in women except cancer of the breast, gallbladder, thyroid and hypopharynx. Although there are geographic and racial variations, *cancer of the breast* is the commonest cancer in *women* throughout the world while *lung cancer* is the commonest cancer in *men*. The differences in incidence of certain cancers in the two sexes may be related to the presence of specific sex hormones.

B. CHRONIC PRE-MALIGNANT AND NON-NEOPLASTIC CONDITIONS

Premalignant lesions are a group of conditions which predispose to the subsequent development of cancer. Such conditions are important to recognise so as to prevent the subsequent occurrence of an invasive cancer. Many of these conditions are characterised by morphologic changes in the cells such as increased nuclear-cytoplasmic ratio, pleomorphism of cells and nuclei, increased mitotic activity, poor differentiation, and sometimes accompanied by chronic inflammatory cells.

Some examples of premalignant lesions are given below:

1. Dysplasia and carcinoma *in situ* (intraepithelial neoplasia) As discussed in Chapter 2, dysplasia is abnormality in cellular features and may be of varying severity (mild, moderate and marked). Most marked cytological atypia confined to epithelial layers above the basement membrane without invading the basement membrane is called as carcinoma *in situ* or intraepithelial neoplasia (CIN). The common sites are as under:

- i) Uterine cervix at the junction of ecto- and endocervix (**Fig. 7.16**)
- ii) Bronchus
- iii) Bowen's disease of the skin
- iv) Actinic or solar keratosis
- v) Oral leukoplakia
- vi) Barrett's oesophagus developing metaplasia and dysplasia
- vii) Intralobular and intraductal carcinoma of the breast.

The area involved in carcinoma *in situ* may be single and small, or multifocal. As regards the behaviour of CIN, it may regress and return to normal or may develop into invasive cancer. In some instances such as in cervical cancer, there is a sequential transformation from squamous metaplasia, to epithelial dysplasia, to carcinoma *in situ*, and eventually to invasive cancer.

2. Some benign tumours Commonly, benign tumours do not become malignant. However, there are some exceptions e.g.

- i) Multiple adenomas of the large intestine have high incidence of developing adenocarcinoma.
- ii) Neurofibromatosis (von Recklinghausen's disease) may develop into sarcoma.
- iii) Pleomorphic adenoma (mixed salivary tumour) may sometimes develop carcinoma (carcinoma ex pleomorphic adenoma).

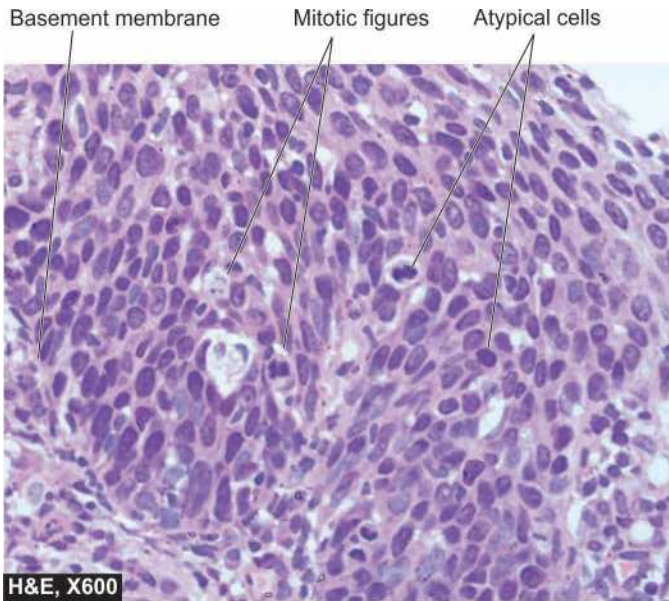

Figure 7.16 Carcinoma *in situ* of uterine cervix. The atypical dysplastic squamous cells are confined to all the layers of the mucosa but the basement membrane on which these layers rest is intact.

3. Miscellaneous conditions Certain inflammatory (both infectious and non-infectious) and hyperplastic conditions are prone to development of cancer, e.g.

- i) HPV-induced chronic cervicitis has high risk of developing cervical cancer.
- ii) Patients of long-standing ulcerative colitis are predisposed to develop colorectal cancer.
- iii) Cirrhosis of the liver has predisposition to develop hepatocellular carcinoma.
- iv) *H. pylori* gastritis developing gastric cancer and lymphoma.
- v) Chronic bronchitis in heavy cigarette smokers may develop cancer of the bronchus.
- vi) Chronic irritation from jagged tooth or ill-fitting denture may lead to cancer of the oral cavity.
- vii) Squamous cell carcinoma developing in an old burn scar (Marjolin's ulcer).

C. HORMONES AND CANCER

Cancer is more likely to develop in organs and tissues which undergo proliferation under the influence of excessive hormonal stimulation. On cessation of hormonal stimulation, such tissues become atrophic. Hormone-sensitive tissues developing tumours are the breast, endometrium, myometrium, vagina, thyroid, liver, prostate and testis. Some examples of hormones influencing carcinogenesis in experimental animals and humans are given below:

1. OESTROGEN Examples of oestrogen-induced cancers are as under:

i) In experimental animals Induction of breast cancer in mice by administration of high-dose of oestrogen and reduction of the tumour development following oophorectomy is the most important example. It has been known that associated infection with mouse mammary tumour virus (MMTV, *Bittner milk factor*) has an added influence on the development of breast cancer in mice. Other cancers which

can be experimentally induced in mice by oestrogens are squamous cell carcinoma of the cervix, connective tissue tumour of the myometrium, Leydig cell tumour of the testis in male mice, tumour of the kidney in hamsters, and benign as well as malignant tumours of the liver in rats.

ii) In humans Women receiving oestrogen therapy and women with oestrogen-secreting granulosa cell tumour of the ovary have increased risk of developing endometrial carcinoma. Adenocarcinoma of the vagina is seen with increased frequency in adolescent daughters of mothers who had received oestrogen therapy during pregnancy.

2. CONTRACEPTIVE HORMONES The sequential types of oral contraceptives increase the risk of developing breast cancer. Other tumours showing a slightly increased frequency in women receiving contraceptive pills for long durations are benign tumours of the liver, and a few patients have been reported to have developed hepatocellular carcinoma.

3. ANABOLIC STEROIDS Consumption of anabolic steroids by athletes to increase the muscle mass is not only unethical athletic practice but also increases the risk of developing benign and malignant tumours of the liver.

4. HORMONE-DEPENDENT TUMOURS It has been shown in experimental animals that induction of hyperfunction of adenohypophysis is associated with increased risk of developing neoplasia of the target organs following preceding functional hyperplasia. There is tumour regression on removal of the stimulus for excessive hormonal secretion. A few examples of such phenomena are seen in humans:

- i) *Prostatic cancer* usually responds to the administration of oestrogens.
- ii) *Breast cancer* may regress with oophorectomy, hypophysectomy or on administration of male hormones.
- iii) *Thyroid cancer* may slow down in growth with administration of thyroxine that suppresses the secretion of TSH by the pituitary.

GIST BOX 7.4

Epidemiology and Predisposition to Neoplasia

- ☐ In general, most common cancers in the developed countries are lung, breast, prostate and colorectal, and in developing countries are liver, cervix, oral cavity and oesophagus.
- ☐ Several factors predispose to occurrence of cancers. These are: familial and genetic factors, racial and geographic factors, environmental and cultural factors, age and sex.
- ☐ Carcinoma *in situ* of some sites such as uterine cervix, bronchus, skin, oral cavity etc may progress to cancer and are thus premalignant conditions.
- ☐ A few benign conditions may predispose to cancer e.g. colorectal adenomas, neurofibromatosis.
- ☐ Some long-standing inflammatory and hyperplastic conditions may develop to cancers e.g. ulcerative colitis, cirrhosis, old burn scar etc.
- ☐ High levels of some hormones have a role in predisposition to cancer e.g. hyperoestrogenism associated with higher risk of endometrial cancer, oral contraceptives in breast cancer, testosterone in prostate cancer etc.

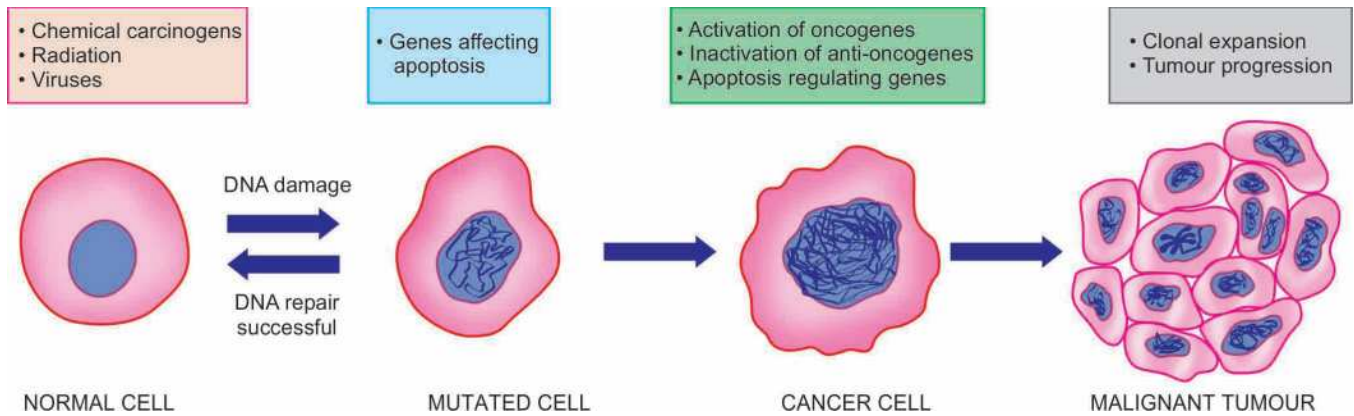

Figure 7.17 Schematic illustration to show molecular basis of cancer.

MOLECULAR BASIS OF CANCER

The mechanism as to how a normal cell is transformed to a cancer cell is complex. At different times, attempts have been made to unravel this mystery by various mechanisms. Currently, a lot of literature continues to accumulate on the pathogenesis of cancer at molecular level. Before discussing the detailed mechanisms, a general basic concept of cancer at molecular level is briefly outlined below and diagrammatically shown in **Fig. 7.17**.

1. Monoclonality of tumours There is strong evidence to support that most human cancers arise from a single clone of cells by genetic transformation or mutation. For example:

i) In a case of multiple myeloma (a malignant disorder of plasma cells), there is production of a single type of immunoglobulin or its chain as seen by monoclonal spike in serum electrophoresis.

ii) Due to inactivation of one of the two X-chromosomes in females (paternal or maternal derived), women are mosaics with two types of cell populations for glucose-6-phosphatase dehydrogenase (G6PD) isoenzyme A and B. It is observed that all the tumour cells in benign uterine tumours (leiomyoma) contain either A or B genotype of G6PD (i.e. the tumour cells are derived from a single progenitor clone of cell), while the normal myometrial cells are mosaic of both types of cells derived from A as well as B isoenzyme (**Fig. 7.18**).

2. Field theory of cancer In an organ developing cancer, in the backdrop of normal cells, limited number of cells only grow in to cancer after undergoing sequence of changes under the influence of etiologic agents. This is termed as 'field effect' and the concept called as field theory of cancer.

3. Multi-step process of cancer growth and progression Carcinogenesis is a gradual multi-step process involving many generations of cells. The various causes may act on the cell one after another (*multi-hit process*). The same process is also involved in further progression of the tumour. Ultimately, the cells so formed are genetically and phenotypically transformed cells having phenotypic features of malignancy—excessive growth, invasiveness and distant metastasis.

4. Genetic theory of cancer Cell growth of normal as well as abnormal types is under genetic control. In cancer, there are either genetic abnormalities in the cell, or there are normal genes with abnormal expression. Thus the abnormalities in genetic composition may be from inherited or induced

mutations (induced by etiologic carcinogenic agents namely: chemicals, viruses, radiation). Eventually, the mutated cells transmit their characters to the next progeny of cells and result in cancer.

5. Genetic regulators of normal and abnormal mitosis In normal cell growth, regulatory genes control mitosis as well as cell aging, terminating in cell death by apoptosis.

◆ **In normal cell growth**, there are 4 regulatory genes:

i) *Proto-oncogenes* are growth-promoting genes i.e. they encode for cell proliferation pathway.

ii) *Anti-oncogenes* are growth-inhibiting or growth suppressor genes.

iii) *Apoptosis regulatory genes* control the programmed cell death.

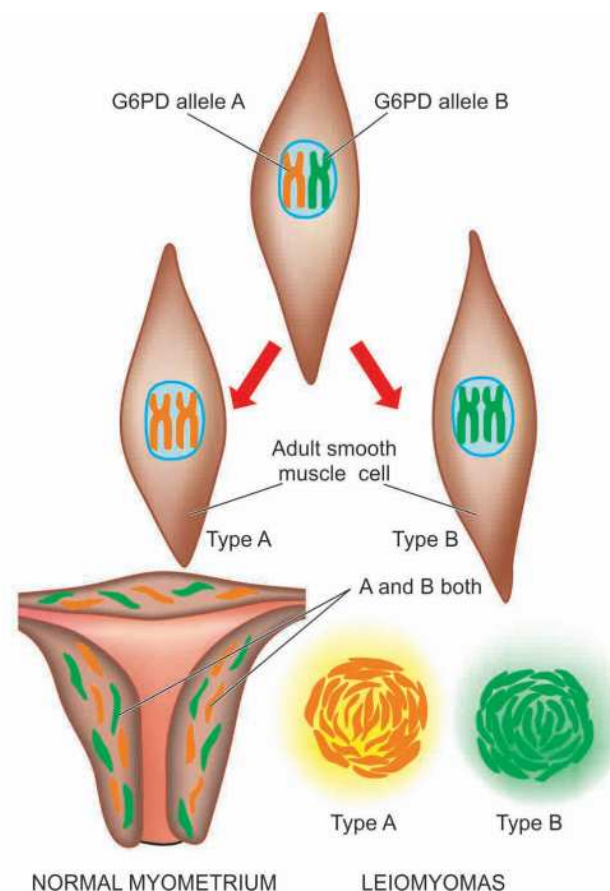

Figure 7.18 The monoclonal origin of tumour cells in uterine leiomyoma.

iv) *DNA repair genes* are those normal genes which regulate the repair of DNA damage that has occurred during mitosis and also control the damage to proto-oncogenes and anti-oncogenes.

◆ **In cancer**, the transformed cells are produced by abnormal cell growth due to genetic damage to these normal controlling genes. Thus, corresponding abnormalities in these 4 cell regulatory genes are as under:

i) *Activation of growth-promoting oncogenes* causing transformation of cell (mutant form of normal proto-oncogene in cancer is termed *oncogene*). Many of these cancer associated genes, oncogenes, were first discovered in viruses, and hence named as *v-onc*. Gene products of oncogenes are called *oncoproteins*. Oncogenes are considered *dominant* since they appear in spite of presence of normal proto-oncogenes.

ii) *Inactivation of cancer-suppressor genes* (i.e. inactivation of anti-oncogenes) permitting the cellular proliferation of transformed cells. Anti-oncogenes are active in *recessive* form i.e. they are active only if both alleles are damaged.

iii) *Abnormal apoptosis regulatory genes* which may act as oncogenes or anti-oncogenes. Accordingly, these genes may be active in dominant or recessive form.

iv) *Failure of DNA repair genes* and thus inability to repair the DNA damage resulting in mutations.

CANCER-RELATED GENES AND CELL GROWTH (HALLMARKS OF CANCER)

It is apparent from the above discussion that genes control the normal cellular growth, while in cancer these controlling genes are altered, typically by mutations. A large number of such cancer-associated genes have been described, each with a specific function in cell growth. Some of these genes are common in many tumours (e.g. *p53* or *TP53*), while others are specific to particular tumours. Therefore, following discussion

correlates the role of cancer-related genes with regard to their functions in normal cellular growth.

Genetic basis of cancer includes following *major genetic properties*, also termed as *molecular hallmarks of cancer*:

1. Excessive and autonomous growth: Growth-promoting oncogenes.
2. Refractoriness to growth inhibition: Growth suppressing anti-oncogenes.
3. Escaping cell death by apoptosis: Genes regulating apoptosis and cancer.
4. Avoiding cellular ageing: Telomeres and telomerase in cancer.
5. Continued perfusion of cancer: Cancer angiogenesis.
6. Invasion and distant metastasis: Cancer dissemination.
7. DNA damage and repair system: Mutator genes and cancer.
8. Cancer progression and tumour heterogeneity: Clonal aggressiveness.
9. Cancer a sequential multistep molecular phenomenon: Multistep theory.
10. MicroRNAs in cancer: OncomiRs.

These properties of cancer cells are schematically shown in **Fig. 7.19** and discussed below.

1. Excessive and Autonomous Growth: Growth Promoting Oncogenes

Mutated form of normal protooncogenes in cancer is called oncogenes. In general, overactivity of oncogenes enhances cell proliferation and promotes development of human cancer. About 100 different oncogenes have been described in various cancers. Transformation of proto-oncogene (i.e. normal cell proliferation gene) to oncogenes (i.e. cancer cell proliferation gene) may occur by three mechanisms:

i) *Point mutations* i.e. an alteration of a single base in the DNA chain. The most important example is *RAS* oncogene carried

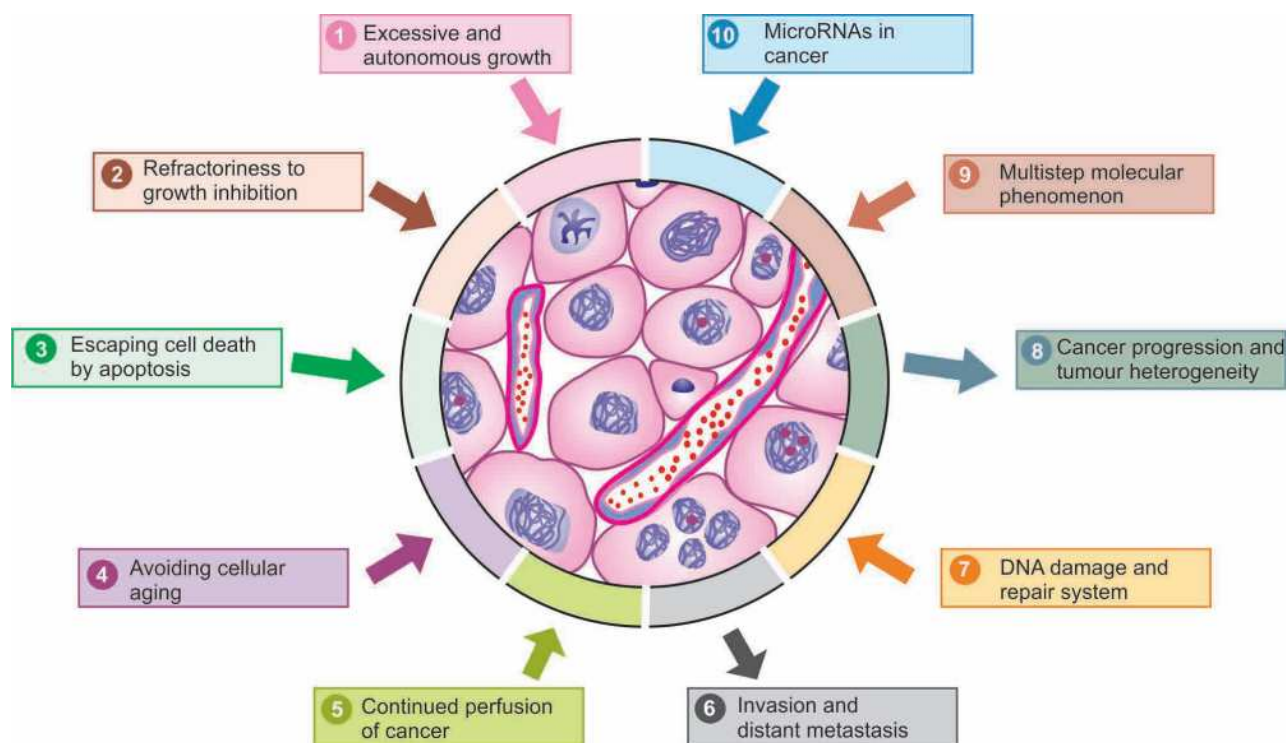

Figure 7.19 Schematic representation of major properties of cancer in terms of molecular carcinogenesis.

in many human tumours such as bladder cancer, pancreatic adenocarcinoma, cholangiocarcinoma.

ii) **Chromosomal translocations** i.e. transfer of a portion of one chromosome carrying protooncogene to another chromosome and making it independent of growth controls. This is implicated in the pathogenesis of leukaemias and lymphomas e.g.

◆ Philadelphia chromosome seen in 95% cases of chronic myelogenous leukaemia in which *c-ABL* protooncogene on chromosome 9 is translocated to BCR of chromosome 22.

◆ In 75% cases of Burkitt's lymphoma, translocation of *c-MYC* proto-oncogene from its site on chromosome 8 to a portion on chromosome 14.

iii) **Gene amplification** i.e. increasing the number of copies of DNA sequence in protooncogene leading to increased mRNA and thus increased or overexpressed gene product (i.e. oncoproteins). Examples of gene amplification are found in some solid human tumours e.g.

◆ Neuroblastoma having *n-MYC* HSR region.

◆ *ERB-B1* in breast and ovarian cancer.

Most of the oncogenes encode for components of cell signaling system for promoting cell proliferation. Accordingly, these are discussed below under following 5 groups pertaining to different components of cell proliferation signaling systems (**Table 7.4**) and are schematically shown in **Fig. 7.20**:

i) Growth factors

ii) Receptors of growth factors

iii) Cytoplasmic signal transduction proteins

iv) Nuclear transduction factors

v) Cell regulatory proteins

i) Growth factors (GFs) GFs were the first protooncogenes to be discovered which encode for cell proliferation cascade. They act by binding to cell surface receptors to activate cell proliferation cascade within the cell. GFs are small polypeptides elaborated by many cells and they normally act on another cell than the one which synthesised it to stimulate its proliferation i.e. *paracrine action*. However, a cancer cell may synthesise a GF and respond to it as well; this way cancer cells acquire growth self-sufficiency.

Most often, growth factor genes in cancer act by overexpression which stimulates large secretion of GFs that stimulate cell proliferation. The examples of such GFs are as under:

a) **Platelet-derived growth factor- β (*PDGF- β*):** Overexpression of *SIS* protooncogene that encodes for *PDGF- β* and thus there is increased secretion of *PDGF- β* e.g. in gliomas and sarcomas.

b) **Transforming growth factor- α (*TGF- α*):** Overexpression of *TGF- β* gene occurs by stimulation of *RAS* protooncogene and induces cell proliferation by binding to epidermal growth factor (*EGF*) receptor e.g. in carcinoma and astrocytoma.

c) **Fibroblast growth factor (*FGF*):** Overexpression of *HST-1* protooncogene and amplification of *INT-2* protooncogene causes excess secretion of *FGF* e.g. in cancer of the bowel and breast.

Table 7.4 Important oncogenes, their mechanism of activation and associated human tumours.

| TYPE | PROTO-ONCOGENE | MECHANISM | ASSOCIATED HUMAN TUMOURS |
|---|--|---------------------------------|--|
| 1. GROWTH FACTORS | | | |
| i) <i>PDGF-β</i> | <i>SIS</i> | Overexpression | Gliomas, sarcoma |
| ii) <i>TGF-α</i> | <i>RAS</i> | Overexpression | Carcinomas, astrocytoma |
| iii) <i>FGF</i> | <i>HST-1</i> <i>INT-2</i> | Overexpression Amplification | Bowel cancers Breast cancer |
| iv) <i>c-MET</i> | <i>HGF</i> | Overexpression | Follicular carcinoma thyroid |
| 2. RECEPTORS FOR GROWTH FACTORS | | | |
| i) <i>EGF</i> receptors | <i>ERB B1 (HER 1)</i> <i>ERB B2 (HER 2/neu)</i> | Overexpression Amplification | Squamous cell carcinoma lung, glioblastoma Ca breast, ovary, stomach, lungs |
| ii) <i>c-KIT</i> receptor (Steel factor) | <i>c-KIT</i> | Point mutation | GIST |
| iii) RET receptor | <i>RET</i> | Point mutation | MEN type 2A and type 2B, medullary ca thyroid |
| iv) FMS-like tyrosine kinase receptor | <i>FLT-3</i> gene | Point mutation | Acute myeloid leukaemia |
| 3. CYTOPLASMIC SIGNAL TRANSDUCTION PROTEINS | | | |
| GTP-bound | <i>RAS</i> | Point mutation | Common in 1/3rd human tumours, Ca lung, colon, pancreas |
| Non-GF receptor tyrosine kinase | <i>ABL-BCR</i> | Translocation | CML, acute leukaemias |
| 4. NUCLEAR TRANSCRIPTION FACTORS | | | |
| <i>C-MYC</i> | <i>MYC</i> | Translocation | Burkitt's lymphoma |
| <i>N-MYC</i> | <i>MYC</i> | Amplification | Neuroblastoma, small cell Ca lung |
| <i>L-MYC</i> | <i>MYC</i> | Amplification | Small cell Ca lung |
| 5. CELL CYCLE REGULATORY PROTEINS | | | |
| Cyclins | <i>Cyclin D</i> <i>Cyclin E</i> | Translocation Overexpression | Ca breast, liver, mantle cell lymphoma Ca breast |
| CDKs | <i>CDK4</i> | Amplification | Glioblastoma, melanoma, sarcomas |

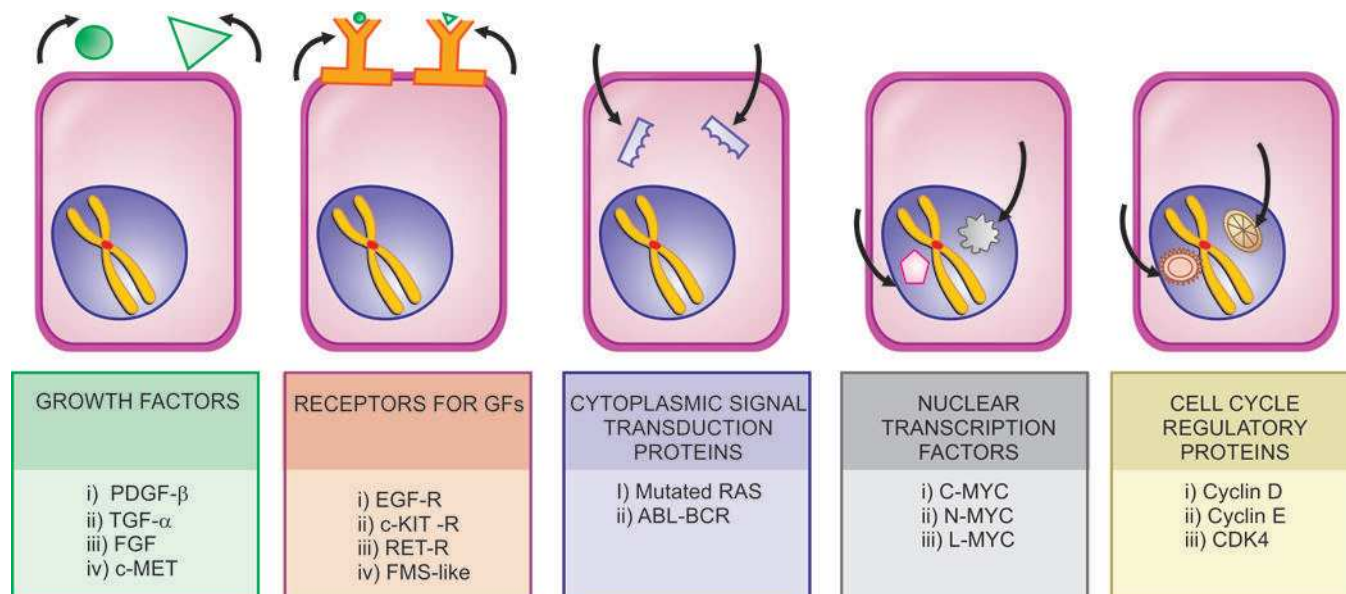

Figure 7.20 Mechanisms of activation of protooncogenes to form growth promoting oncogenes.

d) Hepatocyte growth factor (HGF): Overexpression by binding to its receptor *c-MET* e.g. follicular carcinoma thyroid.

ii) Receptors for GFs Growth factors cannot penetrate the cell directly and require to be transported intracellularly by GF-specific cell surface receptors. These receptors are transmembrane proteins and thus have two surfaces: the outer surface of the membrane has an area for binding growth factor, and the inner surface of the membrane has enzyme-activating area which eventually activates cell proliferation pathway.

Most often, mutated form of growth factor receptors stimulate cell proliferation even without binding to growth factors i.e. with little or no growth factor bound to them. Oncogenes encoding for GF receptors include various mechanisms: overexpression, mutation and gene rearrangement. Examples of tumours by mutated receptors for growth factors are as under:

a) EGF receptors: Normal *EGF* receptor gene is *ERB B1*, and hence this receptor is termed as *EGFR* or *HER1* (i.e. human epidermal growth factor receptor type 1). *EGFR* (or *HER1*) acts by overexpression of normal GF receptor e.g. in 80% of squamous cell carcinoma of lung and 50% cases of glioblastomas.

Another *EGF* receptor gene called *ERB B2* (or *HER2/neu*) acts by gene amplification e.g. in breast cancer (25% cases), carcinoma of lungs, ovary, stomach.

b) c-KIT receptor: The gene coding for receptor for stem cell factor (or steel factor) is *c-KIT*, that activates tyrosine kinase pathway in cell proliferation. Mutated form of *c-KIT* by point mutation activates receptor for tyrosine kinase e.g. in gastrointestinal stromal tumour (GIST).

c) RET receptor: *RET* (abbreviation of 'rearranged during transfection') protooncogene is a receptor for tyrosine kinase normally expressed in neuroendocrine cells of different tissues. Mutated form by point mutation is seen in MEN type 2A and 2B and in medullary carcinoma thyroid.

d) FMS-like tyrosine kinase receptor: Point mutation of *FLT-3* gene (CD 135) that encodes for *FMS*-like tyrosine kinase receptor has been seen in acute myeloid leukaemia.

iii) Cytoplasmic signal transduction proteins The normal signal transduction proteins in the cytoplasm transduce signal from the GF receptors present on the cell surface, to the nucleus of the cell, to activate intracellular growth signaling pathways.

There are examples of oncogenes having mutated forms of cytoplasmic signaling pathways located in the inner surface of cell membrane in some cancers. These are as under:

a) Mutated RAS gene This is the most common form of oncogene in human tumours, the abnormality being induced by point mutation in *RAS* gene. About a third of all human tumours carry mutated *RAS* gene (*RAS* for *Rat Sarcoma* gene where it was first described), seen in examples such as carcinoma colon, lung and pancreas. Normally, the inactive form of *RAS* protein is GDP (guanosine diphosphate)-bound while the activated form is bound to guanosine triphosphate (GTP). GDP/GTP are homologous to G proteins and take part in signal transduction in a similar way just as G proteins act as 'on-off switch' for signal transduction. Normally, active *RAS* protein is inactivated by GTPase activity, while mutated form of *RAS* gene remains unaffected by GTPase, and therefore, continues to signal the cell proliferation.

b) ABL-BCR hybrid gene *ABL* gene is a non-GF receptor protooncogene having tyrosine kinase activity. *ABL* gene from its normal location on chromosome 9 is translocated to chromosome 22 where it fuses with *BCR* (breakpoint cluster region) gene and forms an *ABL-BCR* hybrid gene which is more potent in signal transduction pathway. *ABL-BCR* hybrid gene is seen in chronic myeloid leukaemia and some acute leukaemias (**Fig. 7.21**).

iv) Nuclear transcription factors The signal transduction pathway that started with GFs ultimately reaches the nucleus where it regulates DNA transcription and induces the cell to enter into S phase. Out of various nuclear regulatory transcription proteins described, the most important is *MYC* gene located on long arm of chromosome 8. Normally *MYC* protein binds to the DNA and regulates the cell cycle by transcriptional activation and its levels fall immediately after cell enters the cell cycle.

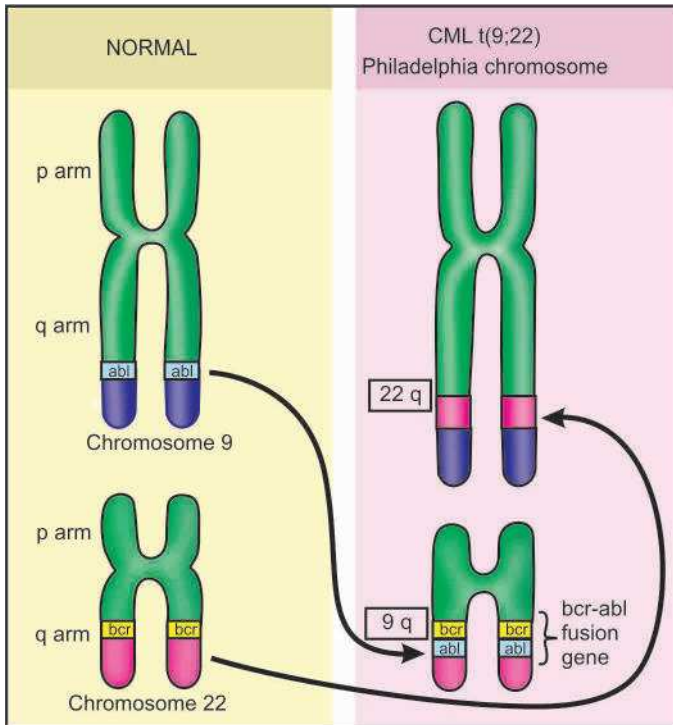

Figure 7.21 ABL-BCR gene translocation in chronic myeloid leukaemia.

MYC oncogene (originally isolated from myelocytomatosis virus and accordingly abbreviated) is seen most commonly in human tumours. It is associated with persistence of or overexpression of *MYC* oncoproteins which, in turn, causes autonomous cell proliferation. The examples of tumours carrying *MYC* oncogene are as under:

- C-MYC oncogene*: Mutated *MYC* gene due to *translocation* t(8;14) seen in Burkitt's lymphoma.
- N-MYC oncogene*: Mutated *MYC* gene due to *amplification* seen in neuroblastoma, small cell carcinoma lung.
- L-MYC oncogene*: Mutated *MYC* gene due to *amplification* seen in small cell carcinoma lung.

v) Cell cycle regulatory proteins Normally, the cell cycle is under regulatory control of cyclins and cyclin-dependent kinases (CDKs) A, B, E and D. Cyclins are so named since they are cyclically synthesised during different phases of the

cell cycle and their degradation is also cyclic. Cyclins activate as well as work together with CDKs, while many inhibitors of CDKs (CDKIs) are also known.

Although all steps in the cell cycle are under regulatory controls, G1 → S phase is the most important checkpoint for regulation by oncogenes as well as anti-oncogenes (discussed below). Mutations in cyclins (in particular cyclin D) and CDKs (in particular CDK4) are most important growth promoting signals in cancers. The examples of tumours having such oncogenes are as under:

- Mutated form of cyclin D* protooncogene by translocation seen in mantle cell lymphoma.
- Mutated form of cyclin E* by overexpression seen in breast cancer.
- Mutated form of CDK4* by gene amplification seen in malignant melanoma, glioblastoma and sarcomas.

2. Refractoriness to Growth Inhibition: Growth Suppressing Anti-Oncogenes

The mutation of normal growth suppressor anti-oncogenes results in removal of the brakes for growth; thus the inhibitory effect to cell growth is removed and the abnormal growth continues unchecked. In other words, mutated anti-oncogenes behave like growth-promoting oncogenes.

As compared to the signals and signal transduction pathways for oncogenes described above, the steps in mechanisms of action by growth suppressors are not so well understood. In general, the point of action by anti-oncogenes is also G1 → S phase transition. Normally, anti-oncogenes act by either inducing the dividing cell from the cell cycle to enter into G0 (resting) phase, or by acting in a way that the cell lies in the post-mitotic pool losing its dividing capability (Fig. 7.22). Just as with activation of protooncogenes to become oncogenes, the mechanisms of loss of tumour suppressor actions of genes are due to chromosomal deletions, point mutations and loss of portions of chromosomes.

Major anti-oncogenes implicated in human cancers are as under (Table 7.5):

i) *RB* gene *RB* gene is located on long arm (q) of chromosome 13. This is the first ever tumour suppressor gene identified and thus has been amply studied. *RB* gene codes for a nuclear transcription protein called pRB. *RB* gene is termed as master 'brake' in the cell cycle and is virtually present in every human cell. It can exist in both an *active* and an *inactive* form:

Table 7.5 Important tumour-suppressor anti-oncogenes and associated human tumours.

| GENE | LOCATION | ASSOCIATED HUMAN TUMOURS |
|--------------------------------------|--|---|
| 1. <i>RB</i> | Nucleus (13q) | Retinoblastoma, osteosarcoma |
| 2. <i>p53 (TP53)</i> | Nucleus (17p) | Most human cancers, common in Ca lung, head and neck, colon, breast |
| 3. <i>TGF-β and its receptor</i> | Extracellular | Ca pancreas, colon, stomach |
| 4. <i>APC and β-catenin proteins</i> | Nucleus, cytosol | Ca colon |
| 5. <i>Others</i> | | |
| i) <i>BRCA 1 and 2</i> | Nucleus (<i>BRCA1</i> 17q21, <i>BRCA2</i> 13q12-13) | Ca breast, ovary |
| ii) <i>VHL</i> | Nucleus (3p) | Renal cell carcinoma |
| iii) <i>WT 1 and 2</i> | Nucleus (11p) | Wilms' tumour |
| iv) <i>NF 1 and 2</i> | Plasma membrane | Neurofibromatosis type 1 and 2 |

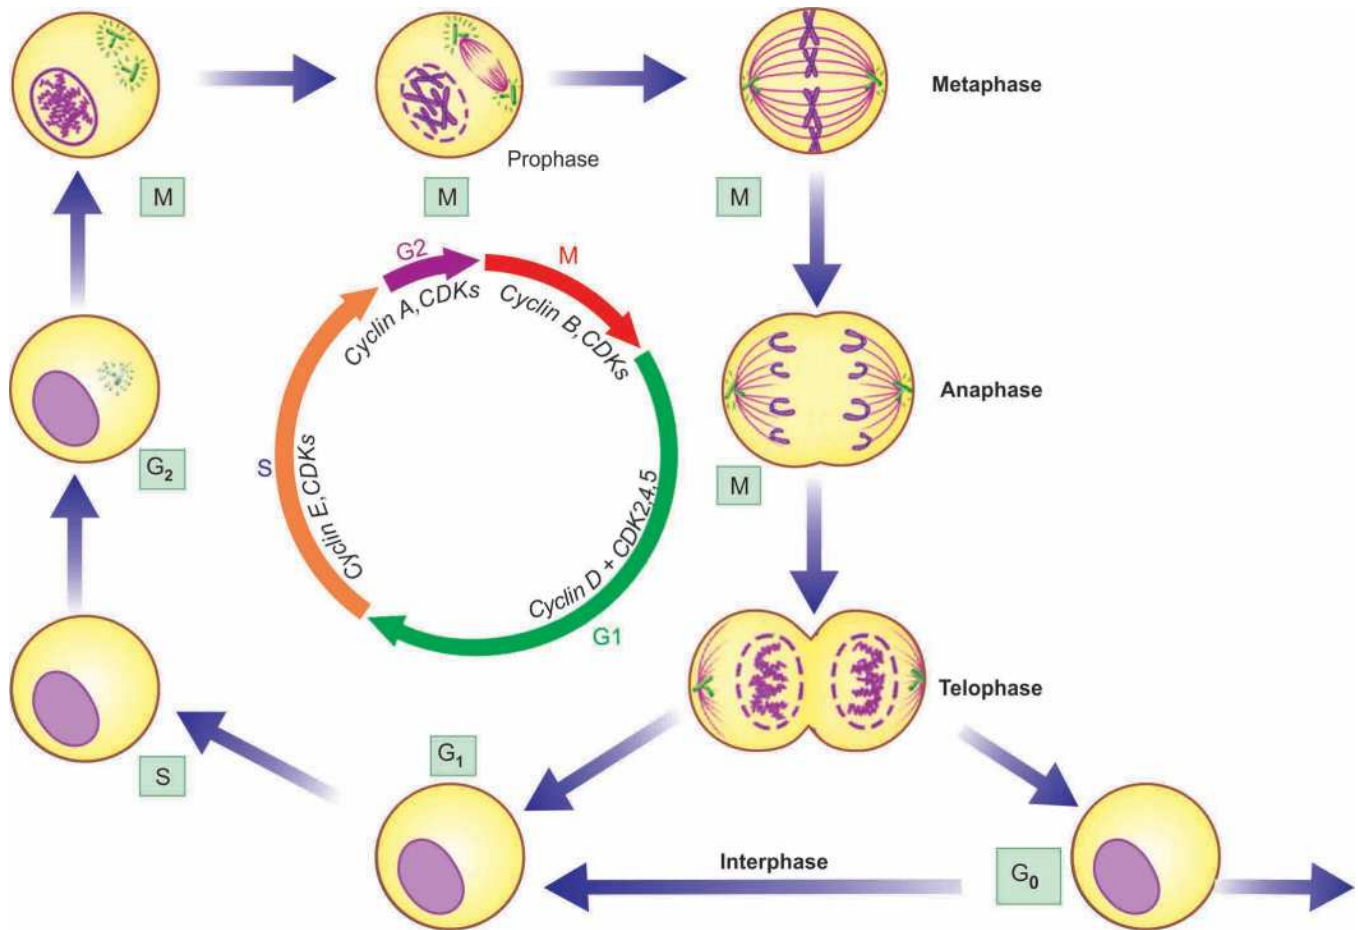

Figure 7.22 Normal cell cycle and its regulators. The cell cycle is driven by kinases which act when bound to proteins called cyclins, hence known as cyclin-dependent kinases (CDKs).

◆ **Active form of RB gene:** It blocks cell division by binding to transcription factor, E2F, and thus inhibits the cell from transcription of cell cycle-related genes, thereby *inhibiting* the cell cycle at G₁ → S phase i.e. cell cycle is arrested at G₁ phase.

◆ **Inactive form of RB gene:** This takes place when RB gene is hyperphosphorylated by cyclin dependent kinases (CDKs) and growth factors bind to their receptors. This removes pRB function from the cell (i.e. the 'brake' on cell division is removed). Resultantly, cell proliferation pathway is stimulated by *permitting* the cell to cross G₁ → S phase. Activity of CDKs is inhibited by activation of inhibitory signal, transforming growth factor-β (TGF-β), on cell through activation of inhibitory protein p16.

The mutant form of *RB* gene (i.e. inactivating mutation of *RB* gene) is involved in several human tumours, most commonly in retinoblastoma, the most common intraocular tumour in young children. The tumour occurs in two forms: sporadic and inherited/familial (**Fig. 7. 23**):

◆ **Sporadic retinoblastoma** constitutes about half the cases and affects one eye. These cases have acquired both the somatic mutations in the two alleles in retinal cells after birth.

◆ **Inherited/Familial retinoblastoma** comprises 40% of cases and may be bilateral. In these cases, all somatic cells (retinal as well as non-retinal cells) inherit one mutant *RB* gene from a carrier parent (i.e. germline mutation). Later during life, the other mutational event of second allele affecting the somatic cells occurs. This forms the basis of *two-hit hypothesis* given by

Knudson in 1971. Besides retinoblastoma, children inheriting mutant *RB* gene have 200 times greater risk of development of other cancers in early adult life, most notably osteosarcoma; others are cancers of breast, colon and lungs.

ii) ***p53* gene (*TP53*)** Located on the short arm (p) of chromosome 17, *p53* gene (also termed *TP53* because of molecular weight of 53 kd for the protein) like *pRB* is inhibitory to cell cycle. However, *p53* is normally present in very small amounts and accumulates only after DNA damage.

The two major functions of *p53* in the normal cell cycle are as under:

a) **In blocking mitotic activity:** *p53* inhibits the cyclins and CDKs and prevents the cell to enter G₁ phase transiently. This breathing time in the cell cycle is utilised by the cell to repair the DNA damage.

b) **In promoting apoptosis:** Normally, *p53* acts together with another anti-oncogene, *RB* gene, and identifies the genes that have damaged DNA which cannot be repaired by inbuilt system. *p53* directs such cells to apoptosis by activating apoptosis-inducing *BAX* gene, and thus bringing the defective cells to an end by apoptosis. This process operates in the cell cycle at G₁ and G₂ phases before the cell enters the S or M phase.

Because of these significant roles in cell cycle, *p53* is called as 'protector of the genome'.

In its mutated form, *p53* ceases to act as protector or as growth suppressor but instead acts like a growth promoter or

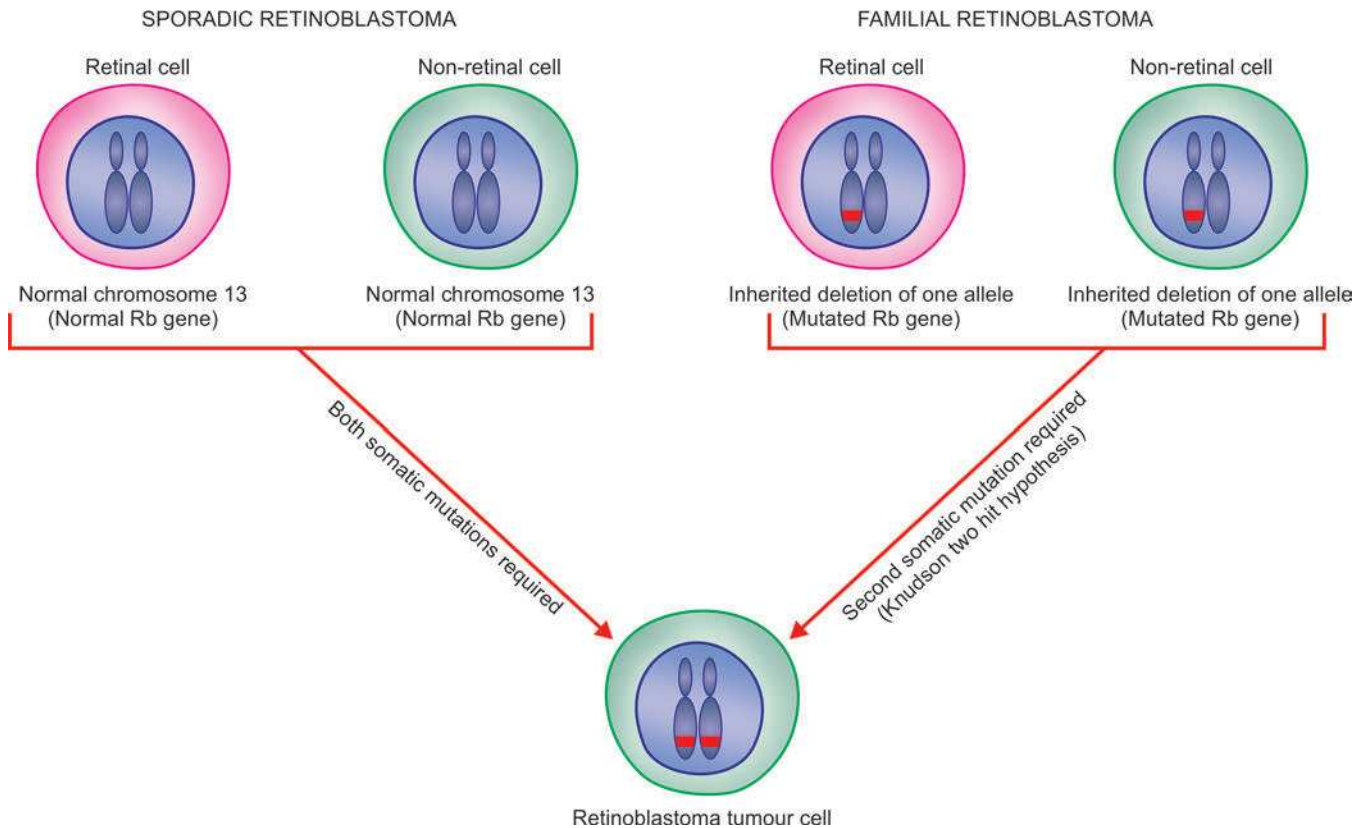

Figure 7.23 Schematic representation of role of *RB* gene in sporadic and familial retinoblastoma. A, In sporadic form, at birth there is no abnormality of either of two alleles of *RB* gene of retinal and non-retinal cells. Here, two mutations occur after birth involving both alleles of *RB* gene. B, In familial/ inherited retinoblastoma, both retinal as well as non-retinal cells have one germline mutation at birth from one of the parents in one allele that encodes for *RB* protein gene. Second mutational event in these cases in the other allele occurs early during life to form homozygous mutation (two hit hypothesis of Hudson).

oncogene. Homozygous loss of *p53* gene allows genetically damaged and unrepaired cells to survive and proliferate resulting in malignant transformation. More than 70% of human cancers have homozygous loss of *p53* by acquired mutations in somatic cells; some common examples are cancers of the lung, head and neck, colon and breast. Besides, mutated *p53* is also seen in the sequential development stages of cancer from hyperplasia to carcinoma *in situ* and into invasive carcinoma.

Less commonly, both alleles of *p53* gene become defective by another way: one allele of *p53* mutated by inheritance in germ cell lines rendering the individual to another hit of somatic mutation on the second allele. Just as in *RB* gene, this defect predisposes the individual to develop cancers of multiple organs (breast, bone, brain, sarcomas etc), termed *Li-Fraumeni syndrome*.

iii) Transforming growth factor- β (TGF- β) and its receptor Normally, TGF- β is significant inhibitor of cell proliferation, especially in epithelial, endothelial and haematopoietic cells. It acts by binding to TGF- β receptor and then the complex so formed acts in G1 phase of cell cycle at two levels:

- It activates CDK inhibitors (CDKIs) with growth inhibitory effect.
- It suppresses the growth promoter genes such as *MYC*, *CDKs* and cyclins.

Mutant form of TGF- β gene or its receptor impairs the growth inhibiting effect and thus permits cell proliferation. Examples of mutated form of TGF- β are seen in cancers of pancreas, colon, stomach and endometrium.

iv) Adenomatous polyposis coli (APC) gene and β -catenin protein The *APC* gene is normally inhibitory to mitosis, which takes place by a cytoplasmic protein, β -catenin. β -catenin normally has dual functions:

- ◆ Firstly, it binds to cytoplasmic E-cadherin that is involved in intercellular interactions.
- ◆ Secondly it can activate cell proliferation signaling pathway.

In colon cancer cells, *APC* gene is lost and thus β -catenin fails to get degraded, allowing the cancer cells to undergo mitosis without the inhibitory influence of β -catenin.

Patients born with one mutant *APC* gene allele develop large number of polyps in the colon early in life, while after the age of 20 years these cases start developing loss of second *APC* gene allele. It is then that almost all these patients invariably develop malignant transformation of one or more polyps.

v) Other antioncogenes A few other tumour-suppressor genes having mutated germline in various tumours are as under:

a) BRCA 1 and BRCA 2 genes: These are two breast (*BR*) cancer (*CA*) susceptibility genes: *BRCA1* located on chromosome 17q21 and *BRCA2* on chromosome 13q12-13. Women with inherited defect in *BRCA1* gene have very high risk (85%) of developing breast cancer and ovarian cancer (40%). Inherited breast cancer constitutes about 5-10% cases, it tends to occur at a relatively younger age and more often tends to be bilateral.

b) VHL gene: von-Hippel-Lindau (VHL) disease is a rare autosomal dominant disease characterised by benign and malignant tumours of multiple tissues. The disease is inherited

Table 7.6 Oncogenes versus antioncogenes.

| FEATURE | ONCOGENE | ANTIONCOGENE |
|-----------------------------------|--|---|
| 1. <i>Derived from</i> | Mutated form of normal protooncogenes | Mutated form of normal growth suppressor genes |
| 2. <i>Genetic abnormality</i> | Mutations (point, translocation, amplification, overexpression) retroviral insertion, DNA damage | Loss of genes by deletion, point mutation and loss of portion of chromosome |
| 3. <i>Major action</i> | Allows cell proliferation by increased growth promotion pathways | Allows cell proliferation by removal of cell growth suppressor pathway |
| 4. <i>Level of action in cell</i> | At different levels (cell surface, cytoplasm, mutations) | At different levels (cell surface, cytoplasm, nucleus) |
| 5. <i>Major types</i> | i) GFs (<i>PDGF-β, TGF-α, FGF, HGF</i>) ii) GF receptors (<i>EGFR, cKIT, RET</i>) iii) Cytoplasmic signal proteins (<i>RAS, BCR-ABL</i>) iv) Nuclear transcription proteins (<i>MYC</i>) v) Cell cycle regular proteins (<i>CDKs, cyclins</i>) | i) <i>RB</i> ii) <i>p53</i> iii) <i>TGF-β</i> and its receptor iv) <i>APC</i> and β -catenin v) Others (<i>BRCA 1 and 2, VHL, WT 1 and 2, NF 1 and 2</i>) |

as a mutation in *VHL* tumour suppressor gene located on chromosome 3p. This results in activation of genes that promote angiogenesis, survival and proliferation; *VHL* gene is found inactivated in 60% cases of renal cell carcinoma.

c) *Wilms' tumour (WT) gene*: *WT1* and *WT2* genes are both located on chromosome 11 and normally prevent neoplastic proliferation of cells in embryonic kidney. Mutant form of *WT-1* and 2 are seen in hereditary Wilms' tumour.

d) *Neurofibroma (NF) gene*: *NF* genes normally prevent proliferation of Schwann cells. Two mutant forms are described: *NF1* and *NF2* seen in neurofibromatosis type 1 and type 2.

The contrasting features of growth-promoting oncogenes and growth-suppressing anti-oncogenes are summarised in **Table 7.6**.

3. Escaping Cell Death by Apoptosis: Genes Regulating Apoptosis and Cancer

Besides the role of mutant forms of growth-promoting oncogenes and growth-suppressing anti-oncogenes, another mechanism of tumour growth is by escaping cell death by apoptosis. Apoptosis in normal cell is guided by cell death receptor, *CD95*, resulting in DNA damage. Besides, there is role of some other pro-apoptotic factors (*BAD, BAX, BID* and *p53*) and apoptosis-inhibitors (*BCL2, BCL-X*).

In cancer cells, the function of apoptosis is interfered due to mutations in the above genes which regulate apoptosis in the normal cell. The examples of tumours by this mechanism are as under:

a) ***BCL2* gene** is seen in normal lymphocytes, but its mutant form with characteristic translocation (t14;18) (q32;q21) was first described in B-cell lymphoma and hence the name BCL. It is also seen in many other human cancers such as that of breast, thyroid and prostate. Mutation in *BCL2* gene removes the apoptosis-inhibitory control on cancer cells, thus more live cells undergoing mitosis contributing to tumour growth. Besides, *MYC* oncogene and *p53* tumour suppressor gene are also connected to apoptosis. While *MYC* allows cell growth *BCL2* inhibits cell death; thus *MYC* and *BCL2* together allow cell proliferation. Normally, *p53* activates proapoptotic gene *BAX* but mutated *p53* (i.e. absence of *p53*) reduces apoptotic activity and thus allows cell proliferation.

b) ***CD95* receptors** are depleted in hepatocellular carcinoma and hence the tumour cells escape apoptosis.

4. Avoiding Cellular Ageing: Telomeres and Telomerase in Cancer

As discussed in pathology of ageing in Chapter 2, after each mitosis (cell doubling) there is progressive shortening of telomeres which are the terminal tips of chromosomes. Telomerase is the RNA enzyme that helps in repair of such damage to DNA and maintains normal telomere length in successive cell divisions. However, it has been seen that after repetitive mitosis for a maximum of 60 to 70 times, telomeres are lost in normal cells and the cells cease to undergo mitosis. Telomerase is active in normal stem cells but not in normal somatic cells.

Cancer cells in most malignancies have markedly upregulated telomerase enzyme, and hence telomere length is maintained. Thus, cancer cells avoid ageing, mitosis does not slow down or cease, thereby immortalising the cancer cells.

5. Continued Perfusion of Cancer: Tumour Angiogenesis

Cancers can only survive and thrive if the cancer cells are adequately nourished and perfused, as otherwise they cannot grow further. Neovascularisation in the cancers not only supplies the tumour with oxygen and nutrients, but the newly formed endothelial cells also elaborate a few growth factors for progression of primary as well as metastatic cancer. The stimulus for angiogenesis is provided by the release of various factors:

i) **Promoters of tumour angiogenesis** include the most important *vascular endothelial growth factor (VEGF)* (released from genes in the parenchymal tumour cells) and *basic fibroblast growth factor (bFGF)*.

ii) **Anti-angiogenesis factors** inhibiting angiogenesis include *thrombospondin-1* (also produced by tumour cells themselves), *angiostatin*, *endostatin* and *vasculostatin*. Mutated form of *p53* gene in both alleles in various cancers results in removal of anti-angiogenic role of thrombospondin-1, thus favouring continued angiogenesis.

6. Invasion and Distant Metastasis: Cancer Dissemination

One of the most important characteristic of cancers is invasiveness and metastasis. The mechanisms involved in the biology of invasion and metastasis are discussed already along with spread of tumours.

7. DNA Damage and Repair System: Mutator Genes and Cancer

Normal cells during complex mitosis suffer from minor damage to the DNA which is detected and repaired before mitosis is completed so that integrity of the genome is maintained. Similarly, small mutational damage to the dividing cell by exogenous factors (e.g. by radiation, chemical carcinogens etc) is also repaired. *p53* gene is held responsible for detection and repair of DNA damage. However, if this system of DNA repair is defective as happens in some inherited mutations (mutator genes), the defect in unrepaired DNA is passed to the next progeny of cells and cancer results.

The examples of mutator genes exist in the following inherited disorders associated with increased propensity to cancer:

i) *Hereditary non-polyposis colon cancer* (HNPCC or Lynch syndrome) is characterised by hereditary predisposition to develop colorectal cancer. It is due to defect in genes involved in DNA mismatch repair which results in accumulation of errors in the form of mutations in many genes.

ii) *Ataxia telangiectasia* (*AT*) has *ATM* (*M* for mutated) gene. These patients have multiple cancers besides other features such as cerebellar degeneration, immunologic derangements and oculo-cutaneous manifestations.

iii) *Xeroderma pigmentosum* is an inherited disorder in which there is defect in DNA repair mechanism. Upon exposure to sunlight, the UV radiation damage to DNA cannot be repaired. Thus, such patients are more prone to various forms of skin cancers.

iv) *Bloom syndrome* is an example of damage by ionising radiation which cannot be repaired due to inherited defect and the patients have increased risk to develop cancers, particularly leukaemia.

v) *Hereditary breast cancer* patients having mutated *BRCA1* and *BRCA2* genes carry inherited defect in DNA repair mechanism. These patients are not only predisposed to develop breast cancer but also cancers of various other organs.

8. Cancer Progression and Heterogeneity: Clonal Aggressiveness

Another feature of note in biology of cancers is that with passage of time cancers become more aggressive; this property is termed *tumour progression*. Clinical parameters of cancer progression are: increasing size of the tumour, higher histologic grade (as seen by poorer differentiation and greater anaplasia), areas of tumour necrosis (i.e. tumour outgrows its blood supply), invasiveness and distant metastasis.

In terms of molecular biology, this attribute of cancer is due to the fact that with passage of time cancer cells acquire more and more *heterogeneity*. This means that though cancer cells remain monoclonal in origin, they acquire more and more mutations which, in turn, produce multiple-mutated subpopulations of more aggressive clones of cancer cells (i.e. heterogeneous cells) in the growth which have tendency to invade, metastasise and be refractory to hormonal influences. Some of these mutations in fact may kill the tumour cells as well.

9. Cancer—A Sequential Multistep Molecular Phenomenon: Multistep Theory

It needs to be appreciated that cancer occurs following several sequential steps of abnormalities in the target cell e.g. initiation,

promotion and progression in proper sequence. Similarly, multiple steps are involved at genetic level by which cell proliferation of cancer cells is activated: by activation of growth promoters, loss of growth suppressors, inactivation of intrinsic apoptotic mechanisms and escaping cellular ageing. A classic example of this sequential genetic abnormalities in cancer is seen in adenoma-carcinoma sequence in development of colorectal carcinoma. Recent studies on human genome in cancers of breast and colon have revealed that there is a multistep phenomenon of carcinogenesis at molecular level; on an average a malignant tumour has large number of genetic mutations in cancers.

10. Micro-RNAs in Cancer: Oncomirs

Unlike protein-coding molecules of the cell, microRNAs (or miRNAs) are short non-coding single-stranded RNA transcripts with a length of 20-24 nucleotides only. About 1400 microRNAs of fundamental importance in various biological processes have been identified and the list is increasing.

◆ Normally, microRNAs function as the post-translational gene regulators of cell proliferation, differentiation and survival.

◆ In cancer, microRNAs have an oncogenic role in initiation and progression and are termed as oncogenic microRNAs, abbreviated as *oncomiRs*. These oncogenic microRNAs influence various cellular processes in cancer such as control of proliferation, cell cycle regulation, apoptosis, differentiation, metastasis and metabolism.

The above properties of cancer cells are schematically illustrated in **Fig. 7.24**.

GIST BOX 7.5

Molecular Basis of Cancer

- ☐ A few properties of cancer render support for its origin at molecular level. For example, most human cancers have a single clone of cellular origin, limited number of cells develop into cancer in a field, cellular growth of cancer is under genetic control with genetic regulators of normal and abnormal mitosis.
- ☐ Normal regulatory genes of cellular growth undergo mutation in cancer. These mutations may occur by alteration in structure of single base in DNA chain by point mutation, by chromosomal translocations, or by increasing number of copies of DNA sequence causing overexpression of gene product.
- ☐ Various cancer-related genes or molecular hallmarks of cancer which undergo such mutational events are: growth promoting oncogenes causing autonomous and excessive growth, removal of brakes on cellular growth by mutation in growth-suppressing antioncogenes, removal of proapoptotic genes making cancer cells immortal, avoiding cellular ageing by mutated telomerase, by continued cancer angiogenesis, by clonal aggressiveness due to cancer heterogeneity, and by short noncoding microRNAs in cancer.

CARCINOGENS AND CARCINOGENESIS

Carcinogenesis or oncogenesis or tumorigenesis means mechanism of induction of tumours (*pathogenesis of cancer*); agents which can induce tumours are called *carcinogens* (*etiology of*

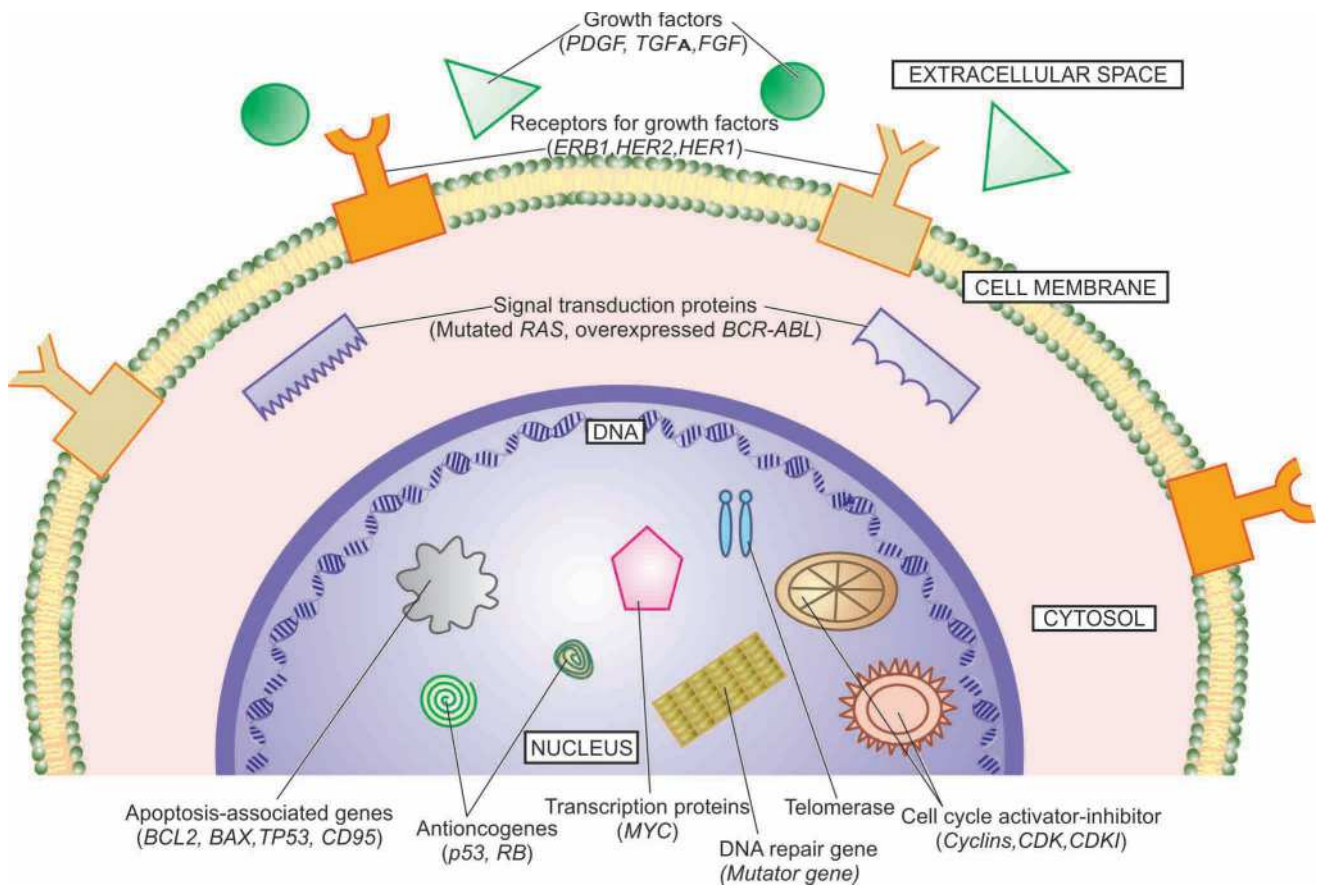

Figure 7.24 Schematic representation of activation-inactivation of cancer-associated genes in cell cycle.

cancer). Since the time first ever carcinogen was identified, there has been ever-increasing list of agents implicated in etiology of cancer. There has been still greater accumulation in volumes of knowledge on pathogenesis of cancer, especially due to tremendous strides made in the field of molecular biology and genetics in recent times as discussed already.

Based on implicated causative agents, etiology and pathogenesis of cancer can be discussed under following 3 headings:

- A. Chemical carcinogens and chemical carcinogenesis
- B. Physical carcinogens and radiation carcinogenesis
- C. Biologic carcinogens and viral oncogenesis.

A. CHEMICAL CARCINOGENESIS

The first ever evidence of any cause for neoplasia came from the observation of Sir Percival Pott in 1775 that there was higher incidence of cancer of the scrotal skin in boys engaged in sweeping industrial chimneys in London than in the general population. This inspired the law-makers in London to pass a ruling that these workers should bathe daily and this simple public health measure lowered the cancer incidence of scrotum in these workers. Similar other observations in occupational workers who have skin soaked in industrial oils and reporting higher incidence of cancer of the skin invoked wide interest in soot and coal tar and its constituents as possible carcinogenic agents. The first successful experimental induction of cancer was produced by two Japanese workers (Yamagiwa and Ichikawa) in 1914 in the rabbit's skin by repeatedly painting

with coal tar. Since then the list of chemical carcinogens which can experimentally induce cancer in animals and have epidemiological evidence in causing human neoplasia, is ever increasing.

STAGES IN CHEMICAL CARCINOGENESIS

The induction of cancer by chemical carcinogens occurs after a delay—weeks to months in the case of experimental animals, and often several years in humans. Other factors that influence the induction of cancer are the dose and mode of administration of carcinogenic chemical, individual susceptibility and various predisposing factors.

Chemical carcinogenesis occurs by induction of mutation in the proto-oncogenes and anti-oncogenes. The phenomena of cellular transformation by chemical carcinogens (as also other carcinogens) is a progressive process involving 3 sequential stages (**Fig. 7.25**):

- ◆ Initiation
- ◆ Promotion
- ◆ Progression

Initiation of Carcinogenesis

Initiation is the first stage in carcinogenesis induced by initiator chemical carcinogens. The change can be produced by a single dose of the initiating agent for a short time, though larger dose for longer duration is more effective. The change so induced is sudden, irreversible and permanent. Chemical carcinogens

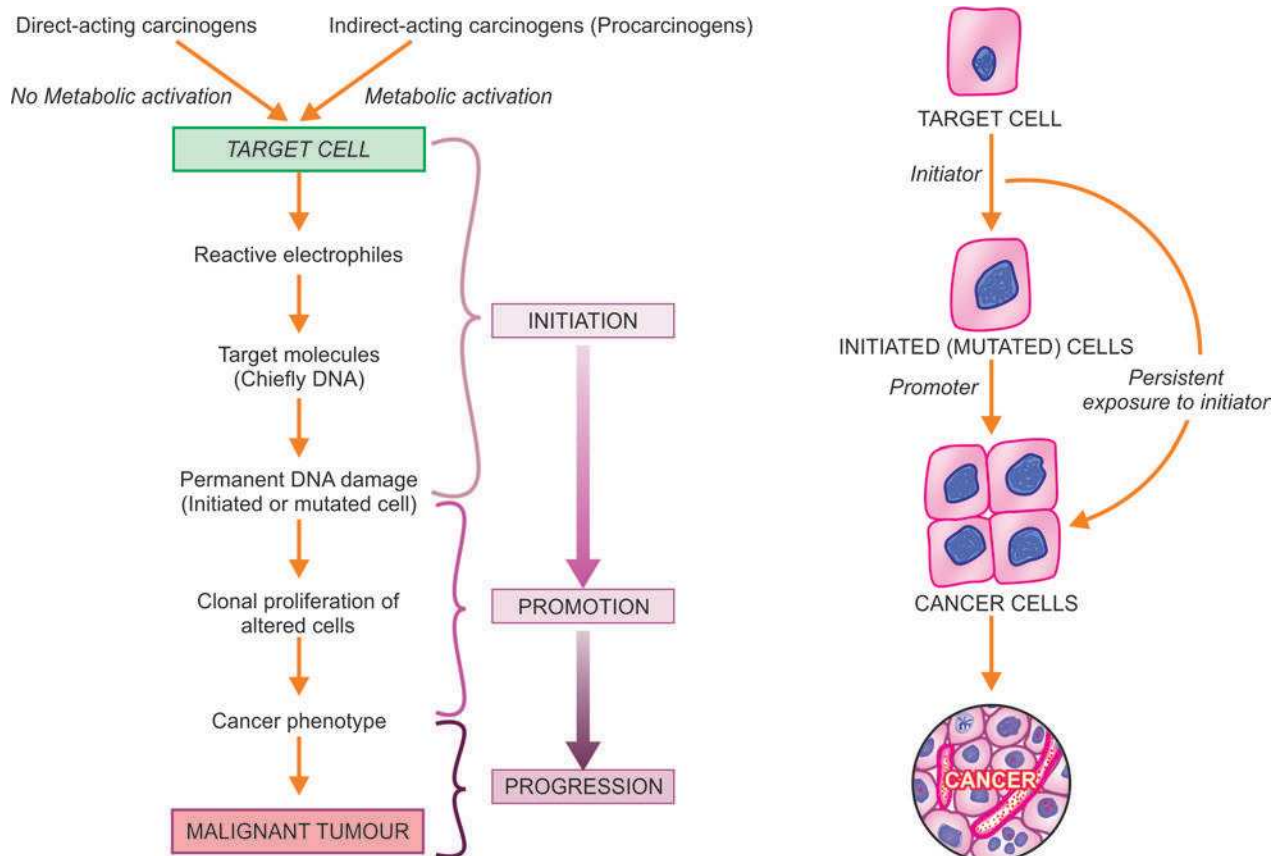

Figure 7.25 Sequential stages in chemical carcinogenesis (left) in evolution of cancer (right).

acting as initiators of carcinogenesis can be grouped into 2 categories (**Table 7.7**):

I. Direct-acting carcinogens These are a few chemical substances (e.g. alkylating agents, acylating agents) which can induce cellular transformation without undergoing any prior metabolic activation.

II. Indirect-acting carcinogens or procarcinogens These require metabolic conversion within the body so as to become 'ultimate' carcinogens having carcinogenicity e.g. polycyclic aromatic hydrocarbons, aromatic amines, azo dyes, naturally-occurring products and others.

In either case, the following steps are involved in transforming 'the target cell' into 'the initiated cell':

1. Metabolic activation Vast majority of chemical carcinogens are indirect-acting or procarcinogens requiring metabolic activation, while direct-acting carcinogens do not require this activation. The indirect-acting carcinogens are activated in the liver by the mono-oxygenases of the cytochrome P-450 system in the endoplasmic reticulum. In some circumstances, the procarcinogen may be detoxified and rendered inactive metabolically.

In fact, following 2 requirements determine the carcinogenic potency of a chemical:

- i) Balance between activation and inactivation reaction of the carcinogenic chemical.
- ii) Genes that code for cytochrome P-450-dependent enzymes involved in metabolic activation e.g. a genotype carrying susceptibility gene *CYP1A1* for the enzyme system has far

higher incidence of lung cancer in light smokers as compared to those not having this permissive gene (page 479).

Besides these two, additional factors such as age, sex and nutritional status of the host also play some role in determining response of the individual to chemical carcinogen.

2. Reactive electrophiles While direct-acting carcinogens are intrinsically electrophilic, indirect-acting substances become electron-deficient after metabolic activation i.e. they become reactive electrophiles. Following this step, both types of chemical carcinogens behave alike and their reactive electrophiles bind to electron-rich portions of other molecules of the cell such as DNA, RNA and other proteins.

3. Target molecules The primary target of electrophiles is DNA, producing mutagenesis. The change in DNA may lead to 'the initiated cell' or some form of cellular enzymes may be able to repair the damage in DNA. The classic example of such a situation occurs in xeroderma pigmentosum, a precancerous condition, in which there is hereditary defect in DNA repair mechanism of the cell and thus such patients are prone to develop skin cancer. The carcinogenic potential of a chemical can be tested *in vitro* by Ames' test for mutagenesis (described later).

Any gene may be the target molecule in the DNA for the chemical carcinogen. However, on the basis of chemically induced cancers in experimental animals and epidemiologic studies in human beings, it has been observed that most frequently affected growth promoter oncogene is *RAS* gene mutation and anti-oncogene (tumour suppressor) is *p53* gene mutation.

Table 7.7 Important chemical carcinogens.

| e) Metals (e.g. nickel, lead, cobalt, chromium etc) | |
| f) Insecticides, fungicides (e.g. aldrin, dieldrin, chlordane etc) | |
| g) Saccharin and cyclomates | |

4. The initiated cell The unrepaired damage produced in the DNA of the cell becomes permanent and fixed only if the altered cell undergoes at least one cycle of proliferation. This results in transferring the change to the next progeny of cells so that the DNA damage becomes *permanent* and *irreversible*, which are the characteristics of the initiated cell, vulnerable to the action of promoters of carcinogenesis.

The stimulus for proliferation may come from regeneration of surviving cells, dietary factors, hormone-induced hyperplasia, viruses etc. A few examples are the occurrence of hepatocellular carcinoma in cases of viral hepatitis, association of endometrial hyperplasia with endometrial carcinoma, effect of oestrogen in breast cancer.

Promotion of Carcinogenesis

Promotion is the next sequential stage in the chemical carcinogenesis. Promoters of carcinogenesis are substances such as phorbol esters, phenols, hormones, artificial sweeteners and drugs like phenobarbital. They differ from initiators in the following respects:

- They do not produce sudden change.
- They require application or administration, as the case may be, *following* initiator exposure, for sufficient time and in sufficient dose.

iii) The change induced may be reversible.

iv) They do not damage the DNA *per se* and are thus not mutagenic but instead enhance the effect of direct-acting carcinogens or procarcinogens.

v) Tumour promoters act by further clonal proliferation and expansion of initiated (mutated) cells, and have reduced requirement of growth factor, especially after *RAS* gene mutation.

It may be mentioned here that persistent and sustained application/exposure of the cell to initiator alone unassociated with subsequent application of promoter may also result in cancer. But the *vice versa* does not hold true since neither application of promoter alone, nor its application prior to exposure to initiator carcinogen, would result in transformation of target cell.

Progression of Carcinogenesis

Progression of cancer is the stage when mutated proliferated cell shows phenotypic features of malignancy. These features pertain to morphology, biochemical composition and molecular features of malignancy. Such phenotypic features appear only when the initiated cell starts to proliferate rapidly and in the process acquires more and more mutations. The new

progeny of cells that develops after such repetitive proliferation inherits genetic and biochemical characteristics of malignancy.

CARCINOGENIC CHEMICALS IN HUMANS

The list of diverse chemical compounds which can produce cancer in experimental animals is a long one but only some of them have sufficient epidemiological evidence in human neoplasia.

Depending upon the mode of action of carcinogenic chemicals, they are divided into 2 broad groups: initiators and promoters (Table 7.7).

Initiator Carcinogens

Chemical carcinogens which can initiate the process of neoplastic transformation are further categorised into 2 subgroups—direct-acting and indirect-acting carcinogens or procarcinogens.

1. DIRECT-ACTING CARCINOGENS These chemical carcinogens do not require metabolic activation and fall into 2 classes:

i) Alkylating agents This group includes mainly various anti-cancer drugs (e.g. cyclophosphamide, chlorambucil, busulfan, melphalan, nitrosourea etc), β -propiolactone and epoxides. They are weakly carcinogenic and are implicated in the etiology of the lymphomas and leukaemias in human beings.

ii) Acylating agents The examples are acetyl imidazole and dimethyl carbamyl chloride.

2. INDIRECT-ACTING CARCINOGENS (PROCARCINOGENS) These are chemical substances which require prior metabolic activation before becoming potent 'ultimate' carcinogens. This group includes vast majority of carcinogenic chemicals. It includes the following 4 categories:

i) Polycyclic aromatic hydrocarbons They comprise the largest group of common procarcinogens which, after metabolic activation, can induce neoplasia in many tissues in experimental animals and are also implicated in a number of human neoplasms. They cause different effects by various modes of administration e.g. by topical application may induce skin cancer, by subcutaneous injection may cause sarcomas, inhalation produces lung cancer, when introduced in different organs by parenteral/metabolising routes may cause cancer of that organ.

Main sources of polycyclic aromatic hydrocarbons are: combustion and chewing of tobacco, smoke, fossil fuel (e.g. coal), soot, tar, mineral oil, smoked animal foods, industrial and atmospheric pollutants. Important chemical compounds included in this group are: anthracenes (benza-, dibenza-, dimethyl benza-), benzapyrene and methylcholanthrene. The following examples have evidence to support the etiologic role of these substances:

a) *Smoking and lung cancer*: There is 20 times higher incidence of lung cancer in smokers of 2 packs (40 cigarettes) per day for 20 years.

b) *Skin cancer*: Direct contact of polycyclic aromatic hydrocarbon compounds with skin is associated with higher incidence of skin cancer. For example, the natives of Kashmir carry an earthen pot containing embers, the *kangri*, under their clothes close to abdomen to keep themselves warm, and skin cancer of the abdominal wall termed *kangri cancer* is common among them.

c) *Tobacco and betel nut chewing and cancer oral cavity*: Cancer of the oral cavity is more common in people chewing tobacco and betel nuts. The *chutta* is a cigar that is smoked in South India (in Andhra Pradesh) with the lighted end in the mouth (i.e. reversed smoking) and such individuals have higher incidence of cancer of the mouth.

ii) Aromatic amines and azo-dyes This category includes the following substances implicated in chemical carcinogenesis:

a) β -*naphthylamine* in the causation of bladder cancer, especially in aniline dye and rubber industry workers.

b) *Benzidine* in the induction of bladder cancer.

c) *Azo-dyes* used for colouring foods (e.g. butter and margarine to give them yellow colour, scarlet red for colouring cherries etc) in the causation of hepatocellular carcinoma.

iii) Naturally-occurring products Some of the important chemical carcinogens derived from plant and microbial sources are aflatoxin B1, actinomycin D, mitomycin C, safrole and betel nuts. Out of these, aflatoxin B1 implicated in causing human hepatocellular carcinoma is the most important, especially when concomitant viral hepatitis B is present. It is derived from the fungus, *Aspergillus flavus*, that grows in stored grains and plants.

iv) Miscellaneous A variety of other chemical carcinogens having a role in the etiology of human cancer are as under:

a) *Nitrosamines and nitrosamides* are involved in gastric carcinoma. These compounds are actually made in the stomach by nitrosylation of food preservatives.

b) *Vinyl chloride monomer* derived from polyvinyl chloride (PVC) polymer in the causation of haemangiosarcoma of the liver.

c) *Asbestos* in bronchogenic carcinoma and mesothelioma, especially in smokers.

d) *Arsenical compounds* in causing epidermal hyperplasia and basal cell carcinoma.

e) *Metals* like nickel, lead, cobalt, chromium etc in industrial workers causing lung cancer.

f) *Insecticides and fungicides* (e.g. aldrin, dieldrin, chlordane) in carcinogenesis in experimental animals.

g) *Saccharin and cyclomates* in cancer in experimental animals.

Promoter Carcinogens

Promoters are chemical substances which lack the intrinsic carcinogenic potential but their application subsequent to initiator exposure helps the initiated cell to proliferate further. These substances include phorbol esters, phenols, certain hormones and drugs.

i) Phorbol esters The best known promoter in experimental animals is *TPA* (tetradecanoyl phorbol acetate) which acts by signal induction protein activation pathway.

ii) Hormones Endogenous or exogenous oestrogen excess in promotion of cancers of endometrium and breast, prolonged administration of diethylstilbestrol in the etiology of postmenopausal endometrial carcinoma and in vaginal cancer in adolescent girls born to mothers exposed to this hormone during their pregnancy.

iii) Miscellaneous e.g. dietary fat in cancer of colon, cigarette smoke and viral infections etc.

The feature of initiators and promoters are contrasted in Table 7.8.

Table 7.8 Contrasting features of initiator and promoter carcinogens.

| FEATURE | INITIATOR CARCINOGENS | PROMOTER CARCINOGENS |
|----------------------|---|---|
| 1. Mechanism | Induction of mutation | Not mutagenic |
| 2. Dose | Single for a short time | Repeated dose exposure, for a long time |
| 3. Response | Sudden response | Slow response |
| 4. Change | Permanent, irreversible | Change may be reversible |
| 5. Sequence | Applied first, then followed by promoter | Applied after prior exposure to initiator |
| 6. Effectivity | Effective alone if exposed in large dose | Not effective alone |
| 7. Molecular changes | Most common mutation of RAS oncogene, p53 anti-oncogene | Clonal expansion of mutated cells |
| 8. Examples | Most chemical carcinogens, radiation | Hormones, phorbol esters |

TESTS FOR CHEMICAL CARCINOGENICITY

There are 2 main methods of testing chemical compound for its carcinogenicity:

1. EXPERIMENTAL INDUCTION The traditional method is to administer the chemical compound under test to a batch of experimental animals like mice or other rodents by an appropriate route e.g. painting on the skin, giving orally or parenterally, or by inhalation. The chemical is administered repeatedly, the dose varied, and promoting agents are administered subsequently. After many months, the animal is autopsied and results obtained. However, all positive or negative tests cannot be applied to humans since there is sufficient species variation in susceptibility to particular carcinogen. Besides, the test is rather prolonged and expensive.

2. TESTS FOR MUTAGENICITY (AMES' TEST) A mutagen is a substance that can permanently alter the genetic composition of a cell. Ames' test evaluates the ability of a chemical to induce mutation in the mutant strain of *Salmonella typhimurium* that cannot synthesise histidine. Such strains are incubated with the potential carcinogen to which liver homogenate is added to supply enzymes required to convert procarcinogen to ultimate carcinogen. If the chemical under test is mutagenic, it will induce mutation in the mutant strains of *S. typhimurium* in the form of functional histidine gene, which will be reflected by the number of bacterial colonies growing on histidine-free culture medium (Fig. 7.26). Most of the carcinogenic chemicals tested positive in Ames' test are carcinogenic *in vivo*.

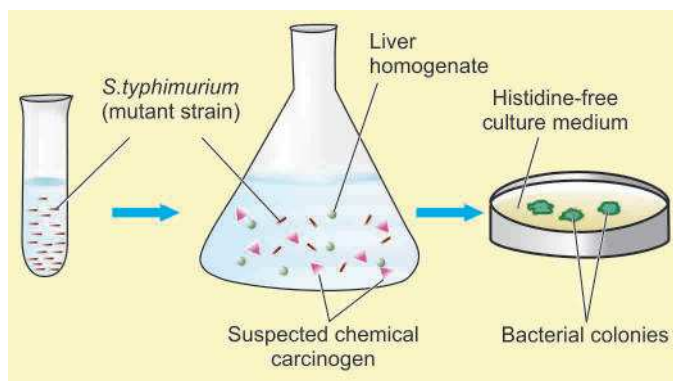

Figure 7.26 Schematic representation of the Ames' test.

B. PHYSICAL CARCINOGENESIS

Physical agents in carcinogenesis are divided into 2 groups:

1. *Radiation*, both ultraviolet light and ionising radiation, is the most important physical agent. The role of radiation as carcinogenic agent is discussed below while its non-neoplastic complications are described in Chapter 3 (page 16).
2. *Non-radiation* physical agents are the various forms of injury and are less important.

RADIATION CARCINOGENESIS

Ultraviolet (UV) light and ionising radiation are the two main forms of radiation carcinogens which can induce cancer in experimental animals and are implicated in causation of some forms of human cancers. A property common between the two forms of radiation carcinogens is the appearance of mutations followed by a long period of latency after initial exposure, often 10-20 years or even later. Also, radiation carcinogens may act to enhance the effect of another carcinogen (co-carcinogens) and, like chemical carcinogens, may have sequential stages of initiation, promotion and progression in their evolution. Ultraviolet light and ionising radiation differ in their mode of action as described below:

1. ULTRAVIOLET LIGHT The main source of UV radiation is the sunlight; others are UV lamps and welder's arcs. UV light penetrates the skin for a few millimetres only so that its effect is limited to epidermis. The efficiency of UV light as carcinogen depends upon the extent of light-absorbing protective melanin pigmentation of the skin. In humans, excessive exposure to UV rays can cause various forms of skin cancers—squamous cell carcinoma, basal cell carcinoma and malignant melanoma. In support of this is the epidemiological evidence of high incidence of these skin cancers in fair-skinned Europeans, albinos who do not tan readily, inhabitants of Australia and New Zealand living close to the equator who receive more sunlight, and in farmers and outdoor workers due to the effect of actinic light radiation.

Mechanism UV radiation may have various effects on the cells. The most important is induction of mutation; others are inhibition of cell division, inactivation of enzymes and sometimes causing cell death. The most important biochemical effect of UV radiation is the formation of pyrimidine dimers in DNA. Such UV-induced DNA damage in normal individuals is

repaired, while in the predisposed persons who are excessively exposed to sunlight such damage remain unrepaired. The proof in favour of mutagenic effect of UV radiation comes from following recessive hereditary diseases characterised by a defect in DNA repair mechanism and associated with high incidence of cancers:

- i) Xeroderma pigmentosum is predisposed to skin cancers at younger age (under 20 years of age).
- ii) Ataxia telangiectasia is predisposed to leukaemia.
- iii) Bloom's syndrome is predisposed to all types of cancers.
- iv) Fanconi's anaemia with increased risk to develop cancer.

Besides, like with other carcinogens, UV radiation also induces mutated forms of oncogenes (in particular *RAS* gene) and anti-oncogenes (*p53* gene).

2. IONISING RADIATION Ionising radiation of all kinds like X-rays, α -, β - and γ -rays, radioactive isotopes, protons and neutrons can cause cancer in animals and in man. Most frequently, radiation-induced cancers are all forms of leukaemias (except chronic lymphocytic leukaemia); others are cancers of the thyroid (most commonly papillary carcinoma), skin, breast, ovary, uterus, lung, myeloma, and salivary glands (Fig. 7.27). The risk is increased by higher dose and with high LET (linear energy transfer) such as in neutrons and α -rays than with low LET as in X-rays and γ -rays. The evidence in support of carcinogenic role of ionising radiation is cited in the following examples:

- i) Higher incidence of radiation dermatitis and subsequent malignant tumours of the skin was noted in X-ray workers and radiotherapists who did initial pioneering work in these fields before the advent of safety measures.
- ii) High incidence of osteosarcoma was observed in young American watch-working girls engaged in painting the dials

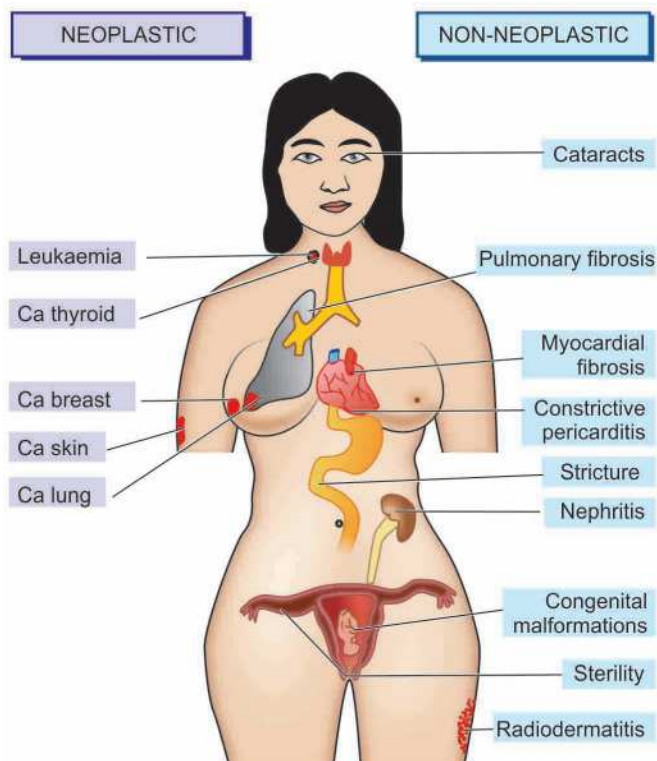

Figure 7.27 Neoplastic (left) and non-neoplastic complications (right) of ionising radiation.

with luminous radium who unknowingly ingested radium while using lips to point their brushes.

iii) Miners in radioactive elements have higher incidence of cancers.

iv) Japanese atom bomb survivors of the twin cities of Hiroshima and Nagasaki after World War II have increased frequency of malignant tumours, notably acute and chronic myeloid leukaemias, and various solid tumours of breast, colon, thyroid and lung.

v) Accidental leakage at nuclear power plant in 1985 in Chernobyl (in former USSR, now in Ukraine) has caused long-term hazardous effects of radioactive material to the population living in the vicinity.

vi) It has been observed that therapeutic irradiation results in increased frequency of cancers, e.g. in patients of ankylosing spondylitis, in children with enlarged thymus, and in children exposed to radiation *in utero* during investigations on the mother.

vii) Thorotrast, a thorium-containing contrast medium, used to be employed in radioimaging of abscess cavities in 1940s. These patients were found to have about twice higher incidence of malignant tumours and thus its use was discontinued.

viii) Recently, there has been debate on the role of electromagnetic radiations emitted by overhead power cables, cellphones and their transmission towers and domestic microwaves in causing cancer. While there is no conclusive link with cancer so far, WHO review report in 2011 has cautioned on *probable* risk of developing brain tumours (glioma and acoustic neuroma) in long-term cellphone users. However, there is no evidence of any health risk by low electromagnetic energy around us from various other sources.

Mechanism Radiation damages the DNA of the cell by one of the 2 possible mechanisms:

- i) It may directly alter the cellular DNA.
- ii) It may dislodge ions from water and other molecules of the cell and result in formation of highly reactive free radicals that may bring about the damage.

Damage to the DNA resulting in mutagenesis is the most important action of ionising radiation. It may cause chromosomal breakage, translocation, or point mutation. The effect depends upon a number of factors such as type of radiation, dose, dose-rate, frequency and various host factors such as age, individual susceptibility, immune competence, hormonal influences and type of cells irradiated.

NON-RADIATION PHYSICAL CARCINOGENESIS

Mechanical injury to the tissues or prolonged contact with certain physical agents has been observed to have higher incidence of certain cancers but without proven basis. A few rare examples of these uncommon associations are as under:

- i) Stones in the gallbladder and in the urinary tract having higher incidence of cancers of these organs.
- ii) Healed scars following burns or trauma for increased risk of carcinoma of affected skin.
- iii) Occupational exposure to asbestos (asbestosis) associated with asbestos-associated tumours of the lung and malignant mesothelioma of the pleura (Chapter 15).
- iv) Workers engaged in hardwood cutting or engraving having high incidence of adenocarcinoma of paranasal sinuses.

- v) Surgical implants of inert materials such as plastic, glass etc in prostheses.
- vi) Foreign bodies embedded in the body for prolonged duration.

C. BIOLOGIC CARCINOGENESIS

The epidemiological studies on different types of cancers indicate the involvement of transmissible biologic agents in their development, chiefly *viruses*. Other microbial agents implicated in carcinogenesis are as follows:

◆ **Parasites** *Schistosoma haematobium* infection of the urinary bladder is associated with high incidence of squamous cell carcinoma of the urinary bladder in some parts of the world such as in Egypt. *Clonorchis sinensis*, the liver fluke, lives in the hepatic duct and is implicated in causation of cholangiocarcinoma.

◆ **Fungus** *Aspergillus flavus* grows in stored grains and liberates aflatoxin; its human consumption, especially by those with HBV infection, is associated with development of hepatocellular carcinoma.

◆ **Bacteria** *Helicobacter pylori*, a gram-positive spiral-shaped micro-organism, colonises the gastric mucosa and has been found in cases of chronic gastritis and peptic ulcer; its prolonged infection may lead to gastric lymphoma and gastric carcinoma; this subject is discussed in detail in Chapter 18.

However, the role of viruses in the causation of cancer is more significant. Therefore, biologic carcinogenesis is largely *viral carcinogenesis*, described below.

VIRAL CARCINOGENESIS

It has been estimated that about 20% of all cancers worldwide are due to persistent virus infection. The association of oncogenic viruses with neoplasia was first observed by an Italian physician Sanarelli in 1889 who noted association between myxomatosis of rabbits with poxvirus. The contagious nature of the common human wart was first established in 1907. Since then, a number of viruses capable of inducing tumours (oncogenic viruses) in experimental animals, and some implicated in humans, have been identified.

Most of the common viral infections (including oncogenic viruses) can be transmitted by one of the 3 routes:

- i) *Horizontal transmission* Commonly, viral infection passes from one to another by direct contact, by ingestion of contaminated water or food, or by inhalation as occurs in most contagious diseases. Most of these infections begin on the epithelial surfaces, spread into deeper tissues, and then through haematogenous or lymphatic or neural route disseminate to other sites in the body.
- ii) *By parenteral route* such as by inoculation as happens in some viruses by inter-human spread and from animals and insects to humans.
- iii) *Vertical transmission*, when the infection is genetically transmitted from infected parents to offsprings.

Based on their nucleic acid content, oncogenic viruses fall into 2 broad groups:

1. Those containing deoxyribonucleic acid are called *DNA oncogenic viruses*.
2. Those containing ribonucleic acid are termed *RNA oncogenic viruses or retroviruses*.

Both types of oncogenic viruses usually have 3 genes and are abbreviated according to the coding pattern by each gene:

- i) *gag* gene: codes for group antigen.
- ii) *pol* gene: codes for polymerase enzyme.
- iii) *env* gene: codes for envelope protein.

Natural history of viral infection can be categorised into primary and persistent:

◆ *Primary viral infections* are majority of the common viral infections in which the infection lasts for a few days to a few weeks and produces clinical manifestations. Primary viral infections are generally cleared by body's innate immunity and specific immune responses. Subsequently, an immunocompetent host is generally immune to the disease or reinfection by the same virus. However, body's immune system is not effective against surface colonization or deep infection or persistence of viral infection.

◆ *Persistence of viral infection or latent infection* in some viruses may occur by acquiring mutations in viruses which resist immune attack by the host, or virus *per se* induces immunosuppression in the host such as HIV.

Viral Oncogenesis: General Aspects

Support to the etiologic role of oncogenic viruses in causation of human cancers is based on the following:

1. Epidemiologic data.
2. Presence of viral DNA in the genome of host target cell.
3. Demonstration of virally induced transformation of human target cells in culture.
4. *In vivo* demonstration of expressed specific transforming viral genes in premalignant and malignant cells.
5. *In vitro* assay of specific viral gene products which produce effects on cell proliferation and survival.

In general, persistence of DNA or RNA viruses may induce mutation in the target host cell, although persistence of viral infection alone is not sufficient for oncogenesis but is one step in the multistep process of cancer development. Generally, RNA viruses have very high mutation rate (e.g. HIV, HCV) than DNA viruses. Mechanisms as to how specific DNA and RNA viruses cause mutation in the host cell are varied, but in general continued presence of DNA or RNA virus in the cell causes activation of growth-promoting pathways or inhibition of tumour-suppressor products in the infected cells. Thus, such virus-infected host cells after having undergone genetic changes enter cell cycle and produce next progeny of transformed cells which have characteristics of autonomous growth and survival completing their role as oncogenic viruses.

General mode of oncogenesis by each group of DNA and RNA oncogenic viruses is briefly considered below:

1. Mode of DNA viral oncogenesis Host cells infected by DNA oncogenic viruses may have one of the following 2 results (**Fig. 7.28**):

- i) *Replication* The virus may replicate in the host cell with consequent lysis of the infected cell and release of virions.
- ii) *Integration* The viral DNA may integrate into the host cell DNA.

The latter event (integration) results in inducing mutation and thus neoplastic transformation of the host cell, while the former (replication) brings about cell death but no neoplastic transformation. A feature essential for host cell transformation

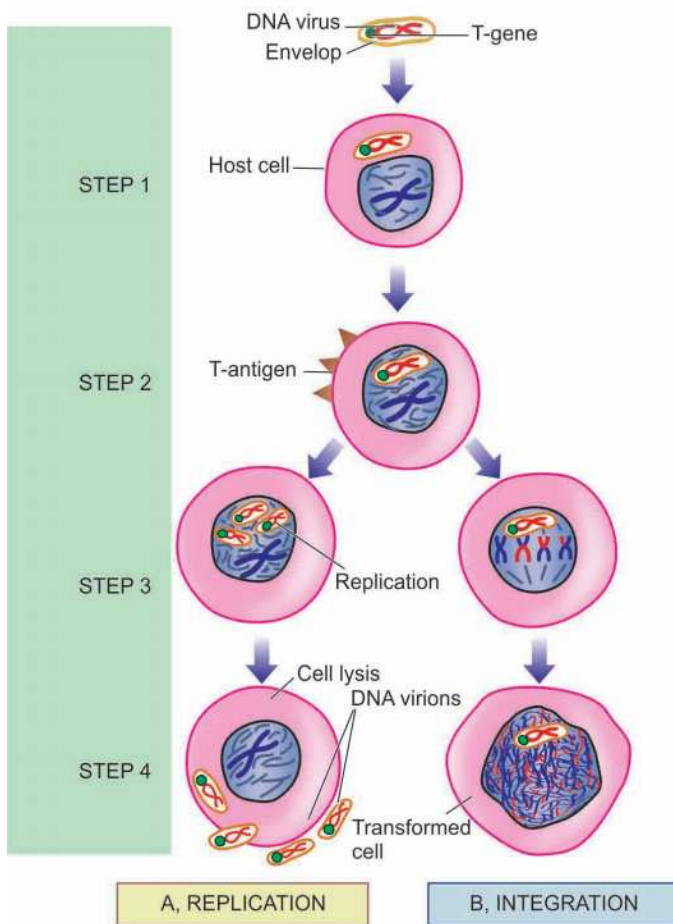

Figure 7.28 Replication and integration of DNA virus in the host cell. **A, Replication:** *Step 1.* The DNA virus invades the host cell. *Step 2.* Viral DNA is incorporated into the host nucleus and T-antigen is expressed immediately after infection. *Step 3.* Replication of viral DNA occurs and other components of virion are formed. The new virions are assembled in the cell nucleus. *Step 4.* The new virions are released, accompanied by host cell lysis. **B, Integration:** *Steps 1 and 2* are similar as in replication. *Step 3.* Integration of viral genome into the host cell genome occurs which requires essential presence of functional T-antigen. *Step 4.* A 'transformed (neoplastic) cell' is formed.

is the expression of virus-specific T-(transforming protein) antigens immediately after infection of the host cell by DNA oncogenic virus (discussed later).

2. Mode of RNA viral oncogenesis RNA viruses or retroviruses contain two identical strands of RNA and the enzyme, reverse transcriptase (**Fig. 7.29**):

- Reverse transcriptase is RNA-dependent DNA synthetase that acts as a template to synthesise a single strand of matching viral DNA i.e. reverse of the normal in which DNA is transcribed into messenger RNA.
- The single strand of viral DNA is then copied by DNA-dependent DNA synthetase to form another strand of complementary DNA resulting in double-stranded viral DNA or provirus.
- The provirus is then integrated into the DNA of the host cell genome and may induce mutation and thus transform the cell into neoplastic cell.
- Retroviruses are replication-competent. The host cells which allow replication of integrated retrovirus are called permissive

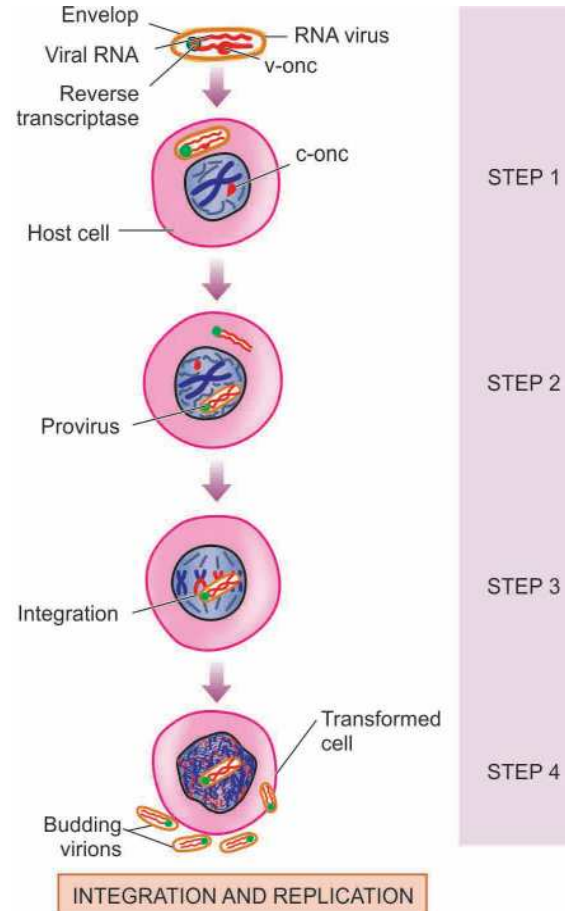

Figure 7.29 Integration and replication of RNA virus (retrovirus) in the host cell.

Step 1. The RNA virus invades the host cell. The viral envelope fuses with the plasma membrane of the host cell; viral RNA genome as well as reverse transcriptase are released into the cytosol. *Step 2.* Reverse transcriptase acts as template to synthesise single strand of matching viral DNA which is then copied to form complementary DNA resulting in double-stranded viral DNA (provirus). *Step 3.* The provirus is integrated into the host cell genome producing 'transformed host cell'. *Step 4.* Integration of the provirus brings about replication of viral components which are then assembled and released by budding.

cells. Non-permissible cells do not permit replication of the integrated retrovirus.

v) Viral replication begins after integration of the provirus into host cell genome. Integration results in transcription of proviral genes or progenes into messenger RNA which then forms components of the virus particle—virion core protein from *gag* gene, reverse transcriptase from *pol* gene, and envelope glycoprotein from *env* gene. The three components of virus particle are then assembled at the plasma membrane of the host cell and the virus particles released by budding off from the plasma membrane, thus completing the process of replication.

With these general comments, we now turn to specific DNA and RNA oncogenic viruses and their specific oncogenic role.

DNA Oncogenic Viruses

DNA oncogenic viruses have direct access to the host cell nucleus and are incorporated into the genome of the host cell. DNA viruses are classified into 5 subgroups, each of

Table 7.9 DNA oncogenic viruses.

| VIRUS | HOST | ASSOCIATED TUMOUR |
|---|--------------------------------------|---|
| 1. PAPOVAVIRUSES | | |
| <i>Human papilloma virus</i> | Humans | Cervical cancer and its precursor lesions, squamous cell carcinoma at other sites Skin cancer in epidermodysplasia verruciformis Papillomas (warts) on skin, larynx, genitals (genital warts) |
| <i>Papilloma viruses</i> | Cotton-tail rabbits Bovine | Papillomas (warts) Alimentary tract cancer |
| <i>Polyoma virus</i> | Mice | Various carcinomas, sarcomas |
| <i>SV-40 virus</i> | Monkeys Hamsters Humans | Harmless Sarcoma ? Mesothelioma |
| 2. HERPESVIRUSES | | |
| <i>Epstein-Barr virus</i> | Humans | Burkitt's lymphoma Nasopharyngeal carcinoma |
| <i>Human herpesvirus 8 (Kaposi's sarcoma herpesvirus)</i> | Humans | Kaposi's sarcoma Pleural effusion lymphoma |
| <i>Lucke' frog virus</i> | Frog | Renal cell carcinoma |
| <i>Marek's disease virus</i> | Chickens | T-cell leukaemia-lymphoma |
| 3. ADENOVIRUSES | Hamsters | Sarcomas |
| 4. POXVIRUSES | Rabbits Humans | Myxomatosis Molluscum contagiosum, papilloma |
| 5. HEPADNAVIRUSES | | |
| <i>Hepatitis B virus</i> | Humans | Hepatocellular carcinoma |

which is capable of producing neoplasms in different hosts (Table 7.9). These are: Papovaviruses, Herpesviruses, Adenoviruses, Poxviruses and Hepadna viruses.

1. PAPOVAVIRUSES This group consists of the papilloma virus including the human papilloma virus (HPV), polyoma virus and SV-40 (simian vacuolating) virus. These viruses have an etiologic role in following benign and malignant neoplasms in animals and in humans:

i) Papilloma viruses These viruses were the first to be implicated in the etiology of any human neoplasia. These viruses appear to replicate in the layers of stratified squamous epithelium. More than 100 HPV types have been identified; the individual types are associated with different lesions. The following examples of benign and malignant tumours are cited to demonstrate their role in oncogenesis:

In humans—

◆ HPV was first detected as etiologic agent in common *skin warts* or *verruca vulgaris* (squamous cell papillomas) by Shope in 1933; the condition is infectious. Current evidence supports implication of low-risk HPV types 1,2, 4 and 7 in common viral warts.

◆ Low-risk HPV types 6 and 11 are involved in the etiology of genital warts (*condyloma acuminata*).

◆ Viral DNA of high-risk HPV types 16, 18, 31, 33 and 45 has been seen in 75-100% cases of *invasive cervical cancer* and its precursor lesions (carcinoma *in situ* and dysplasia) and is strongly implicated.

◆ High-risk HPVs are also involved in causation of *other squamous cell carcinomas* and dysplasias such as of anus, perianal region, vagina, vulva, penis and oral cavity.

◆ HPV types 5 and 8 are responsible for causing an uncommon condition, *epidermodysplasia verruciformis*. The condition is characterised by multiple skin warts and a genetic defect in the cell-mediated immunity. About one-third of cases develop squamous cell carcinoma in the sun-exposed warts.

◆ Some strains of HPV are responsible for causing multiple *juvenile papillomas* of the larynx.

In animals—

◆ Benign warty lesions similar to those seen in humans are produced by different members of the papilloma virus family in susceptible animals such as in rabbits by cottontail rabbit papilloma virus, and in cattle by bovine papilloma virus (BPV).

◆ There is evidence to suggest the association of BPV and cancer of the alimentary tract in cattle.

HPV ONCOGENESIS IN HUMAN CANCER—

Persistent infection with high-risk HPV types in target epithelial cells drives the molecular hallmarks of cancer discussed earlier and directly affect cell growth by following mechanisms:

i) HPV integrates into the host cell DNA which results in overexpression of viral proteins E6 and E7 from high-risk HPV types. E6 and E7 from high-risk HPVs have high affinity for target host cells than these viral oncoproteins from low-risk HPVs.

ii) E6 and E7 viral proteins cause loss of *p53* and *pRB*, the two cell proteins with tumour-suppressor properties. Thus the brakes in cell proliferation are removed, permitting the uncontrolled proliferation.

iii) These viral proteins activate cyclin A and E, and inactivate CDKIs, thus permitting further cell proliferation.

- iv) These viral proteins mediate and degrade *BAX*, a proapoptotic gene, thus inhibiting apoptosis.
- v) These viral proteins activate telomerase, immortalising the transformed host target cells.

ii) Polyoma virus Polyoma virus occurs as a natural infection in mice.

◆ *In animals*—Polyoma virus infection is responsible for various kinds of carcinomas and sarcomas in immunodeficient (nude) mice and other rodents. In view of its involvement in causation of several unrelated tumours in animals, it was named polyoma.

◆ *In humans*—Polyoma virus infection is not known to produce any human tumour. But it is involved in causation of polyomavirus nephropathy in renal allograft recipients and is also implicated in the etiology of progressive demyelinating leucoencephalopathy, a fatal demyelinating disease.

iii) SV-40 virus Simian vacuolating (SV) virus exists in monkeys without causing any harm but was found in cell cultures being prepared for human polio vaccine in 1960. It was subsequently found that SV-40 could induce sarcoma in hamsters but in humans. There is some evidence of involvement of SV-40 infection in mesothelioma of the pleura.

2. HERPESVIRUSES Primary infection of all the herpesviruses in man persists probably for life in a latent stage which can get reactivated later. Important members of herpesvirus family are Epstein-Barr virus, herpes simplex virus type 2 (HSV-2) and human herpesvirus 8 (HHV8), cytomegalovirus (CMV), Lucke's frog virus and Marek's disease virus. Out of these, Lucke's frog virus and Marek's disease virus are implicated in animal tumours only (renal cell carcinoma and T-cell leukaemia-lymphoma respectively). There is no oncogenic role of HSV-2 and CMV in human tumours. The other two—EBV and HHV are implicated in human tumours as under.

EPSTEIN-BARR VIRUS (EBV) EBV infects human B-lymphocytes and epithelial cells and long-term infection stimulates them to proliferate and development of malignancies. EBV is implicated in the following human tumours—Burkitt's lymphoma, anaplastic nasopharyngeal carcinoma, post-transplant lymphoproliferative disease, primary CNS lymphoma in AIDS patients, and Hodgkin's lymphoma. It is also shown to be causative for infectious mononucleosis, a self-limiting disease in humans. The role of EBV in the first two human tumours is given below while others have been discussed elsewhere in relevant chapters.

Burkitt's lymphoma Burkitt's lymphoma was initially noticed in African children by Burkitt in 1958 but is now known to occur in 2 forms—*African endemic form*, and *sporadic form* seen elsewhere in the world. The morphological aspects of the tumour are explained in Chapter 12, while oncogenesis is described here.

There is strong evidence linking Burkitt's lymphoma, a B-lymphocyte neoplasm, with EBV as observed from the following features:

- Over 90% of Burkitt's lymphomas are EBV-positive in which the tumour cells carry the viral DNA.
- 100% cases of Burkitt's lymphoma show elevated levels of antibody titers to various EBV antigens.
- EBV has strong tropism for B lymphocytes. EBV-infected B cells grown in cultures are immortalised i.e. they continue to

develop further along B cell-line to propagate their progeny in the altered form.

d) Though EBV infection is almost worldwide in all adults and is also known to cause self-limiting infectious mononucleosis, but the fraction of EBV-infected circulating B cells in such individuals is extremely small.

e) Linkage between Burkitt's lymphoma and EBV infection is very high in African endemic form of the disease and probably in cases of AIDS than in sporadic form of the disease.

However, a few observations, especially regarding sporadic cases of Burkitt's lymphoma, suggest that certain other supportive factors may be contributing. *Immunosuppression* appears to be one such most significant factor. The evidence in favour is as follows:

◆ Normal individuals harbouring EBV-infection as well as cases developing infectious mononucleosis are able to mount good immune response so that they do not develop Burkitt's lymphoma.

◆ In immunosuppressed patients such as in HIV infection and organ transplant recipients, there is marked reduction in body's T-cell immune response and higher incidence of this neoplasm.

◆ It is observed that malaria, which confers immunosuppressive effect on the host, is prevalent in endemic proportions in regions where endemic form of Burkitt's lymphoma is frequent. This supports the linkage of EBV infection and immunosuppression in the etiology of Burkitt's lymphoma.

Anaplastic nasopharyngeal carcinoma This is the other tumour having close association with EBV infection. The tumour is prevalent in South-East Asia, especially in the Chinese, and in Eskimos. The morphology of nasopharyngeal carcinoma is described in Chapter 16 (page 499). The evidence linking EBV infection with this tumour is as follows:

- 100% cases of nasopharyngeal carcinoma carry DNA of EBV in nuclei of tumour cells.
- Individuals with this tumour have high titers of antibodies to various EBV antigens.

However, like in case of Burkitt's lymphoma, there may be some *co-factors* such as genetic susceptibility that account for the unusual geographic distribution.

EBV ONCOGENESIS IN HUMAN CANCER—

Persistent EBV infection is implicated in the causation of malignancies of B lymphocytes and epithelial cells. The mechanism of oncogenesis is as under:

- Latently infected epithelial cells or B lymphocytes express viral oncogene *LMP1* (latent membrane protein) which is most crucial step in evolution of EBV-associated malignancies. Immunosuppressed individuals are unable to mount attack against EBV infection and thus are more affected.
- LMP1* viral protein dysregulates normal cell proliferation and survival of infected cells and acts like CD40 receptor molecule on B cell surface. Thus, it stimulates B-cell proliferation by activating growth signaling pathways via nuclear factor κ B (NF- κ B) and *JAK/STAT* pathway.
- LMP-1* viral oncoprotein also activates *BCL2* and thereby prevents apoptosis.
- Persistent EBV infection elaborates another viral protein *EBNA-2* (EB virus nuclear antigen) which activates cyclin D in the host cells and thus promotes cell proliferation.
- In immunocompetent individuals, *LMP1* is kept under control by the body's immune system and in these persons

therefore lymphoma cells appear only after another characteristic mutation t(8;14) activates growth promoting *MYC* oncogene.

HUMAN HERPESVIRUS 8 (HHV-8) It has been shown that infection with HHV-8 or Kaposi's sarcoma-associated herpesvirus (KSHV) is associated with Kaposi's sarcoma, a vascular neoplasm common in patients of AIDS. Compared to sporadic Kaposi's sarcoma, the AIDS-associated tumour is multicentric and more aggressive. HHV-8 has lymphotropism and is also implicated in causation of pleural effusion lymphoma and multicentric variant of Castleman's disease.

HHV-8 (KSHV) ONCOGENESIS IN HUMAN CANCER—

- i) Viral DNA is seen in nuclei of all tumour cells in Kaposi's sarcoma.
- ii) There is overexpression of several KSHV oncoproteins by latently infected cells: v-cyclin, v-interferon regulatory factor (v-IRF) and *LANA* (latency-associated nuclear antigen).
- iii) These viral proteins cause increased proliferation and survival of host cells and thus induce malignancy.

3. ADENOVIRUSES The human adenoviruses cause upper respiratory infections and pharyngitis.

- ◆ *In humans*, they are not known to be involved in any tumour.
- ◆ *In hamsters*, they may induce sarcomas.

4. POXVIRUSES This group of oncogenic viruses is involved in the etiology of following lesions:

- ◆ *In rabbits*—poxviruses cause myxomatosis.
- ◆ *In humans*—poxviruses cause molluscum contagiosum and may induce squamous cell papilloma.

5. HEPADNAVIRUSES *Hepatitis B virus (HBV)* is a member of hepadnavirus (*hepa-* from hepatitis, *-dna* from DNA) family. HBV infection in man causes an acute hepatitis and is responsible for a carrier state, which can result in some cases to chronic hepatitis progressing to hepatic cirrhosis, and onto hepatocellular carcinoma. These lesions and the structure of HBV are described in detail in Chapter 19. Suffice this to say here that there is strong epidemiological evidence linking HBV infection to development of hepatocellular carcinoma as evidenced by the following:

- a) The geographic differences in the incidence of hepatocellular carcinoma closely match the variation in prevalence of HBV infection e.g. high incidence in Far-East and Africa.
- b) Epidemiological studies in high incidence regions indicate about 200 times higher risk of developing hepatocellular carcinoma in HBV-infected cases as compared to uninfected population in the same area.

Possible mechanism of hepatocellular carcinoma occurring in those harbouring long-standing infection with HBV is chronic destruction of HBV-infected hepatocytes followed by continued hepatocyte proliferation. This process renders the hepatocytes vulnerable to the action of other risk factors such as aflatoxin causing mutation and neoplastic proliferation.

Evidence has linked an oncogenic role to another hepatotropic virus, hepatitis C virus (HCV) as well which is an RNA virus, while HBV is a DNA virus. HCV is implicated in about half the cases of hepatocellular carcinoma in much the same way as HBV.

HEPATITIS VIRUS ONCOGENESIS IN HUMAN CANCER—

Epidemiologic data firmly support that two hepatotropic viruses, HBV—a DNA virus, and HCV—an RNA virus, are currently involved in causation of 70-80% cases of hepatocellular carcinoma worldwide. Although HBV DNA has been found integrated in the genome of human hepatocytes in many cases of liver cancer which causes mutational changes but a definite pattern is lacking. Thus, exact molecular mechanism as to how HBV and HCV cause hepatocellular carcinoma is yet not quite clear. Probably, multiple factors are involved:

- i) Chronic and persistent viral infection with HBV or HCV incites repetitive cycles of inflammation, immune response, cell degeneration/cell death, and regeneration of the hepatocytes which leads to DNA damage of host liver cells.
- ii) It is possible that immune response by the host to persistent unresolved infection with these hepatitis viruses becomes defective which promotes tumour development.
- iii) On regeneration, proliferation of hepatocytes is stimulated by several growth factors and cytokines elaborated by activated immune cells which contribute to tumour development e.g. factors for angiogenesis, cell survival etc.
- iv) Activated immune cells produce nuclear factor κ B (NF- κ B) that inhibits apoptosis, thus allowing cell survival and growth.
- v) HBV genome contains a gene HBx which activates growth signaling pathway.
- vi) HBV and HCV do not encode for any specific viral oncoproteins.

RNA Oncogenic Viruses

RNA oncogenic viruses are retroviruses i.e. they contain the enzyme reverse transcriptase (RT), though all retroviruses are not oncogenic (**Table 7.10**). The enzyme, reverse transcriptase, is required for reverse transcription of viral RNA to synthesise viral DNA strands i.e. reverse of normal—rather than DNA encoding for RNA synthesis, viral RNA transcripts for the DNA by the enzyme RT present in the RNA viruses. RT is a DNA polymerase and helps to form complementary DNA (cDNA) that moves into host cell nucleus and gets incorporated into it.

Based on their activity to transform target cells into neoplastic cells, RNA viruses are divided into 3 subgroups—acute transforming viruses, slow transforming viruses, and human T-cell lymphotropic viruses (HTLV). The former two are implicated in inducing a variety of tumours in animals only while HTLV is causative for human T-cell leukaemia and lymphoma.

1. ACUTE TRANSFORMING VIRUSES This group includes retroviruses which transform all the cells infected by them into malignant cells rapidly ('acute'). All the viruses in this group possess one or more viral oncogenes (*v-oncs*). All the members of acute transforming viruses discovered so far are defective viruses in which the particular *v-onc* has substituted other essential genetic material such as *gag*, *pol* and *env*. These defective viruses cannot replicate by themselves unless the host cell is infected by another 'helper virus.' Acute oncogenic viruses have been identified in tumours in different animals only e.g.

- a) Rous sarcoma virus in chickens.
- b) Leukaemia-sarcoma viruses of various types such as avian, feline, bovine and primate.

Table 7.10 RNA oncogenic viruses.

| VIRUS | HOST | ASSOCIATED TUMOUR |
|---|--------------------------------|--|
| 1. ACUTE TRANSFORMING VIRUSES | | |
| <i>Rous sarcoma virus</i> | Chickens | Sarcoma |
| <i>Leukaemia-sarcoma virus</i> | Avian, feline, bovine, primate | Leukaemias, sarcomas |
| 2. SLOW TRANSFORMING VIRUSES | | |
| | Mice, cats, bovine | Leukaemias, lymphomas |
| <i>Mouse mammary tumour virus</i> (<i>Bittner milk factor</i>) | Daughter mice | Breast cancer |
| 3. HUMAN T-CELL LYMPHOTROPIC VIRUS (HTLV) | | |
| <i>HTLV-I</i> | Human | Adult T-cell leukaemia lymphoma (ATLL) |
| <i>HTLV-II</i> | Human | T-cell variant of hairy cell leukaemia |
| 4. HEPATITIS C VIRUS | | |
| <i>HCV</i> | Human | Hepatocellular carcinoma |

2. SLOW TRANSFORMING VIRUSES These oncogenic retroviruses cause development of leukaemias and lymphomas in different species of animals (e.g. in mice, cats and bovine) and include the mouse mammary tumour virus (MMTV) that causes breast cancer in the daughter-mice suckled by the MMTV-infected mother via the causal agent in the mother's milk (*Bittner milk factor*). These viruses have long incubation period between infection and development of neoplastic transformation ('slow'). Slow transforming viruses cause neoplastic transformation by *insertional mutagenesis* i.e. viral DNA synthesised by viral RNA via reverse transcriptase is *inserted* or integrated near the protooncogenes of the host cell resulting in damage to host cell genome (*mutagenesis*) leading to neoplastic transformation.

3. HUMAN T-CELL LYMPHOTROPIC VIRUSES (HTLV) HTLV is a form of slow transforming virus but is described separately because of 2 reasons:

- i) This is the only retrovirus implicated in human cancer.
- ii) The mechanism of neoplastic transformation is different from slow transforming as well as from acute transforming viruses.

Four types of HTLVs are recognised—HTLV-1, HTLV-2, HTLV-3 and HTLV-4. It may be mentioned in passing here that the etiologic agent for AIDS, HIV, is also an HTLV (HTLV-3) as described in Chapter 3.

A link between HTLV-1 infection and cutaneous adult T-cell leukaemia-lymphoma (ATLL) has been identified while HTLV-2 is implicated in causation of T-cell variant of hairy cell leukaemia. HTLV-1 is transmitted through sexual contact, by blood, or to infants during breastfeeding. The highlights of this association and mode of neoplastic transformation are as under:

- i) Epidemiological studies by tests for antibodies have shown that HTLV-1 infection is endemic in parts of Japan and West Indies where the incidence of ATLL is high. The latent period after HTLV-1 infection is, however, very long (20-30 years).
- ii) The initiation of neoplastic process is similar to that for Burkitt's lymphoma except that HTLV-1 has tropism for CD4+T lymphocytes as in HIV infection, while EBV of Burkitt's lymphoma has tropism for B lymphocytes.
- iii) As in Burkitt's lymphoma, immunosuppression plays a supportive role in the neoplastic transformation by HTLV-1 infection.

HTLV ONCOGENESIS IN HUMAN CANCER—

The molecular mechanism of ATLL leukaemogenesis by HTLV infection of CD4+ T lymphocytes is not clear. Neoplastic transformation by HTLV-I infection differs from acute transforming viruses because it does not contain *v-onc*, and from other slow transforming viruses because it does not have fixed site of insertion for insertional mutagenesis. Probably, the process is multifactorial:

- i) HTLV-1 genome has unique region called pX distinct from other retroviruses, which encodes for two essential viral oncoproteins— *TAX* and *REX*. *TAX* protein up-regulates the expression of cellular genes controlling T-cell replication, while *REX* gene product regulates viral protein production by affecting mRNA expression.
- ii) *TAX* viral protein interacts with transcription factor, NF- κ B, which stimulates genes for cytokines (interleukins) and their receptors in infected T cells which activates proliferation of T cells by autocrine pathway.
- iii) The inappropriate gene expression activates pathway of the cell proliferation by activation of cyclins and inactivation of tumour suppressor genes *CDKN2A/p16* and *p53*, stimulating cell cycle.
- iv) Initially, proliferation of infected T cells is polyclonal but subsequently several mutations appear due to *TAX*-based genomic changes in the host cell and monoclonal proliferation of leukaemia occurs.

VIRUSES AND HUMAN CANCER: A SUMMARY

In humans, epidemiological as well as circumstantial evidence has been accumulating since the discovery of contagious nature of common human wart (papilloma) in 1907 that cancer may have viral etiology. Presently, about 20% of all human cancers worldwide are virally induced. Aside from experimental evidence, the etiologic role of DNA and RNA viruses in a variety of human neoplasms has already been explained above. Here, a summary of different viruses implicated in human tumours is presented (**Fig. 7.30**):

Benign tumours Following 2 benign conditions which are actually doubtful as tumours have a definite viral etiology:

- i) Human wart (papilloma) caused by human papilloma virus
- ii) Molluscum contagiosum caused by poxvirus

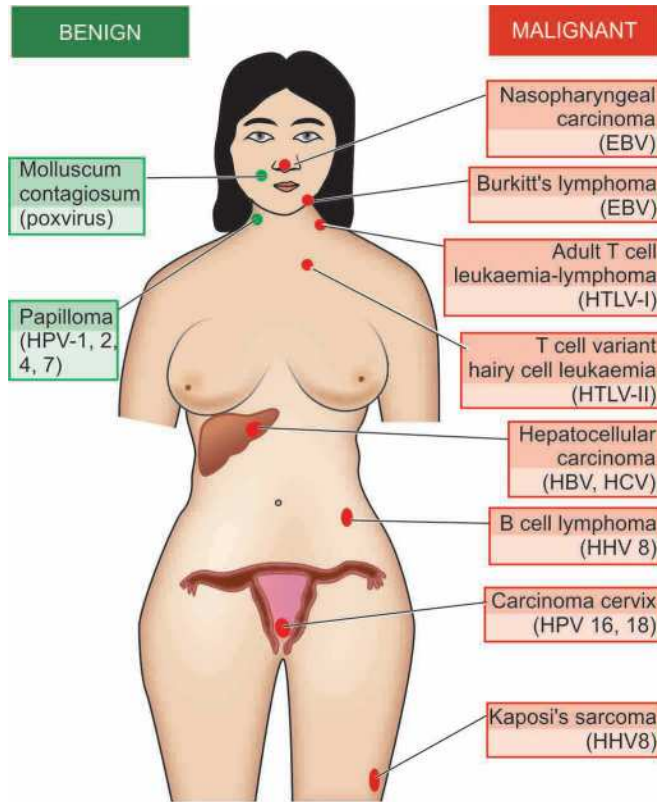

Figure 7.30 Viruses (in brackets) in human tumours.

Malignant tumours The following 8 human cancers have enough epidemiological, serological, and in some cases genomic evidence, that viruses are implicated in their etiology:

- i) *Burkitt's lymphoma* by Epstein-Barr virus.
- ii) *Nasopharyngeal carcinoma* by Epstein-Barr virus.
- iii) *Primary hepatocellular carcinoma* by hepatitis B virus and hepatitis C virus.
- iv) *Cervical cancer* by high risk human papilloma virus types (HPV 16 and 18).
- v) *Kaposi's sarcoma* by human herpes virus type 8 (HHV-8).
- vi) *Pleural effusion B cell lymphoma* by HHV8.
- vii) *Adult T-cell leukaemia and lymphoma* by HTLV-1.
- viii) *T-cell variant of hairy cell leukaemia* by HTLV-2

Current knowledge and understanding of viral carcinogenesis has provided an opportunity to invent specific vaccines and suggest appropriate specific therapy. For example, hepatitis B vaccines is being widely used to control hepatitis B and is expected to lower incidence of HBV-related hepatocellular carcinoma in high risk populations. HPV vaccine is being used in some countries in young women and is expected to protect them against HPV-associated precancerous lesions of the cervix.

GIST BOX 7.6

Carcinogens and Carcinogenesis

- Important groups of carcinogenic agents having role in carcinogenesis are chemical, physical and biologic agents.
- Chemical carcinogenesis occurs by induction of mutation in the proto-oncogenes and anti-oncogenes and goes through sequential stages of initiation, promotion and progression.
- Carcinogenic chemicals are of 2 types: direct-acting and indirect-acting.

- Direct-acting carcinogens (e.g. alkylating agents, acylating agents) can induce cellular transformation without undergoing any prior metabolic activation.
- More common are indirect-acting carcinogens (e.g. polycyclic aromatic hydrocarbons, aromatic amines, azo dyes, naturally-occurring products etc) which require metabolic conversion within the body so as to become 'ultimate' carcinogens.
- Physical agents in carcinogenesis are radiation (ultraviolet light and ionising radiation) which is more important, and some non-radiation physical agents.
- Excessive exposure to UV rays in humans can cause various forms of skin cancers while ionising radiation is implicated in several human cancers e.g. leukaemias, cancers of the thyroid, skin, breast, ovary, uterus, lung, myeloma, and salivary glands.
- Out of biologic agents (viruses, bacteria, parasites, fungi), persistence of DNA or RNA viral infection is of major significance and may induce mutation in the target host cell which is one step in the multistep process of cancer development.
- DNA oncogenic viruses with evidence in human cancers are Epstein-Barr virus (Burkitt's lymphoma and nasopharyngeal carcinoma), hepatitis B virus (hepatocellular carcinoma), human papilloma virus types HPV 16 and 18 (carcinoma cervix) and human herpes virus type 8 (Kaposi's sarcoma and pleural effusion B cell lymphoma).
- RNA viruses having oncogenic role are HTLV-1 (adult T-cell leukaemia and lymphoma), HTLV-2 (T-cell variant of hairy cell leukaemia) and hepatitis C virus (hepatocellular carcinoma).

CLINICAL ASPECTS OF NEOPLASIA

Natural biology of tumours relates to host-tumour inter-relationship that includes response of host against tumour and the effect of tumour on host. Another clinically significant aspect discussed here is the final diagnosis of tumours.

HOST RESPONSE AGAINST TUMOUR (TUMOUR IMMUNOLOGY)

It has long been known that body's immune system can recognise tumour cells as 'non-self' and they attempt to destroy them and limit the spread of cancer. The following observations provide basis for this concept:

1. Certain cancers evoke significant *lymphocytic infiltrate* composed of immunocompetent cells and such tumours have somewhat better prognosis e.g. medullary carcinoma breast (as compared with infiltrating ductal carcinoma), seminoma testis (as compared with other germ cell tumours of testis).
2. Rarely, a cancer may *spontaneously regress* partially or completely, probably under the influence of host defense mechanism. For example, rare spontaneous disappearance of malignant melanoma temporarily from the primary site which may then reappear as metastasis.
3. It is highly unusual to have primary and *secondary tumours in the spleen* due to its ability to destroy the growth and proliferation of tumour cells.
4. Existence of immune surveillance is substantiated by increased frequency of *cancers in immunodeficient host*

e.g. in AIDS patients, or development of post-transplant lymphoproliferative disease.

In an attempt to support the above observations and to understand the underlying host defense mechanisms, experimental animal studies involving tumour transplants were carried out. The findings of animal experiments coupled with research on human cancers has led to the concept of immunology of cancer which is discussed under the following headings:

1. Tumour antigens
2. Antitumour immune responses
3. Immunotherapy.

1. TUMOUR ANTIGENS

Tumour cells express surface antigens which have been seen in animals and in some human tumours. Older classification of tumour antigens was based on their surface sharing characteristics on normal versus tumour cells and on their recognition by cytotoxic T lymphocytes CTL (CD8+T cells) on the basis of class I MHC molecules. Accordingly, tumour antigens were categorised into following two types:

i) *Tumour-specific antigens (TSAs)* located on tumour cells and are unique or specific antigens for particular tumour and not shared by normal cells.

ii) *Tumour associated antigens (TAAs)* are present on tumour cells as well as on some normal cells from where the tumour originated.

However, it is now known that TSAs and TAAs can both be present on normal cells and categorisation into TSA and TAA does not hold true. Thus, presently distinction of tumour antigens is based on their recognition by the host immune cells, i.e. CD8+ T cells (CTL), and by the molecular structure of the tumour antigens. Currently, various groups of tumour antigens are as follows:

i) Oncoproteins from mutated oncogenes Protein products derived from mutated oncogenes result in expression of cell surface antigens on tumour cells. The examples include products of *RAS*, *BCL/RABL* and *CDK4*.

ii) Protein products of tumour suppressor genes In some tumours, protein products of mutated tumour suppressor genes cause expression of tumour antigens on the cell surface. The examples are mutated proteins *p53* and β -catenin.

iii) Overexpressed cellular proteins Some tumours are associated with a normal cellular protein but is excessively expressed in tumour cells and incite host immune response. For example, in melanoma the tumour antigen is structurally normal melanocyte specific protein, tyrosinase, which is overexpressed compared with normal cells. Similarly, *HER2/neu* protein is overexpressed in many cases of breast cancer.

iv) Abnormally expressed cellular proteins Sometimes, a cellular protein is present in some normal cells but is abnormally expressed on the surface of tumour cells of some cancers. The classic example is presence of *MAGE* gene silent in normal adult tissues except in male germ line but *MAGE* genes are expressed on surface of many tumours such as melanoma (abbreviation *MAGE* from 'melanoma antigen' in which it was first found), cancers of liver, lung, stomach and oesophagus. Other examples of similar aberrantly expressed gene products in cancers are *GAGE* (G antigen), *BAGE* (B melanoma antigen) and *RAGE* (renal tumour antigen).

v) Tumour antigens from viral oncoproteins As already discussed above, many oncogenic viruses express viral oncoproteins which result in expression of antigens on tumour cells e.g. viral oncoproteins of HPV (E6, E7) in cervical cancer and EBNA proteins of EBV in Burkitt's lymphoma.

vi) Tumour antigens from randomly mutated genes Various other carcinogens such as chemicals and radiation induce random mutations in the target cells. These mutated cells elaborate protein products targeted by the CTL of the immune system causing expression of tumour antigens.

vii) Cell specific differentiation antigens Normally differentiated cells have cellular antigens which forms the basis of diagnostic immunohistochemistry. Cancers have varying degree of loss of differentiation but particular lineage of the tumour cells can be identified by tumour antigens. For example, various CD markers for various subtypes of lymphomas, prostate specific antigen (PSA) in carcinoma of prostate.

viii) Oncofoetal antigens Oncofoetal antigens such as α -foetoprotein (AFP) and carcinoembryonic antigen (CEA) are normally expressed in embryonic life. But these antigens appear in certain cancers—AFP in liver cancer and CEA in colon cancer which can be detected in serum as cancer markers.

ix) Abnormal cell surface molecules The normal cell expresses surface molecules of glycolipids, glycoproteins, mucins and blood group antigens. In some cancers, there is abnormally changed expression of these molecules. For example, there may be changed blood group antigen, or abnormal expression of mucin in ovarian cancer (CA-125) and in breast cancer (MUC-1).

2. ANTI-TUMOUR IMMUNE RESPONSES

Although both cell-mediated and humoral immunity is mounted by the host against the tumour, significant anti-tumour effector mechanism is mainly cell-mediated. However, despite the existence of immune mechanisms, most of the cancers outsmart these host defenses and gain an upper hand in their battle against the host due to failed immune regulatory mechanisms.

i) Cell-mediated mechanism This is the main mechanism of destruction of tumour cells by the host. The following cellular responses can destroy the tumour cells and induce tumour immunity in humans:

a) *Specifically sensitised cytotoxic T lymphocytes (CTL)* i.e. CD8+ T cells are directly cytotoxic to the target cell and require contact between them and tumour cells. CTL have been found to be effective against virally-induced cancers e.g. in Burkitt's lymphoma (EBV-induced), invasive squamous cell carcinoma of cervix (HPV-induced).

b) *Natural killer (NK) cells* are lymphocytes which after activation by IL-2, destroy tumour cells without sensitisation, either directly or by antibody-dependent cellular cytotoxicity (ADCC). NK cells together with T lymphocytes are the first line of defense against tumour cells and can lyse tumour cells.

c) *Macrophages* are activated by interferon- γ secreted by T-cells and NK-cells, and therefore there is close collaboration of these two subpopulation of lymphocytes and macrophages. Activated macrophages mediate cytotoxicity by production of oxygen free radicals or by tumour necrosis factor.

ii) Humoral mechanism As such there are no anti-tumour humoral antibodies which are effective against cancer cells

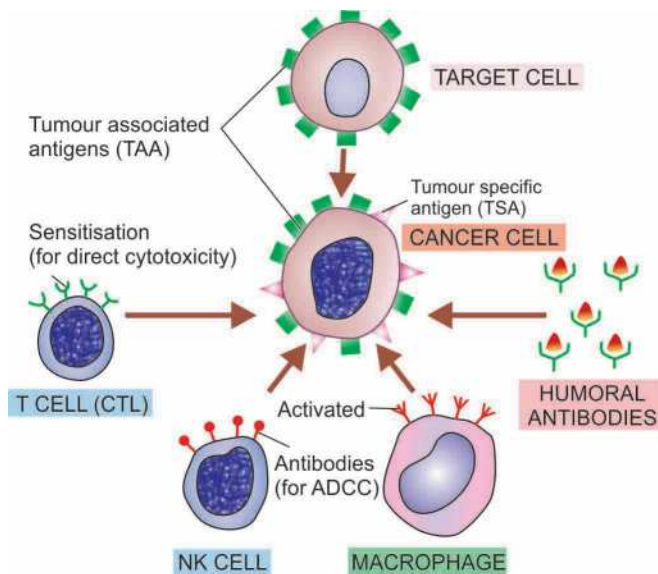

Figure 7.31 Schematic illustration of immune responses in cancer. For details see the text (CTL = cytotoxic T-lymphocyte; NK cell = natural killer cell; ADCC = antibody-dependent cellular cytotoxicity).

in vivo. However, *in vitro* humoral antibodies may kill tumour cells by complement activation or by antibody-dependent cytotoxicity. Based on this, monoclonal antibody treatment is offered to cases of some types of non-Hodgkin's lymphoma.

iii) Immune regulatory mechanisms Most cancers grow relentlessly in spite of host immunity. This is explained due to deranged controlling mechanisms of immunity as under:

- During progression of the cancer, immunogenic cells may disappear.
- Cytotoxic T-cells and NK-cells may play a self-regulatory role.
- Immunosuppression mediated by various acquired carcinogenic agents (viruses, chemicals, radiation).
- Immunosuppressive role of factors secreted by tumour cells e.g. transforming growth factor- β .
- The tumour cells arise from own cells and hence the immune system fails to recognise them as "foreign" which creates a phenomenon of tumour tolerance.

The mechanisms of these immune responses are schematically illustrated in **Fig. 7.31**.

3. CANCER IMMUNOTHERAPY

It is a generally-accepted hypothesis that the best defense against human diseases is our own immune system. As outlined above, in cancer the immune system starts failing and requires to be boosted to become more effective in fighting against cancer. While there is no magic bullet against cancer, immunotherapy has been used as treatment against cancer in combination with other therapies (surgery, radiation, chemotherapy).

i) Non-specific stimulation of the host immune response was initially attempted with BCG, *Corynebacterium parvum* and levamisole, but except slight effect in acute lymphoid leukaemia, it failed to have any significant influence in any other tumour.

ii) Specific stimulation of the immune system was attempted next by immunising the host with irradiated tumour cells but

failed to yield desired results because if the patient's tumour within the body failed to stimulate effective immunity, the implanted cells of the same tumour are unlikely to do so.

iii) Current status of immunotherapy is focussed on following three main approaches:

a) **Cellular immunotherapy** consists of infusion of tumour-specific cytotoxic T cells which will increase the population of tumour-infiltrating lymphocytes (TIL). The patient's peripheral blood lymphocytes are cultured with interleukin-2 which generates lymphokine-activated killer cells having potent anti-tumour effect.

b) **Cytokine therapy** is used to build up specific and non-specific host defenses. These include: interleukin-2, interferon- α and - γ , tumour necrosis factor- α , and granulocyte-monocyte colony stimulating factor (GM-CSF).

c) **Monoclonal antibody therapy** is undergoing trial against CD20 molecule of B cells in certain B cell leukaemias and lymphomas.

EFFECT OF TUMOUR ON HOST

Malignant tumours produce more ill-effects than the benign tumours. The effects may be local, or generalised and more widespread.

A. LOCAL EFFECTS

Both benign and malignant tumours cause local effects on the host due to their size or location. Malignant tumours due to rapid and invasive growth potential have more serious effects. Some of the local effects of tumours are as under:

i) Compression Many benign tumours pose only a cosmetic problem. Some benign tumours, however, due to their critical location, have more serious consequences e.g. pituitary adenoma may lead to serious endocrinopathy; a small benign tumour in ampulla of Vater may lead to biliary obstruction.

ii) Mechanical obstruction Benign and malignant tumours in the gut may produce intestinal obstruction.

iii) Tissue destruction Malignant tumours, both primary and metastatic, infiltrate and destroy the vital structures.

iv) Infarction, ulceration, haemorrhage Cancers have a greater tendency to undergo infarction, surface ulceration and haemorrhage than the benign tumours. Secondary bacterial infection may supervene. Large tumours in mobile organs (e.g. an ovarian tumour) may undergo torsion and produce infarction and haemorrhage.

B. SYSTEMIC MANIFESTATIONS

Generalised effects of cancer include cancer cachexia, fever, tumour lysis syndrome and paraneoplastic syndromes.

1. CANCER CACHEXIA Patients with advanced and disseminated cancers terminally have asthenia (emaciation), and anorexia, together referred to as cancer cachexia (meaning wasting). Exact mechanism of cachexia is not clear but it does not occur due to increased nutritional demands of the tumour. Certain cytokines such as tumour necrosis factor α (TNF- α), interleukin-1 and interferon- γ play a contributory role in cachexia. Various other causes of cancer cachexia include necrosis, ulceration, haemorrhage, infection, malabsorption, anxiety, pain, insomnia, hypermetabolism and pyrexia.

Table 7.11 Summary of paraneoplastic syndromes.

| CLINICAL SYNDROME | UNDERLYING CANCER | MECHANISM |
|--|---|---|
| 1. ENDOCRINE SYNDROME | | |
| <i>i. Hypercalcaemia</i> | Lung (sq. cell Ca), kidney, breast, Adult T-cell leukaemia-lymphoma | Parathormone-like protein Vitamin D |
| <i>ii. Cushing's syndrome</i> | Lung (small cell carcinoma), pancreas, neural tumours | ACTH or ACTH-like substance |
| <i>iii. Inappropriate anti-diuresis</i> | Lung (small cell Ca), prostate, intracranial tumour | ADH or atrial natriuretic factor |
| <i>iv. Hypoglycaemia</i> | Pancreas (islet cell tumour), mesothelioma, fibrosarcoma | Insulin or insulin-like substance |
| <i>v. Carcinoid syndrome</i> | Bronchial carcinoid tumour, carcinoma pancreas, stomach | Serotonin, bradykinin |
| <i>vi. Polycythaemia</i> | Kidney, liver, cerebellar haemangioma | Erythropoietin |
| 2. NEUROMUSCULAR SYNDROMES | | |
| <i>i. Myasthenia gravis</i> | Thymoma | Immunologic |
| <i>ii. Neuromuscular disorders</i> | Lung (small cell Ca), breast | Immunologic |
| 3. OSSEOUS, JOINT AND SOFT TISSUE | | |
| <i>i. Hypertrophic osteoarthropathy</i> | Lung | Not known |
| <i>ii. Clubbing of fingers</i> | Lung | Not known |
| 4. HAEMATOLOGIC SYNDROMES | | |
| <i>i. Thrombophlebitis (Trousseau's phenomenon)</i> | Pancreas, lung, GIT | Hypercoagulability |
| <i>ii. Non-bacterial thrombotic endocarditis</i> | Advanced cancers | Hypercoagulability |
| <i>iii. Disseminated intravascular coagulation (DIC)</i> | AML, adenocarcinoma | Chronic thrombotic phenomena |
| <i>iv. Anaemia</i> | Thymoma | Unknown |
| 5. GASTROINTESTINAL SYNDROMES | | |
| <i>i. Malabsorption</i> | Lymphoma of small bowel | Hypoalbuminaemia |
| 6. RENAL SYNDROMES | | |
| <i>i. Nephrotic syndrome</i> | Advanced cancers | Renal vein thrombosis, systemic amyloidosis |
| 7. CUTANEOUS SYNDROMES | | |
| <i>i. Acanthosis nigricans</i> | Stomach, large bowel | Immunologic |
| <i>ii. Seborrheic dermatitis</i> | Bowel | Immunologic |
| <i>iii. Exfoliative dermatitis</i> | Lymphoma | Immunologic |
| 8. AMYLOIDOSIS | | |
| <i>i. Primary</i> | Multiple myeloma | Immunologic (AL protein) |
| <i>ii. Secondary</i> | Kidney, lymphoma, solid tumours | AA protein |

2. FEVER Fever of unexplained origin may be presenting feature in some malignancies such as in Hodgkin's disease, adenocarcinoma kidney, osteogenic sarcoma and many other tumours. The exact mechanism of tumour-associated fever is not known but probably the tumour cells themselves elaborate pyrogens.

3. TUMOUR LYSIS SYNDROME This is a condition caused by extensive destruction of a large number of rapidly proliferating tumour cells. The condition is seen more often in cases of lymphomas and leukaemias than solid tumours and may be due to large tumour burden (e.g. in Burkitt's lymphoma), chemotherapy, administration of glucocorticoids or certain hormonal agents (e.g. tamoxifen). It is characterised by hyperuricaemia, hyperkalaemia, hyperphosphataemia and

hypocalcaemia, all of which may result in acidosis and renal failure.

4. PARANEOPLASTIC SYNDROMES Paraneoplastic syndromes (PNS) are a group of conditions developing in patients with advanced cancer which are neither explained by direct and distant spread of the tumour, nor by the usual hormone elaboration by the tissue of origin of the tumour. About 10 to 15% of the patients with advanced cancer develop one or more of the syndromes included in the PNS. Rarely, PNS may be the earliest manifestation of a latent cancer.

The various clinical syndromes included in the PNS are as summarised in **Table 7.11** and are briefly outlined here:

i) Endocrine syndrome Elaboration of hormones or hormone-like substances by cancer cells of non-endocrine

origin is called as ectopic hormone production. Some examples are given below:

a) **Hypercalcaemia** Symptomatic hypercalcaemia unrelated to hyperparathyroidism is the most common syndrome in PNS. It occurs from elaboration of parathormone-like substance by tumours such as squamous cell carcinoma of the lung, carcinoma kidney, breast and adult T cell leukaemia lymphoma.

b) **Cushing's syndrome** About 10% patients of small cell carcinoma of the lung elaborate ACTH or ACTH-like substance producing Cushing's syndrome. In addition, cases with pancreatic carcinoma and neurogenic tumours may be associated with Cushing's syndrome.

c) **Polycythaemia** Secretion of erythropoietin by certain tumours such as renal cell carcinoma, hepatocellular carcinoma and cerebellar haemangioma may cause polycythaemia.

d) **Hypoglycaemia** Elaboration of insulin-like substance by fibrosarcomas, islet cell tumours of pancreas and mesothelioma may cause hypoglycaemia.

ii) Neuromyopathic syndromes About 5% of cancers are associated with progressive destruction of neurons throughout the nervous system without evidence of metastasis in the brain and spinal cord. This is probably mediated by immunologic mechanisms. The changes in the neurons may affect the muscles as well. The changes are: peripheral neuropathy, cortical cerebellar degeneration, myasthenia gravis syndrome, polymyositis.

iii) Effects on osseous, joints and soft tissue e.g. hypertrophic pulmonary osteoarthropathy and clubbing of fingers in cases of bronchogenic carcinoma, by unknown mechanism but is probably due to increased blood flow to the limb.

iv) Haematologic and vascular syndrome e.g. venous thrombosis (Trousseau's phenomenon), non-bacterial thrombotic endocarditis, disseminated intravascular coagulation (DIC), leukemoid reaction and normocytic normochromic anaemia occurring in advanced cancers. Auto-immune haemolytic anaemia may be associated with B-cell malignancies.

v) Gastrointestinal syndromes Malabsorption of various dietary components as well as hypoalbuminaemia may be associated with a variety of cancers which do not directly involve small bowel.

vi) Renal syndromes Renal vein thrombosis or systemic amyloidosis may produce nephrotic syndrome in patients with cancer.

vii) Cutaneous syndromes Acanthosis nigricans characterised by the appearance of black warty lesions in the axillae and the groins may appear in the course of adenocarcinoma of gastrointestinal tract. Other cutaneous lesions in PNS include seborrheic dermatitis in advanced malignant tumours and exfoliative dermatitis in lymphomas and Hodgkin's disease.

viii) Amyloidosis Primary amyloid deposits may occur in multiple myeloma whereas renal cell carcinoma and other solid tumours may be associated with secondary systemic amyloidosis.

GIST BOX 7.7

Tumour-Host Interrelationship

- The natural history of a neoplasm depends upon host response against tumour (or cancer immunology) and effect of tumour on host.

- The existence of host immune defense is supported by the observation of lymphocytic infiltrate in certain tumours with good prognosis, spontaneous regression of some tumours due to host immune attack and increased incidence of tumours in immunodeficient host.
- Tumour cells express a variety of antigens which include: protein products from mutated oncogenes and antioncogenes, overexpression and abnormal expression of normal cellular proteins, virally derived oncoproteins, cell surface differentiation antigens, oncofoetal antigens and abnormal cell surface molecules.
- Significant immune response by the host is by cell-mediated immunity exerted by specifically sensitised cytotoxic T cells, natural killer cells and activated macrophages, and to a lesser extent by anti-tumour humoral antibodies.
- Malignant tumours produce more ill-effects on the host than the benign tumours and these may be local, or generalised and more widespread.
- Local effects of the tumour depend upon the site. These effects are due to mechanical compression, obstruction, tissue destruction and infarction, ulceration and haemorrhage.
- Systemic effects are in the form of cancer cachexia, fever, tumour lysis syndrome, and paraneoplastic syndrome.
- Paraneoplastic syndrome has several presentations with widespread manifestations. Some of the important features are due to ectopic hormone elaboration, and neuromuscular, osseous, haematologic, gastrointestinal cutaneous and renal manifestations.

PATHOLOGIC DIAGNOSIS OF CANCER

When the diagnosis of cancer is suspected on clinical examination and on other investigations, it must be confirmed. The most certain and reliable method which has stood the test of time is the histological examination of biopsy, though recently many other methods to arrive at the correct diagnosis or confirm the histological diagnosis are available.

1. HISTOLOGICAL METHODS

These methods are most valuable in arriving at the accurate diagnosis and are based on microscopic examination of excised tumour mass or open/needle biopsy from the mass supported with complete clinical and investigative data. The tissue must be fixed in 10% formalin for light microscopic examination and in glutaraldehyde for electron microscopic studies, while quick-frozen section and hormonal analysis are carried out on fresh unfixed tissues. These methods are as under:

i) Paraffin-embedding technique In this, 10% formalin-fixed tissue is used. The representative tissue piece from larger tumour mass or biopsy is processed through a tissue processor having an overnight cycle, embedded in molten paraffin wax for making tissue blocks. These blocks are trimmed followed by fine-sectioning into 3-4 μm sections using rotary microtome for which either fixed knife or disposable blades are used for cutting. These sections are then stained with haematoxylin and eosin (H & E) and examined microscopically.

ii) Frozen section In this technique, unfixed tissue is used and the procedure is generally carried out when the patient is undergoing surgery and is still under anaesthesia. Here, instead of tissue processor and paraffin-embedding, cryostat machine is used and fresh unfixed tissue is used. The tissue biopsy is quickly frozen to ice at about -25°C that acts as embedding medium and then sectioned. Sections are then ready for rapid H & E or toluidine blue staining. Frozen section is a rapid intraoperative diagnostic procedure for tissues before proceeding to a major radical surgery or may be used to know the extent of presence of cancer at the surgical margin.

The histological diagnosis by either of these methods is made on the basis that morphological features of *benign tumours* resemble those of normal tissue and that they are unable to invade and metastasise, while *malignant tumours* are identified by lack of differentiation in cancer cells termed 'anaplasia' or 'cellular atypia' and may invade as well as metastasise. The light microscopic and ultrastructural characteristics of neoplastic cell have been described in earlier part of this chapter.

2. CYTOLOGICAL METHODS

Cytological methods for diagnosis consist of 2 types of methods: study of cells shed off into body cavities (exfoliative cytology) and study of cells by putting a fine needle introduced under vacuum into the lesion (fine needle aspiration cytology, FNAC).

i) Exfoliative cytology Cytologic smear (Papanicolaou or Pap smear) method was initially employed for detecting dysplasia, carcinoma *in situ* and invasive carcinoma of the uterine cervix. However, its use has now been widely extended to include examination of sputum and bronchial washings; pleural, peritoneal and pericardial effusions; urine, gastric secretions, and CSF. The method is based on microscopic identification of the characteristics of malignant cells which are incohesive and loose and are thus shed off or 'exfoliated' into the lumen. However, a 'negative diagnosis' does not altogether rule out malignancy due to possibility of sampling error.

ii) Fine needle aspiration cytology (FNAC) Currently, cytopathology includes not only study of exfoliated cells but also materials obtained from superficial and deep-seated lesions in the body which do not shed off cells freely. The latter method consists of study of cells obtained by a fine needle introduced under vacuum into the lesion, so called *fine needle aspiration cytology (FNAC)*. The superficial masses can be aspirated under direct vision while deep-seated masses such as intra-abdominal, pelvic organs and retroperitoneum are frequently investigated by ultrasound (US)-or computed tomography (CT)-guided fine needle aspirations. The smears are fixed in 95% ethanol by wet fixation, or may be air-dried unfixed. While Papanicolaou method of staining is routinely employed in most laboratories for *wet fixed smears*, others prefer H and E due to similarity in staining characteristics in the sections obtained by paraffin-embedding. *Air-dried smears* are stained by May-Grünwald-Giemsa or Leishman stain. FNAC has a diagnostic reliability between 80-97% but it must not be substituted for clinical judgement or compete with an indicated histopathologic biopsy.

These methods are discussed in detail in Appendix I.

Table 7.12 Common histochemical/cytochemical stains in tumour diagnosis.

| SUBSTANCE | STAIN |
|--|---|
| 1. Basement membrane/ collagen | Periodic acid-Schiff (PAS) Reticulin Van Gieson Masson's trichrome |
| 2. Glycogen | PAS with diastase loss |
| 3. Glycoproteins, glycolipids, glycomucins (epithelial origin) | PAS with diastase persistence |
| 4. Acid mucin (mesenchymal origin) | Alcian blue |
| 5. Mucin (in general) | Combined Alcian blue-PAS |
| 6. Argyrophilic/ argentaffin granules | Silver stains |
| 7. Cross striations | PTAH stain |
| 8. Enzymes | Myeloperoxidase Acid phosphatase Alkaline phosphatase |
| 9. Nucleolar organiser regions (NORs) | Colloidal silver stain |

3. HISTOCHEMISTRY AND CYTOCHEMISTRY

Histochemistry and cytochemistry are additional diagnostic tools which help the pathologist in identifying the chemical composition of cells, their constituents and their products by special staining methods.

Though immunohistochemical techniques are more useful for tumour diagnosis (see below), histochemical and cytochemical stains (also called as special stains) are still employed for this purpose. Some of the common examples are summarised in **Table 7.12**.

4. IMMUNOHISTOCHEMISTRY

With current technology, it is possible to use routinely processed paraffin-embedded tissue blocks for immunohistochemistry (IHC), thus making profound impact on diagnostic surgical pathology. Earlier, diagnostic surgical pathology used to be considered a subjective science with inter-observer variation, particularly in borderline lesions and lesions of undetermined origin, but use of IHC has added *objectivity, specificity* and *reproducibility* to the surgical pathologist's diagnosis.

IHC is an immunological method of recognising a cell by one or more of its specific components in the cell membrane, cytoplasm or nucleus and are accordingly interpreted (**Fig. 7.32**). These cell components (called antigens) combine with specific antibodies on the formalin-fixed paraffin sections or cytological smears. The complex of antigen-antibody on slide is made visible for light microscopic identification by either fluorescent dyes ('fluorochromes') or by enzyme system ('chromogens'). The specific antibody against a particular cellular antigen is obtained by hybridoma technique for monoclonal antibody production. These monoclonal antibodies, besides being *specific* against antigen, are highly sensitive in detection of antigenic component, and, therefore,

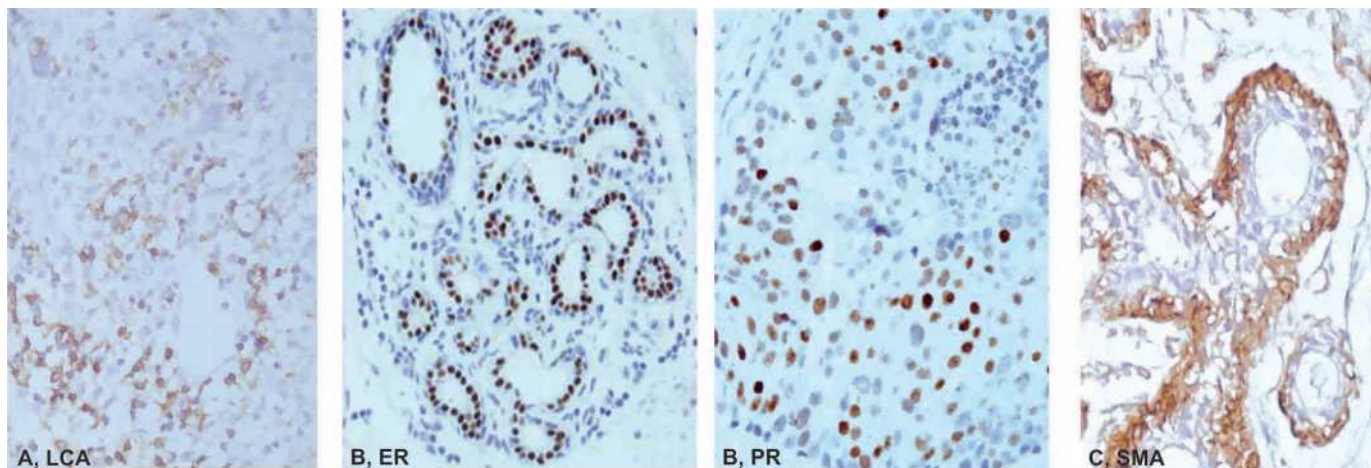

Figure 7.32 Examples of IHC staining at different sites in the tumour cells. A, Membranous staining for leucocyte common antigen (LCA) or CD45 in lymphomas. B, Cytoplasmic staining for smooth muscle actin (SMA) in myoepithelium on breast acinus. C, Nuclear staining for breast ER-PR receptor studies in breast cancer.

impart objectivity to the subjective tumour diagnosis made by the surgical pathologist.

Various applications of IHC in tumour diagnosis are under:

i) Tumours of uncertain histogenesis IHC has brought about a revolution in approach to diagnosis of tumours of uncertain origin, primary as well as metastatic from an unknown primary tumour. A panel of antibodies is chosen to resolve such diagnostic problem cases; the selection of antibodies being made is based on clinical history, morphologic features, and results of other relevant investigations. Towards this, IHC stains for *intermediate filaments* (keratin, vimentin, desmin, neurofilaments, and glial fibrillary acidic proteins) expressed by the tumour cells are of immense value besides other common IHC stains listed in **Table 7.13**.

ii) Prognostic markers in cancer The second important application of IHC is to predict the prognosis of tumours by detection of micrometastasis, occult metastasis, and by identification of certain features acquired, or products elaborated, or genes overexpressed, by the malignant cells to predict the biologic behaviour of the tumour. A few examples are: proto-oncogenes (e.g. HER-2/neu overexpression in carcinoma breast), tumour suppressor genes or antioncogenes (e.g. *Rb* gene, *p53*), growth factor receptors (e.g. epidermal growth factor receptor or *EGFR*), and tumour cell proliferation markers (e.g. *Ki67*, proliferation cell nuclear antigen *PCNA*).

iii) Prediction of response to therapy IHC is widely used to predict therapeutic response in two important tumours—carcinoma of the breast and prostate. Both these tumours are under the growth regulation of hormones—oestrogen and androgen, respectively. The specific receptors for these growth regulating hormones are located on respective tumour cells. Tumours expressing high level of receptor positivity would respond favourably to removal of the endogenous source of such hormones (oophorectomy in oestrogen-positive breast cancer and orchiectomy in androgen-positive prostatic carcinoma). Alternatively, hormonal therapy is administered to lower their levels: oestrogen therapy in prostatic cancer and androgen therapy in breast cancer. The results of oestrogen-receptors and progesterone-receptors in breast cancer have significant prognostic correlation, though the results of

androgen-receptor studies in prostatic cancer have limited prognostic value.

iv) Infections IHC stains can be applied to confirm infectious agent in tissues by use of specific antibodies against microbial DNA or RNA e.g. detection of viruses (HBV, CMV, HPV, herpesviruses), bacteria (e.g. *Helicobacter pylori*), and parasites (*Pneumocystis carinii*) etc.

Table 7.13 Common panel of immunohistochemical stains for tumours of uncertain origin.

| TUMOUR | IMMUNOSTAIN |
|---|---|
| 1. <i>Epithelial tumours (Carcinomas)</i> | i) Pankeratin (fractions: high and low molecular weight keratins, HMW-K, LMW-K) ii) Epithelial membrane antigen (EMA) iii) Carcinoembryonic antigen (CEA) iv) Neuron-specific enolase (NSE) |
| 2. <i>Mesenchymal tumours (Sarcomas)</i> | i) Vimentin (general mesenchymal) ii) Desmin (for general myogenic) iii) Muscle specific actin (for general myogenic) iv) Myoglobin (for skeletal myogenic) v) α -1-anti-chymotrypsin (for malignant fibrous histiocytoma) vi) Factor VIII (for vascular tumours) vii) CD34 (endothelial marker) |
| 3. <i>Special groups</i> | |
| a) Melanoma | i) HMB-45 (most specific) ii) Vimentin iii) S-100 |
| b) Lymphoma | i) Leucocyte common antigen (LCA/CD45) ii) Pan-B (Immunoglobulins, CD20) iii) Pan-T (CD3) iv) CD15, CD30 (RS cell marker for Hodgkin's) |
| c) Neural and neuro-endocrine tumours | i) Neurofilaments (NF) ii) NSE iii) GFAP (for glial tumours) iv) Chromogranin (for neuroendocrine) |

5. ELECTRON MICROSCOPY

Ultrastructural examination of tumour cells offers selective role in diagnostic pathology. EM examination may be helpful in confirming or substantiating a tumour diagnosis arrived at by light microscopy and immunohistochemistry. A few general features of malignant tumour cells by EM examination can be appreciated:

- i) Cell junctions, their presence and type.
- ii) Cell surface, e.g. presence of microvilli.
- iii) Cell shape and cytoplasmic extensions.
- iv) Shape of the nucleus and features of nuclear membrane.
- v) Nucleoli, their size and density.
- vi) Cytoplasmic organelles—their number is generally reduced.
- vii) Dense bodies in the cytoplasm.
- viii) Any other secretory product in the cytoplasm e.g. melanosomes in melanoma and membrane-bound granules in endocrine tumours.

6. TUMOUR MARKERS (BIOCHEMICAL ASSAYS)

In order to distinguish from the preceding techniques of tumour diagnosis in which 'stains' are imparted on the tumour cells in section or smear, tumour markers are biochemical assays of products elaborated by the tumour cells in blood or other body fluids. It is, therefore, pertinent to keep in mind that many of these products are produced by normal body cells too, and thus the biochemical estimation of the product in blood or other fluid reflects the total substance and not by the tumour cells alone. These methods, therefore, lack sensitivity as well as specificity and can only be employed for the following:

- ◆ *Firstly*, as an adjunct to the pathologic diagnosis arrived at by other methods and not for primary diagnosis of cancer.
- ◆ *Secondly*, it can be used for prognostic and therapeutic purposes.

Tumour markers include: cell surface antigens (or onco-fetal antigens), cytoplasmic proteins, enzymes, hormones

and cancer antigens; these are listed in **Table 7.14**. However, two of the best known examples of oncofetal antigens secreted by foetal tissues as well as by tumours are alpha-foetoproteins (AFP) and carcinoembryonic antigens (CEA):

i) Alpha-foetoprotein (AFP) This is a glycoprotein synthesised normally by foetal liver cells. Their serum levels are elevated in hepatocellular carcinoma and non-seminomatous germ cell tumours of the testis. Certain non-neoplastic conditions also have increased serum levels of AFP e.g. in hepatitis, cirrhosis, toxic liver injury and pregnancy.

ii) Carcino-embryonic antigen (CEA) CEA is also a glycoprotein normally synthesised in embryonic tissue of the gut, pancreas and liver. Their serum levels are high in cancers of the gastrointestinal tract, pancreas and breast. As in AFP, CEA levels are also elevated in certain non-neoplastic conditions e.g. in ulcerative colitis, Crohn's disease, hepatitis and chronic bronchitis.

7. OTHER MODERN AIDS IN PATHOLOGIC DIAGNOSIS OF TUMOURS

In addition to the methods described above, some other modern diagnostic techniques have emerged for tumour diagnostic pathology but their availability as well as applicability are limited. Briefly, their role in tumour diagnosis is outlined below.

i) Flow cytometry This is a computerised technique by which the detailed characteristics of individual tumour cells are recognised and quantified and the data can be stored for subsequent comparison too. Since for flow cytometry, single cell suspensions are required to 'flow' through the 'cytometer', it can be employed on blood cells and their precursors in bone marrow aspirates and body fluids, and sometimes on fresh-frozen unfixed tissue. The method employs either identification of cell surface antigen (e.g. in classification of leukaemias and lymphomas), or by the DNA content analysis (e.g. aneuploidy in various cancers).

Table 7.14 Important tumour markers.

| MARKER | CANCER |
|--|--|
| 1. ONCOFOETAL ANTIGENS | |
| i. <i>Alpha-foetoprotein (AFP)</i> | Hepatocellular carcinoma, non-seminomatous germ cell tumours of testis |
| ii. <i>Carcinoembryonic antigen (CEA)</i> | Cancer of bowel, pancreas, breast |
| 2. Enzymes | |
| i. <i>Prostate acid phosphatase (PAP)</i> | Prostatic carcinoma |
| ii. <i>Neuron-specific enolase (NSE)</i> | Neuroblastoma, oat cell carcinoma lung |
| iii. <i>Lactic dehydrogenase (LDH)</i> | Lymphoma, Ewing's sarcoma |
| 3. HORMONES | |
| i. <i>Human chorionic gonadotropin (hCG)</i> | Trophoblastic tumours, non-seminomatous germ cell tumours of testis |
| ii. <i>Calcitonin</i> | Medullary carcinoma thyroid |
| iii. <i>Catecholamines and vanillylmandelic acid (VMA)</i> | Neuroblastoma, pheochromocytoma |
| iv. <i>Ectopic hormone production</i> | Paraneoplastic syndromes |
| 4. CANCER ASSOCIATED PROTEINS | |
| i. <i>CA-125</i> | Ovary |
| ii. <i>CA 15-3</i> | Breast |
| iii. <i>CA 19-9</i> | Colon, pancreas, breast |
| iv. <i>CD30</i> | Hodgkin's disease, anaplastic large cell lymphoma (ALCL) |
| v. <i>CD25</i> | Hairy cell leukaemia (HCL), adult T cell leukaemia lymphoma (ATLL) |
| vi. <i>Monoclonal immunoglobulins</i> | Multiple myeloma, other gammopathies |
| vii. <i>Prostate specific antigen (PSA)</i> | Prostate carcinoma |

ii) *In situ* hybridisation This is a molecular technique by which nucleic acid sequences (cellular/viral DNA and RNA) can be localised by specifically-labelled nucleic acid probe directly in the intact cell (*in situ*) rather than by DNA extraction (see below). A modification of *in situ* hybridisation technique is fluorescence *in situ* hybridisation (FISH) in which fluorescence dyes applied and is used to detect microdeletions, subtelomere deletions and to look for alterations in chromosomal numbers. *In situ* hybridisation may be used for analysis of certain human tumours by the study of oncogenes aside from its use in diagnosis of viral infection.

iii) Cell proliferation analysis Besides flow cytometry, the degree of proliferation of cells in tumours can be determined by various other methods as under:

a) *Mitotic count*. This is the oldest but still widely used method in routine diagnostic pathology work. The number of cells in mitosis are counted per high power field e.g. in categorising various types of smooth muscle tumours.

b) *Radioautography*. In this method, the proliferating cells are labelled *in vitro* with thymidine and then the tissue processed for paraffin-embedding. Thymidine-labelled cells (corresponding to S-phase) are then counted per 2000 tumour cell nuclei and expressed as thymidine-labelling index. The method is employed as prognostic marker in breast carcinoma.

c) *Microspectrophotometric analysis*. The section is stained with Feulgen reaction which imparts staining to DNA content of the cell and then DNA content is measured by microspectrophotometer. The method is tedious and has limited use.

d) *IHC proliferation markers*. The nuclear antigen specific for cell growth and division is stained by immunohistochemical method and then positive cells are counted under the microscope or by an image analyzer e.g. *Ki-67*, *MIB-1*, *PCNA*, cyclins.

e) *Nucleolar organiser region (NOR)*. Nucleolus contains ribosomal components which are formed at chromosomal regions containing DNA called NORs. NORs have affinity for silver. This property is made use in staining the section with silver (AgNOR technique). NORs appear as black intranuclear dots while the background is stained yellow-brown.

iv) Image analyzer and morphometry Image analyser is a software system in the computer attached to a microscope which is fitted with an image capture board. The system is used to perform measurement of architectural, cellular and nuclear features of tumour cells. Image analyser can be used for following purposes:

a) *Morphometric study* of tumour cells by measurement of architectural, cellular and nuclear features.

b) *Quantitative nuclear DNA ploidy* measurement.

c) Quantitative valuation of *immunohistochemical staining*.

v) Molecular diagnostic techniques The group of molecular biologic methods in the tumour diagnostic laboratory are

a variety of DNA/RNA-based molecular techniques in which the DNA/RNA are extracted (compared from *in situ* above) from the cell and then analysed. These techniques are highly sensitive, specific and rapid and have revolutionised diagnostic pathology in neoplastic as well as non-neoplastic conditions (e.g. in infectious and inherited disorders, and in identity diagnosis). Molecular diagnostic techniques include: DNA analysis by Southern blot, RNA analysis by northern blot, and polymerase chain reaction (PCR). The following techniques of molecular methods in tumour diagnosis have applications in haematologic as well as non-haematologic malignancies:

a) Analysis of molecular cytogenetic abnormalities

b) Mutational analysis

c) Antigen receptor gene rearrangement

d) Study of oncogenic viruses at molecular level.

Besides the application of these molecular techniques for diagnosis of tumour, many of the newer molecular techniques are being applied for predicting prognosis, biologic behaviour of tumour, detection of minimal residual disease and for hereditary predisposition of other family members to develop a particular cancer.

vi) DNA microarray analysis of tumours Currently, it is possible to perform molecular profiling of a tumour by use of gene chip technology which allows measurement of levels of expression of several thousand genes (up-regulation or down-regulation) simultaneously. Fluorescent labels are used to code the cDNA synthesised by trigger from mRNA. The conventional DNA probes are substituted by silicon chip which contains the entire range of genes and high resolution scanners are used for the measurement.

GIST BOX 7.8

Pathologic Diagnosis of Cancer

- ☐ Tissue diagnosis of a biopsy or excised specimen by histologic examination is of paramount importance. It includes conventional paraffin-embedding technique and a rapid intraoperative frozen section method.
- ☐ Besides routine H & E staining, paraffin-embedded sections can be stained with special stains to demonstrate some cytoplasmic constituents, or more importantly by immunohistochemical stains which may localise at the cell membrane, nucleus or the cytoplasm, and accordingly help in identification of the cell of origin of the tumour of uncertain histogenesis and also act as prognostic markers.
- ☐ Serum tumour markers are biochemical assays of certain products elaborated by cancers which may help in prognostication of the case e.g. CEA, AFP, HCG, CA-125 etc.
- ☐ Besides, a few other modern ancillary techniques which have become available in diagnostic pathology are flow cytometry, *in situ* hybridisation, image analysers, cell proliferation analysis, molecular studies (e.g. PCR) and DNA microarrays for molecular profiling of tumours.

ENVIRONMENTAL DISEASES

The subject of environmental hazards to health has assumed great significance in the modern world. In olden times, the discipline of 'tropical medicine' was of interest to the physician, largely due to contamination of air, food and water by infectious and parasitic organisms. Subsequently, the interest got focussed on 'geographic pathology' due to occurrence of certain environment-related diseases confined to geographic boundaries. Then emerged the knowledge of 'occupational diseases' caused by overexposure to a pollutant by virtue of an individual's occupation. Currently, the field of 'environmental pathology' encompasses all such diseases caused by progressive deterioration in the environment, most of which is man-made. In addition, there is the related problem of over- and undernutrition.

Some of the important factors which have led to the alarming environmental degradation are as under:

1. Population explosion
2. Urbanisation of rural and forest land to accommodate the increasing numbers
3. Accumulation of wastes
4. Unsatisfactory disposal of radioactive and electronic waste
5. Industrial effluents and automobile exhausts.

But the above atmospheric pollutants appear relatively minor compared with *voluntary intake of three pollutants*—use of tobacco, consumption of alcohol and intoxicant drugs. The WHO estimates that 80% cases of cardiovascular disease and type 2 diabetes mellitus, and 40% of all cancers are preventable through 'three pillars of prevention': avoidance of tobacco, healthy diet and physical activity. The WHO has further determined that about a quarter of global burden of diseases and 23% of all deaths are related to modifiable environmental factors. Infant mortality related to environmental factors in developing countries is 12 times higher than in the developed countries.

Attempts at prohibition of alcohol in some states in India have not been quite effective due to difficulty in implementation. Instead, prohibition has only resulted in off and on catastrophe of 'hooch tragedies' in some parts of this country due to illicit liquor consumption.

The present discussion on environmental and nutritional diseases is covered under the following groups:

1. *Environmental pollution*:
 - i. Air pollution
 - ii. Environmental chemicals
 - iii. Tobacco smoking
2. *Chemical and drug injury*:
 - i. Therapeutic (iatrogenic) drug injury
 - ii. Non-therapeutic toxic agents (e.g. alcohol, lead, carbon monoxide, drug abuse)
 - iii. Environmental chemicals

3. *Injury by physical agents*:
 - i. Thermal and electrical injury
 - ii. Injury by ionising radiation
4. *Nutritional diseases*:
 - i. Overnutrition (obesity)
 - ii. Undernutrition (starvation, protein energy malnutrition, vitamin deficiencies).

ENVIRONMENTAL POLLUTION

Environment is air we collectively breathe and share with others at all places—outside, inside homes and at work place. *Pollution* is the contamination of the natural environment which determines adverse effects on health. Any agent—chemical, physical or microbial, that alters the composition of environment is called pollutant. In addition, our personal environment gets affected by smoking of tobacco, water we drink and food we eat. Thus, the subject of environmental pollution is briefly reviewed below under 3 headings: air pollution, environmental chemicals and tobacco smoking.

AIR POLLUTION

For survival of mankind, it is important to prevent depletion of ozone layer (O₃) in the outer space from pollutants such as chlorofluorocarbons and nitrogen dioxide produced in abundance by day-to-day activities on our planet earth due to industrial effluent and automobile exhausts.

A vast variety of pollutants are inhaled daily, some of which may cause trivial irritation to the upper respiratory pathways, while others may lead to acute or chronic injury to the lungs, and some are implicated in causation of lung cancer. Whereas some pollutants are prevalent in certain industries (such as coal dust, silica, asbestos), others are general pollutants present widespread in the ambient atmosphere (e.g. sulphur dioxide, nitrogen dioxide, carbon monoxide). The latter group of environmental pollutants is acted upon by sunlight to produce secondary pollutants such as ozone and free radicals capable of oxidant cell injury to respiratory passages. In highly polluted cities where coal consumption and automobile exhaust accumulate in the atmosphere, the air pollutants become visible as 'smog'. It has been reported that 6 out of 10 largest cities in India have such severe air pollution problem that the annual level of suspended particles is about three times higher than the WHO standards. An estimated 50,000 persons die prematurely every year due to high level of pollution in these cities.

The adverse effects of air pollutants on lung depend upon a few variables that include:

- i) longer duration of exposure;
- ii) total dose of exposure;
- iii) impaired ability of the host to clear inhaled particles; and

iv) particle size of 1-5 μm capable of getting impacted in the distal airways to produce tissue injury.

Pneumoconiosis—the group of lung diseases due to occupational over-exposure to pollutants is discussed in Chapter 15.

ENVIRONMENTAL CHEMICALS

Our environment gets affected by long-term or accidental exposure to certain man-made or naturally-occurring chemicals. A large number of chemicals are found as contaminants in the ecosystem, food and water supply and find their way into the food chain of man. These substances exert their toxic effects depending upon their mode of absorption, distribution, metabolism and excretion. Some of the substances are directly toxic while others cause ill-effects via their metabolites. Environmental chemicals may have slow damaging effect or there may be sudden accidental exposure such as the Bhopal gas tragedy in India due to accidental leakage of methyl isocyanate (MIC) gas in December 1984.

Some of the common examples of environmental chemicals are given below:

1. Agriculture chemicals Modern agriculture thrives on pesticides, fungicides, herbicides and organic fertilisers which may pose a potential acute poisoning as well as long-term hazard. The problem is particularly alarming in developing countries like India, China and Mexico where farmers and their families are unknowingly exposed to these hazardous chemicals during aerial spraying of crops.

◆ Acute poisoning by organophosphate insecticides is quite well known in India as accidental or suicidal poison by inhibiting acetyl cholinesterase and sudden death.

◆ Chronic human exposure to low level agricultural chemicals is implicated in cancer, chronic degenerative diseases, congenital malformations and impotence but the exact cause-and-effect relationship is lacking.

According to the WHO estimates, about 7.5 lakh people are taken ill every year worldwide with pesticide poisoning, half of which occur in the developing countries due to ready availability and indiscriminate use of hazardous pesticides which are otherwise banned in developed countries. Pesticide residues in food items such as in fruits, vegetables, cereals, grains, pulses etc. is of greatest concern.

2. Volatile organic solvents Volatile organic solvents and vapours are used in industry quite commonly and their exposure may cause acute toxicity or chronic hazard, often by inhalation than by ingestion. Such substances include methanol, chloroform, petrol, kerosene, benzene, ethylene glycol, toluene etc.

3. Metals Pollution by occupational exposure to toxic metals such as mercury, arsenic, cadmium, iron, nickel and aluminium are important hazardous environmental chemicals.

4. Aromatic hydrocarbons The halogenated aromatic hydrocarbons containing polychlorinated biphenyl which are contaminant in several preservatives, herbicides and antibacterial agents are a chronic health hazard.

5. Cyanide Cyanide in the environment is released by combustion of plastic, silk and is also present in cassava and the seeds of apricots and wild cherries. Cyanide is a very toxic

chemical and kills by blocking cellular respiration by binding to mitochondrial cytochrome oxidase.

6. Environmental dusts These substances causing pneumoconioses are discussed in chapter 15 while those implicated in cancer have been discussed in Chapter 7.

TOBACCO SMOKING

Habits

Tobacco smoking is the most prevalent and preventable cause of disease and death. The harmful effects of smoking pipe and cigar are somewhat less. Long-term smokers of filter-tipped cigarettes appear to have 30-50% lower risk of development of cancer due to reduced inhalation of tobacco smoke constituents.

Cigarette smoking is a major health problem all over the world. In India, a country of 1.25 billion people, a quarter (300 million) are tobacco users in one form or the other (**Fig. 8.1**). Smoking *bidis* and chewing *pan masala*, *zarda* and *gutka* are more widely practiced than cigarettes. Habit of smoking *chutta* (a kind of indigenous cigar) in which the lighted end is put in mouth is practiced in the Indian state of Andhra Pradesh and is associated with higher incidence of squamous cell carcinoma of hard palate. Another habit prevalent in Indian states of Uttar Pradesh and Bihar is chewing of tobacco alone or mixed with slaked lime as a bolus of *paan* kept in mouth for long hours which is the major cause of cancer of upper aerodigestive tract and oral cavity. *Hookah* smoking, in which tobacco smoke passes through a water-filled chamber which cools the smoke before it is inhaled by the smoker, is believed by some reports to deliver less tar and nicotine than cigarettes and hence fewer tobacco-related health consequences.

In view of serious health hazards of tobacco, the WHO launched Tobacco Free Initiative in 2002. India enacted a law in 2008 banning smoking at all public places, imposing world's biggest smoking ban which is showing favourable results. In US, Canada and most European countries, health awareness by people has resulted in decline in tobacco smoking by about 20%.

Besides the harmful effects of smoking on active smokers themselves, involuntary exposure of smoke to bystanders (passive smoking) is also injurious to health, particularly to infants and children.

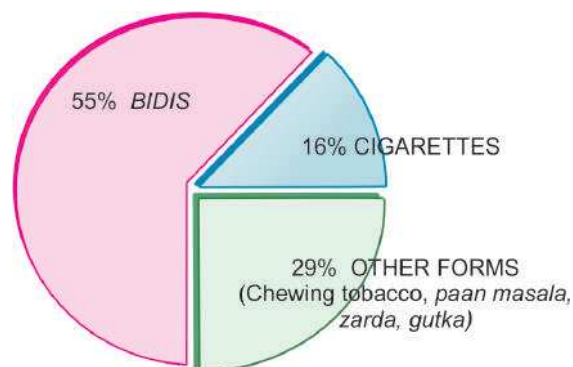

Figure 8.1 Consumption of tobacco in India as estimated by weight (Source: National Council of Applied Economic Research, New Delhi).

Dose and Duration

Tobacco contains several harmful constituents which include nicotine, many carcinogens, carbon monoxide and other toxins (Table 8.1).

The harmful effects of smoking are related to a variety of factors, the most important of which is dose of exposure expressed in terms of pack years. For example, one pack of cigarettes daily for 5 years means 5 pack years. It is estimated that a person who smokes 2 packs of cigarettes daily at the age of 30 years reduces his life by 8 years than a non-smoker. On cessation of smoking, the higher mortality slowly declines and the beneficial effect reaches the level of non-smokers after 20 or more of smoke-free years.

Tobacco-Related Diseases

Tobacco contains numerous toxic chemicals having adverse effects varying from minor throat irritation to carcinogenesis. Some of the important constituents of tobacco smoke with adverse effects are given in Table 8.1.

The relative risk of major diseases in tobacco smokers compared from non-smokers and accounting for higher mortality include the following (Fig. 8.2) (in descending order of frequency):

- i) Cancer of the lung: 12 to 23 times (Chapter 15)
- ii) Chronic obstructive pulmonary disease (COPD): 10-13 times (Chapter 15)
- iii) Cancers of upper aerodigestive tract (larynx, pharynx, lip, oral cavity, oesophagus): 6 to 14 times
- iv) Aortic aneurysm: 6-7 times (Chapter 13)
- v) Other cancers by systemic effects (kidneys, pancreas, urinary bladder, stomach, cervix): 2-3 times

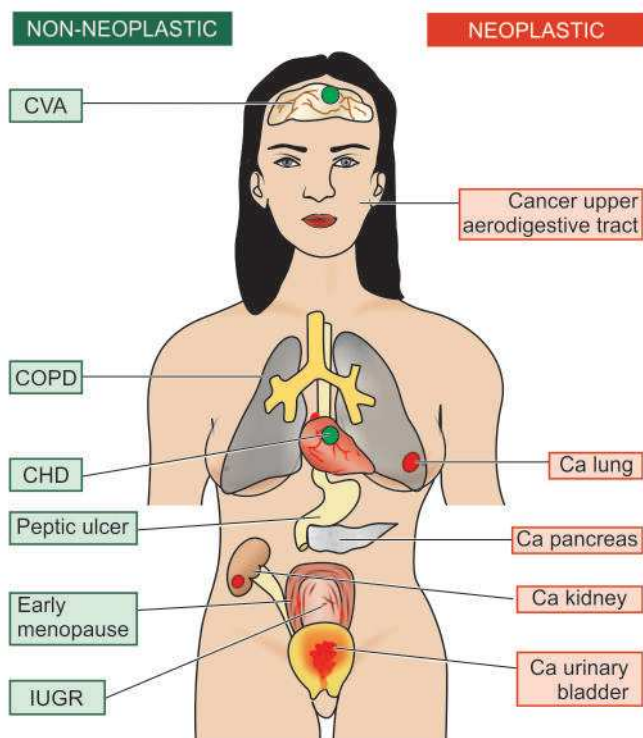

Figure 8.2 Major adverse effects of tobacco smoking. Right side shows smoking-related neoplastic diseases while left side indicates non-neoplastic diseases associated with smoking, numbered serially in order of frequency of occurrence.

Table 8.1 Major constituents of tobacco smoke with adverse effects.

| ADVERSE EFFECT | CONSTITUENTS |
|--|---|
| 1. Carcinogenesis | • Tar • Polycyclic aromatic hydrocarbons • Nitrosamines |
| 2. Tumour promoters | • Nicotine • Phenol |
| 3. Irritation and toxicity to respiratory mucosa | • Formaldehyde • Nitrogen oxide |
| 4. Reduced oxygen transport | • Carbon monoxide |

- vi) Cerebrovascular accidents (CVA): 2-4 times (Chapter 13)
- vii) Coronary heart disease: 2 to 3 times relative risk
- viii) Sudden infant death syndrome: 2 times
- ix) Buerger's disease (thromboangiitis obliterans)
- x) Peptic ulcer disease with 70% higher risk in smokers.
- xi) Early menopause in smoker women.
- xii) In smoking pregnant women, higher risk of lower birth weight of foetus, higher perinatal mortality and intellectual deterioration of newborn.

GIST BOX 8.1

Environmental Pollution

- ▣ The adverse effects of air pollutants on lung depend upon duration of exposure, total dose of exposure, impaired ability of the host to clear inhaled particles and particle size of 1-5 μm . The effects may range from trivial upper respiratory irritation to pneumoconiosis.
- ▣ Our environment gets affected by long-term or accidental exposure to certain man-made or naturally-occurring chemicals e.g. pesticides, volatile organic solvents, toxic metals, aromatic hydrocarbons, cyanide and several environmental dusts.
- ▣ Cigarette smoking is a major health problem all over the world. Its effects depend upon the dose and duration.
- ▣ Smoking is strongly implicated in many cancers (lung, upper aerodigestive tract, kidneys, pancreas, urinary bladder, cervix) and there is increased incidence of certain non-neoplastic diseases (coronary artery disease, cerebrovascular accidents, Buerger's disease, COPD, peptic ulcer).

CHEMICAL AND DRUG INJURY

During life, each one of us is exposed to a variety of chemicals and drugs. These are broadly divided into the following two categories:

1. *Therapeutic (iatrogenic) agents* e.g. drugs, which when administered indiscriminately are associated with adverse effects.
2. *Non-therapeutic agents* e.g. alcohol, lead, carbon monoxide, drug abuse.

THERAPEUTIC (IATROGENIC) DRUG INJURY

Though the basis of patient management is rational drug therapy, nevertheless adverse drug reactions do occur in

2-5% of patients. In general, the risk of adverse drug reaction increases with increasing number of drugs administered. Adverse effects of drugs may appear due to:

- i) overdose;
- ii) genetic predisposition;
- iii) exaggerated pharmacologic response;
- iv) interaction with other drugs; and
- v) unknown factors.

It is beyond the scope of this book to delve into the list of drugs with their harmful effects which forms a separate subject of study. However, some of the common forms of iatrogenic drug injury and the offending drugs are listed in **Table 8.2**.

NON-THERAPEUTIC TOXIC AGENTS

1. ALCOHOLISM

Chronic alcoholism is defined as the regular imbibing of an amount of ethyl alcohol (ethanol) that is sufficient to harm an individual socially, psychologically or physically. It is difficult to give the number of 'drinks' after which the diagnosis of alcoholism can be made because of differences in individual susceptibility. However, adverse effects—acute as well as chronic, are related to the quantity of alcohol content imbibed and duration of consumption. Generally, 10 gm of ethanol is present in:

- ◆ one can of beer (or half a bottle of beer);
- ◆ 120 ml of neat wine; or
- ◆ 30 ml of 43% liquor (small peg).

A daily consumption of 40 gm of ethanol (4 small pegs or 2 large pegs) is likely to be harmful; intake of 100 gm or more daily is certainly dangerous. Daily and heavy consumption of alcohol is more harmful than moderate social drinking having gap periods, since the liver where ethanol is metabolised, gets time to heal.

Metabolism

Absorption of alcohol begins in the stomach and small intestine and appears in blood shortly after ingestion. Alcohol is then distributed to different organs and body fluids proportionate to the blood levels of alcohol. About 2-10% of absorbed alcohol is excreted via urine, sweat and exhaled through breath, the last one being the basis of breath test employed by law-enforcement agencies for alcohol abuse. Metabolism of alcohol is discussed in detail in Chapter 19 (page 604); in brief alcohol is metabolised in the liver by the following 3 pathways (**Fig. 8.3**):

1. By the major rate-limiting pathway of alcohol dehydrogenase (ADH) in the cytosol, which is then quickly destroyed by aldehyde dehydrogenase (ALDH), especially with low blood alcohol levels.
2. Via microsomal P-450 system (microsomal ethanol oxidising system, MEOS) when the blood alcohol level is high.
3. Minor pathway via catalase from peroxisomes.

In any of the three pathways, ethanol is biotransformed to toxic acetaldehyde in the liver and finally to carbon dioxide and water by acetyl coenzyme A.

III-Effects of Alcoholism

Alcohol consumption in moderation and socially acceptable limits is practiced mainly for its mood-altering effects. Heavy alcohol consumption in unhabituated person is likely to cause acute ill-effects on different organs. Though the diseases

Table 8.2 Iatrogenic drug injury.

| | ADVERSE EFFECT | OFFENDING DRUG |
|-----|--|--|
| 1. | GASTROINTESTINAL TRACT | |
| | <i>Gastritis, peptic ulcer</i> | Aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs) |
| | <i>Jejunal ulcer</i> | Enteric-coated potassium tablets |
| | <i>Pancreatitis</i> | Thiazide diuretics |
| 2. | LIVER | |
| | <i>Cholestatic jaundice</i> | Phenothiazines, tranquilisers, oral contraceptives |
| | <i>Hepatitis</i> | Halothane, isoniazid |
| | <i>Fatty change</i> | Tetracycline |
| 3. | NERVOUS SYSTEM | |
| | <i>Cerebrovascular accidents</i> | Anticoagulants, |
| | <i>Peripheral neuropathy</i> | Oral contraceptives |
| | <i>8th nerve deafness</i> | Vincristine, antimalarials |
| | | Streptomycin |
| 4. | SKIN | |
| | <i>Acne</i> | Corticosteroids |
| | <i>Urticaria</i> | Penicillin, sulfonamides |
| | <i>Exfoliative dermatitis,</i> | Penicillin, sulfonamides, |
| | <i>Stevens-Johnson syndrome</i> | phenyl butazone |
| | <i>Fixed drug eruptions</i> | Chemotherapeutic agents |
| 5. | HEART | |
| | <i>Arrhythmias</i> | Digitalis, propranolol |
| | <i>Congestive heart failure</i> | Corticosteroids |
| | <i>Cardiomyopathy</i> | Adriamycin |
| 6. | BLOOD | |
| | <i>Aplastic anaemia</i> | Chloramphenicol |
| | <i>Agranulocytosis,</i> | Antineoplastic drugs |
| | <i>thrombocytopenia</i> | |
| | <i>Immune haemolytic anaemia</i> | Penicillin |
| | <i>Megaloblastic anaemia</i> | Methotrexate |
| 7. | LUNGS | |
| | <i>Alveolitis, interstitial pulmonary fibrosis</i> | Anti-neoplastic drugs |
| | <i>Asthma</i> | Aspirin, indomethacin |
| 8. | KIDNEYS | |
| | <i>Acute tubular necrosis</i> | Gentamycin, kanamycin |
| | <i>Nephrotic syndrome</i> | Gold salts |
| | <i>Chronic interstitial nephritis, papillary necrosis</i> | Phenacetin, salicylates |
| 9. | METABOLIC EFFECTS | |
| | <i>Hypercalcaemia</i> | Hypervitaminosis D, thiazide diuretics |
| | <i>Hepatic porphyria</i> | Barbiturates |
| | <i>Hyperuricaemia</i> | Anti-cancer chemotherapy |
| 10. | FEMALE REPRODUCTIVE TRACT | |
| | <i>Cholelithiasis, thrombophlebitis, thromboembolism, benign liver cell adenomas</i> | Long-term use of oral contraceptives |
| | <i>Vaginal adenosis, adenocarcinoma in daughters</i> | Diethylstilbesterol by pregnant women |
| | <i>Foetal congenital anomalies</i> | Thalidomide in pregnancy |

associated with alcoholism are discussed in respective chapters later, the spectrum of ill-effects is outlined below.

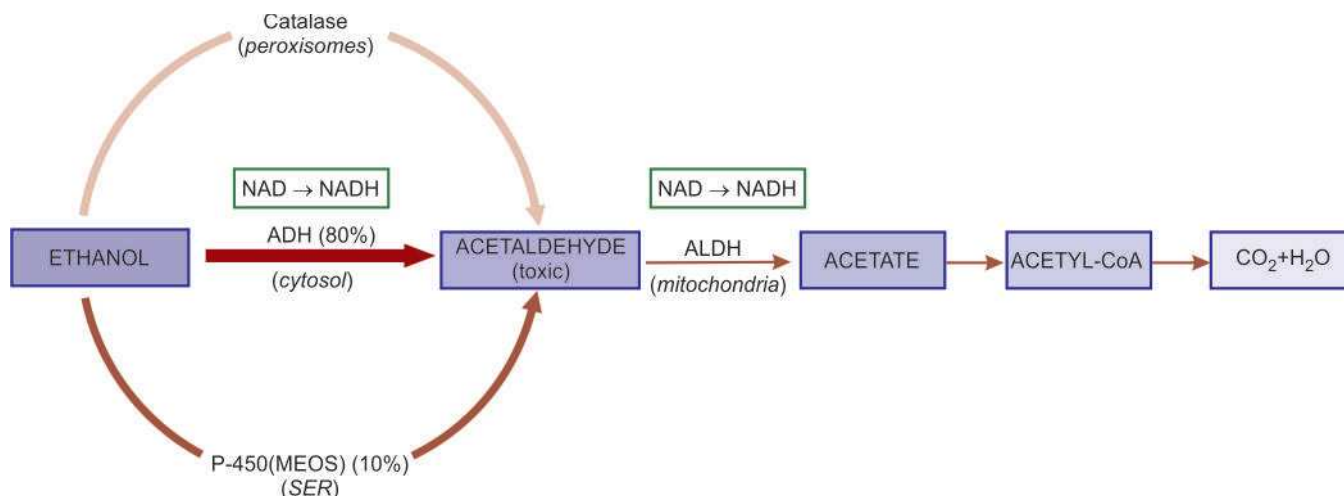

Figure 8.3 Metabolism of ethanol in the liver. Thickness and intensity of colour of arrow on left side of figure corresponds to extent of metabolic pathway followed (MEOS = microsomal ethanol oxidizing system; ADH = alcohol dehydrogenase; ALDH = aldehyde dehydrogenase; NAD = nicotinamide adenine dinucleotide; NADH = reduced NAD; NADP = nicotinamide adenine dinucleotide phosphate; NADPH = reduced NADPH).

A. ACUTE ALCOHOLISM The acute effects of inebriation are most prominent on the central nervous system but it also injures the stomach and liver.

1. Central nervous system Alcohol acts as a CNS depressant; the intensity of effects of alcohol on the CNS is related to the quantity consumed and duration over which consumed, which are reflected by the blood levels of alcohol:

i) Initial effect of alcohol is on subcortical structures which is followed by disordered cortical function, motor ataxia and behavioural changes. These changes are apparent when blood alcohol level does not exceed *100 mg/dl* which is the upper limit of sobriety in drinking as defined by law-enforcing agencies in most Western countries while dealing with cases of driving in drunken state.

ii) Blood level of *100-200 mg/dl* is associated with depression of cortical centres, lack of coordination, impaired judgement and drowsiness.

iii) Stupor and coma supervene when blood alcohol level is *about 300 mg/dl*.

iv) Blood level of alcohol *above 400 mg/dl* can cause anaesthesia, depression of medullary centre and death from respiratory arrest.

However, chronic alcoholics develop CNS tolerance and adaptation and, therefore, can withstand higher blood levels of alcohol without such serious effects.

2. Stomach Acute alcohol intoxication may cause vomiting, acute gastritis and peptic ulceration.

3. Liver Acute alcoholic injury to the liver is explained in Chapter 19.

B. CHRONIC ALCOHOLISM Chronic alcoholism produces widespread injury to organs and systems. Contrary to the earlier belief that chronic alcoholic injury results from nutritional deficiencies, it is now known that most of the alcohol-related injury to different organs is due to toxic effects of alcohol and accumulation of its main toxic metabolite, acetaldehyde, in the blood. Other proposed mechanisms of tissue injury in chronic alcoholism are free-radical mediated injury and genetic susceptibility to alcohol-dependence and tissue damage.

Some of the more important organ effects in chronic alcoholism are as under (**Fig. 8.4**):

1. Liver Alcoholic liver disease and cirrhosis are the most common and important effects of chronic alcoholism (Chapter 19).

2. Pancreas Chronic calcifying pancreatitis and acute pancreatitis are serious complications of chronic alcoholism.

3. Gastrointestinal tract Gastritis, peptic ulcer and oesophageal varices associated with fatal massive bleeding may occur.

4. Central nervous system Peripheral neuropathies and Wernicke-Korsakoff syndrome, cerebral atrophy, cerebellar degeneration and amblyopia (impaired vision) are seen in chronic alcoholics.

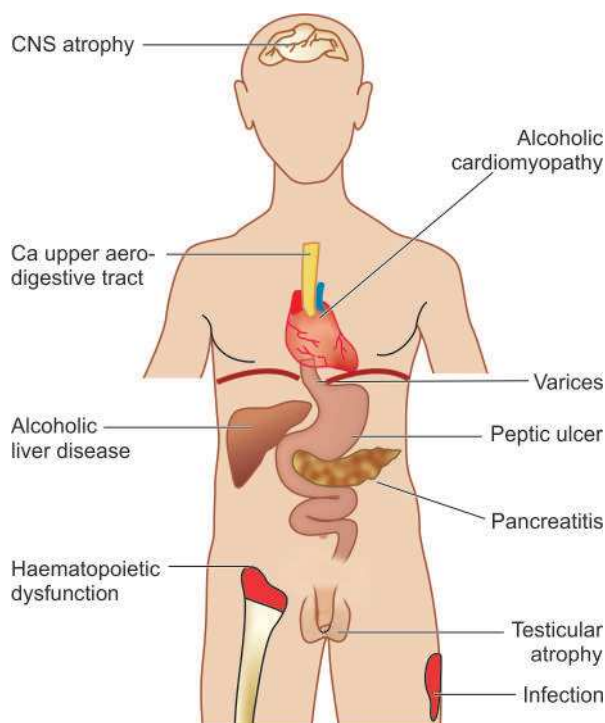

Figure 8.4 Complications of chronic alcoholism.

5. Cardiovascular system Alcoholic cardiomyopathy and beer-drinkers' myocardiosis with consequent dilated cardiomyopathy may occur. Level of HDL (atherosclerosis-protective lipoprotein), however, has been shown to increase with moderate consumption of alcohol.

6. Endocrine system In men, testicular atrophy, feminisation, loss of libido and potency, and gynaecomastia may develop. These effects appear to be due to lowering of testosterone levels.

7. Blood Haematopoietic dysfunction with secondary megaloblastic anaemia and increased red blood cell volume may occur.

8. Immune system Alcoholics are more susceptible to various infections.

9. Cancer There is higher incidence of cancers of upper aerodigestive tract in chronic alcoholics but the mechanism is not clear.

2. LEAD POISONING

Lead poisoning may occur in children or adults due to accidental or occupational ingestion.

In children, following are the main sources of lead poisoning:

- i) Chewing of lead-containing furniture items, toys or pencils.
- ii) Eating of lead paint flakes from walls.

In adults, the sources are as follows:

1. Occupational exposure to lead during spray painting, recycling of automobile batteries (lead oxide fumes), mining, and extraction of lead.
2. Accidental exposure by contaminated water supply, house freshly coated with lead paint, and sniffing of lead-containing petrol (hence unleaded petrol introduced as fuel).

Lead is absorbed through the gastrointestinal tract or lungs. The absorbed lead is distributed in two types of tissues (**Fig. 8.5**):

a) *Bones, teeth, nails and hair* representing relatively harmless pool of lead. About 90% of absorbed lead accumulates in the developing metaphysis of bones in children and appears as areas of increased bone densities ('lead lines') on X-ray. Lead lines are also seen in the gingiva.

b) *Brain, liver, kidneys and bone marrow* accumulate the remaining 10% lead which is directly toxic to these organs. It is excreted via kidneys.

Lead toxicity occurs in the following organs predominantly:

1. Nervous system The changes are as under:

- i) *In children*, lead encephalopathy; oedema of brain, flattening of gyri and compression of ventricles.
- ii) *In adults*, demyelinating peripheral motor neuropathy which typically affects radial and peroneal nerves resulting in wristdrop and footdrop respectively.

2. Haematopoietic system The changes in blood are quite characteristic:

- i) *Microcytic hypochromic anaemia* due to inhibition of two enzymes: delta-aminolevulinic acid dehydrogenase required for haem synthesis, and through inhibition of ferroketolase required for incorporation of ferrous iron into the porphyrin ring.
- ii) Prominent basophilic stippling of erythrocytes.

3. Kidneys Lead is toxic to proximal tubular cells of the kidney and produces *lead nephropathy* characterised by

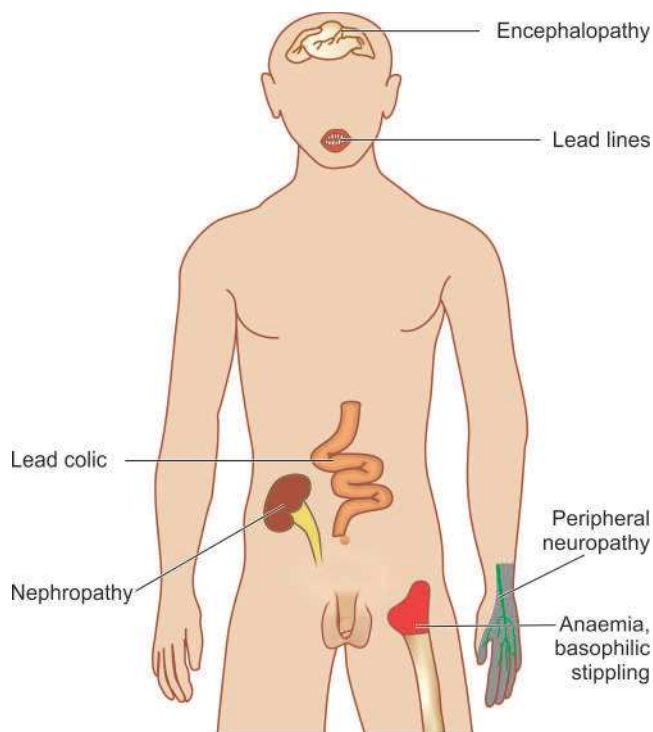

Figure 8.5 Complications of lead poisoning.

accumulation of intranuclear inclusion bodies consisting of lead-protein complex in the proximal tubular cells.

4. Gastrointestinal tract Lead toxicity in the bowel manifests as acute abdomen presenting as lead colic.

3. CARBON MONOXIDE POISONING

Carbon monoxide (CO) is a colourless and odourless gas produced by incomplete combustion of carbon. Sources of CO gas are:

- i) automobile exhaust;
- ii) burning of fossil fuel in industries or at home; and
- iii) tobacco smoke.

CO is an important cause of accidental death due to systemic oxygen deprivation of tissues. This is because haemoglobin has about 200-times higher affinity for CO than for O₂ and thus varying amount of carboxyhaemoglobin is formed depending upon the extent of CO poisoning. Besides, carboxyhaemoglobin interferes with the release of O₂ from oxyhaemoglobin causing further aggravation of tissue hypoxia. Diagnosis of CO poisoning is, therefore, best confirmed by carboxyhaemoglobin levels in the blood.

CO poisoning may present in 2 ways:

- ◆ **Acute CO poisoning** in which there is sudden development of brain hypoxia characterised by oedema and petechial haemorrhages.
- ◆ **Chronic CO poisoning** presents with nonspecific changes of slowly developing hypoxia of the brain.

4. DRUG ABUSE

Drug abuse is defined as the use of certain drugs for the purpose of 'mood alteration' or 'euphoria' or 'kick' but subsequently leading to habit-forming, dependence and eventually addiction. Some of the commonly abused drugs and substances are as under:

1. **Marijuana or 'pot'** is psychoactive substance most widely used. It is obtained from the leaves of the plant *Cannabis sativa* and contains tetrahydrocannabinol (THC). It may be smoked or ingested.
2. **Derivatives of opium** that includes heroin and morphine. Opioids are derived from the poppy plant. Heroin and morphine are self-administered intravenously or subcutaneously.
3. **CNS depressants** include barbiturates, tranquilisers and alcohol.
4. **CNS stimulants** e.g. cocaine and amphetamines.
5. **Psychedelic drugs** (meaning enjoyable perception-giving) e.g. LSD.
6. **Inhalants** e.g. glue, paint thinner, nail polish remover, aerosols, amyl nitrite.

It is beyond the scope of the present discussion to go into the pharmacologic actions of all these substances. However, apart from pharmacologic and physiologic actions of these street drugs, the most common complication is introduction of infection by parenteral use of many of these drugs. Sharing of needles by the drug-addicts accounts for high risk of most feared viral infections in them, AIDS and viral hepatitis (HBV and HCV). Following are a few common drug abuse-related infectious complications:

1. At the site of injection—cellulitis, abscesses, ulcers, thrombosed veins
2. Thrombophlebitis
3. Bacterial endocarditis
4. High risk for AIDS
5. Viral hepatitis and its complications
6. Focal glomerulonephritis
7. Talc (foreign body) granuloma formation in the lungs.

**GIST BOX 8.2****Chemical and Drug Injury**

- ☐ Harmful chemicals and drugs can be broadly divided into 2 groups: therapeutic (iatrogenic) agents (e.g. drugs, which when administered indiscriminately are associated with adverse effects) and non-therapeutic agents (e.g. alcohol, lead, carbon monoxide, drug abuse).
- ☐ Alcoholism may produce acute and chronic effects on the body. Most prominent ill-effect of acute alcoholism is on the central nervous system; other acute effects are on the stomach and liver. Chronic alcoholism causes alcoholic liver disease, pancreatitis, and other systemic adverse manifestations pertaining to CNS, CVS, endocrines, blood, and immune system.
- ☐ Lead poisoning may occur in children by eating lead-contaminated items and in adults from occupational or accidental exposure. The adverse effects pertain to nervous system and blood.
- ☐ Carbon monoxide poisoning may cause accidental death or may produce chronic effects.
- ☐ Drug abuse from marijuana, opium, barbiturates, cocaine, inhalants etc may cause a variety of local and systemic effects.

INJURY BY PHYSICAL AGENTS**THERMAL AND ELECTRICAL INJURY**

Thermal and electrical burns, fall in body temperature below 35°C (hypothermia) and elevation of body temperature above 41°C (hyperthermia), are all associated with tissue injury.

1. **Hypothermia** may cause focal injury as in frostbite, or systemic injury and death as occurs on immersion in cold water for varying time.
2. **Hyperthermia** likewise, may be localised as in cutaneous burns, and systemic as occurs in fevers.
3. **Thermal burns** depending upon severity are categorised into full thickness (third degree) and partial thickness (first and second degree). The most serious complications of burns are haemoconcentration, infections and contractures on healing.
4. **Electrical burns** may cause damage *firstly*, by electrical dysfunction of the conduction system of the heart and death by ventricular fibrillation, and *secondly* by heat produced by electrical energy.

INJURY BY RADIATION

As discussed in the preceding chapter, the most important form of radiation injury is ionising radiation which has three types of effects on cells:

- i) Somatic effects which cause acute cell killing.
- ii) Genetic damage by mutations and therefore, passes genetic defects in the next progeny of cells.
- iii) Malignant transformation of cells (Chapter 7).

Ionising radiation is widely employed for diagnostic purpose as well as for radiotherapy of malignant tumours. Radiation-induced cell death is mediated by radiolysis of water in the cell with generation of toxic hydroxyl radicals (page 16). During radiotherapy, some normal cells coming in the field of radiation are also damaged. In general, radiation-induced tissue injury predominantly affects endothelial cells of small arteries and arterioles, causing necrosis and ischaemia.

Ionising radiation causes damage to the following major organs:

1. **Skin:** radiation dermatitis, cancer.
2. **Lungs:** interstitial pulmonary fibrosis.
3. **Heart:** myocardial fibrosis, constrictive pericarditis.
4. **Kidney:** radiation nephritis.
5. **Gastrointestinal tract:** strictures of small bowel and oesophagus.
6. **Gonads:** testicular atrophy in males and destruction of ovaries.
7. **Haematopoietic tissue:** pancytopenia due to bone marrow depression.
8. **Eyes:** cataract.

Besides ionising radiation, other form of harmful radiation is *solar (u.v.) radiation* which may cause acute skin injury as sunburns, chronic conditions such as solar keratosis and early onset of cataracts in the eyes. It may, however, be mentioned in passing here that electromagnetic radiation produced by microwaves (ovens, radars, diathermy) or ultrasound waves used for diagnostic purposes do not produce ionisation and thus are not known to cause any tissue injury.

**GIST BOX 8.3****Injury by Physical Agents**

- ☐ Physical agents causing tissue injury are thermal and electrical burns, fall in body temperature below 35°C (hypothermia) and elevation of body temperature above 41°C (hyperthermia).
- ☐ Ionising radiation and solar radiation cause damage to somatic cells, genetic damage and malignant transformation.

NUTRITIONAL REQUIREMENT

Nutritional status of a society varies according to the socio-economic conditions. In the Western world, nutritional imbalance is more often a problem accounting for increased frequency of obesity, while in developing countries of Africa, Asia and South America, chronic malnutrition is a serious health problem, particularly in children.

Before describing the nutritional diseases, it is essential to know the components of normal and adequate nutrition. For good health, humans require energy-providing nutrients (proteins, fats and carbohydrates), vitamins, minerals, water and some non-essential nutrients.

1. Energy The requirement of energy by the body is calculated in Kcal per day. In order to retain stable weight and undertake day-to-day activities, the energy intake must match the energy output. The average requirement of energy for an individual is estimated by the formula: $900+10w$ for males, and $700+7w$ for females (where w stands for the weight of the individual in kilograms). Since the requirement of energy varies according to the level of physical activities performed by the person, the figure arrived at by the above formula is multiplied by: 1.2 for sedentary person, 1.4 for moderately active person and 1.8 for very active person.

2. Proteins Dietary proteins provide the body with amino acids for endogenous protein synthesis and are also a metabolic fuel for energy (1 g of protein provides 4 Kcal). *Nine essential amino acids* (histidine, isoleucine, leucine, lysine, methionine/cystine, phenylalanine/tyrosine, theonine, tryptophan and valine) must be supplied by dietary intake as these cannot be synthesised in the body. The recommended average requirement of proteins for an adult is 0.6 g/kg of the desired weight per day. For a healthy person, 10-14% of caloric requirement should come from proteins.

3. Fats Fats and fatty acids (in particular linolenic, linoleic and arachidonic acid) should comprise about 35% of diet. In order to minimise the risk of atherosclerosis, poly-unsaturated fats should be limited to <10% of calories and saturated fats and trans-fats should comprise <10% of calories while monounsaturated fats to constitute the remainder of fat intake (1 g of fat yields 9 Kcal).

4. Carbohydrates Dietary carbohydrates, are the major source of dietary calories, especially for the brain, RBCs and muscles (1 g of carbohydrate provides 4 Kcal). At least 55% of total caloric requirement should be derived from carbohydrates.

5. Vitamins These are mainly derived from exogenous dietary sources and are essential for maintaining the normal structure and function of cells. A healthy individual requires 4 fat-soluble vitamins (A, D, E and K) and 11 water-soluble vitamins (C, B₁/thiamine, B₂/riboflavin, B₃/niacin/nicotinic acid, B₅/pantothenic acid, B₆/pyridoxine, folate/folic acid, B₁₂/cyanocobalamin, choline, biotin, and flavonoids). Vitamin deficiencies result in individual deficiency syndromes, or may be part of a multiple deficiency state.

6. Minerals A number of minerals like iron, calcium, phosphorus and certain trace elements (e.g. zinc, copper,

selenium, iodine, chlorine, sodium, potassium, magnesium, manganese, cobalt, molybdenum etc) are essential for health. Their deficiencies result in a variety of lesions and deficiency syndromes.

7. Water Water intake is essential to cover the losses in faeces, urine, exhalation and insensible loss so as to avoid under- or over-hydration. Although body's water needs vary according to physical activities and weather conditions, average requirement of water is 1.0-1.5 ml water/ Kcal of energy spent. Infants and pregnant women have relatively higher requirements of water.

8. Non-essential nutrients Dietary fibre composed of cellulose, hemicellulose and pectin, though considered non-essential, are important due to their beneficial effects in lowering the risk of colonic cancer, diabetes and coronary artery disease.

PATHOGENESIS OF DEFICIENCY DISEASES

The nutritional deficiency disease develops when the essential nutrients are not provided to the cells adequately. The nutritional deficiency may be of 2 types:

1. Primary deficiency This is due to either the lack or decreased amount of essential nutrients in diet.

2. Secondary or conditioned deficiency Secondary or conditioned deficiency is malnutrition occurring as a result of the various factors. These are as under:

- i) *Interference with ingestion* e.g. in gastrointestinal disorders such as malabsorption syndrome, chronic alcoholism, neuropsychiatric illness, anorexia, food allergy, pregnancy.
- ii) *Interference with absorption* e.g. in hypermotility of the gut, achlorhydria, biliary disease.
- iii) *Interference with utilisation* e.g. in liver dysfunction, malignancy, hypothyroidism.
- iv) *Increased excretion* e.g. in lactation, perspiration, polyuria.
- v) *Increased nutritional demand* e.g. in fever, pregnancy, lactation, hyperthyroidism.

Irrespective of the type of nutritional deficiency (primary or secondary), nutrient reserves in the tissues begin to get depleted, which initially result in biochemical alterations and eventually lead to functional and morphological changes in tissues and organs.

In the following pages, a brief account of nutritional imbalance (viz. *obesity*) is followed by description of multiple or mixed deficiencies (e.g. *starvation*, *protein-energy malnutrition*) and individual nutrient deficiencies (e.g. *vitamin deficiencies*).

OBESITY

Dietary imbalance and overnutrition may lead to obesity. *Obesity is defined as an excess of adipose tissue that imparts health risk; a body weight of 20% excess over ideal weight for age, sex and height is considered a health risk.* The most widely used method to gauge obesity is body mass index (BMI) which is equal to weight in kg/height in m². A cut-off BMI value of 30 is used for obesity in both men and women.

ETIOLOGY *Obesity results when caloric intake exceeds utilisation.* The imbalance of these two components can occur in the following situations:

1. *Inadequate pushing of oneself away from the dining table* causing overeating.
2. *Insufficient pushing of oneself out of the chair* leading to inactivity and sedentary life style.
3. *Genetic predisposition* to develop obesity.
4. *Diets largely derived from carbohydrates* and fats than protein-rich diet.
5. *Secondary obesity* may result following a number of underlying diseases such as hypothyroidism, Cushing's disease, insulinoma and hypothalamic disorders.

PATHOGENESIS The lipid storing cells, adipocytes comprise the adipose tissue, and are present in vascular and stromal compartment in the body. Besides the generally accepted role of adipocytes for fat storage, these cells also release endocrine-regulating molecules. These molecules include: energy regulatory hormone (leptin), cytokines (TNF- α and interleukin-6), insulin sensitivity regulating agents (adiponectin, resistin and RBP4), prothrombotic factors (plasminogen activator inhibitor), and blood pressure regulating agent (angiotensinogen).

Adipose mass is increased due to enlargement of adipose cells due to excess of intracellular lipid deposition as well as due to increase in the number of adipocytes. The most important environmental factor is excess consumption of nutrients which can lead to obesity. However, underlying molecular mechanisms of obesity are beginning to unfold based on observations that obesity is familial and is seen in identical twins. Recently, two obesity genes have been found: *ob* gene and its protein product leptin, and *db* gene and its protein product leptin receptor.

SEQUELAE OF OBESITY Marked obesity is a serious health hazard and may predispose to a number of clinical disorders and pathological changes described below and illustrated in Fig. 8.6.

MORPHOLOGIC FEATURES Obesity is associated with increased adipose stores in the subcutaneous tissues, skeletal muscles, internal organs such as the kidneys, heart, liver and omentum; fatty liver is also more common in obese individuals. There is increase in both size and number of adipocytes i.e. there is hypertrophy as well as hyperplasia.

EFFECTS OF OBESITY These are as under:

1. **Hyperinsulinaemia** Increased insulin secretion is a feature of obesity. Many obese individuals exhibit hyperglycaemia or frank diabetes despite hyperinsulinaemia. This is due to a state of insulin-resistance consequent to tissue insensitivity.
2. **Type 2 diabetes mellitus** There is a strong association of type 2 diabetes mellitus with obesity. Obesity often exacerbates the diabetic state and in many cases weight reduction often leads to amelioration of diabetes.
3. **Hypertension** A strong association between hypertension and obesity is observed which is perhaps due to increased blood volume. Weight reduction leads to significant reduction in systolic blood pressure.
4. **Hyperlipoproteinaemia** The plasma cholesterol circulates in the blood as low-density lipoprotein (LDL) containing

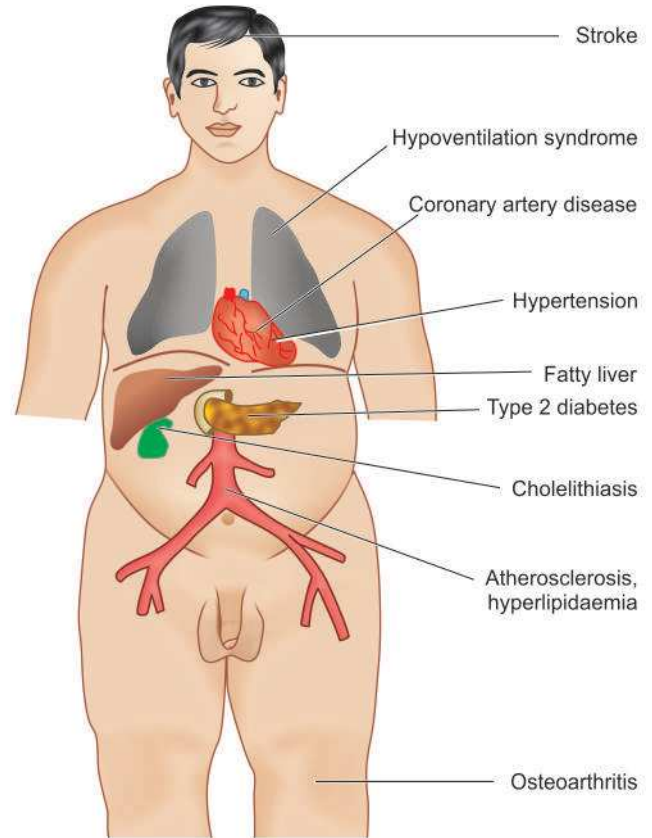

Figure 8.6 Major sequelae of obesity.

most of the circulating triglycerides. Obesity is strongly associated with VLDL and mildly with LDL. Total blood cholesterol levels are also elevated in obesity.

5. **Atherosclerosis** Obesity predisposes to development of atherosclerosis. As a result of atherosclerosis and hypertension, there is increased risk of myocardial infarction and stroke in obese individuals.

6. **Nonalcoholic fatty liver disease (NAFLD)** Obesity contributes to development of NAFLD which may progress further to cirrhosis of the liver.

7. **Cholelithiasis** There is six times higher incidence of gallstones in obese persons, mainly due to increased total body cholesterol.

8. **Hypoventilation syndrome (Pickwickian syndrome)** This is characterised by hypersomnolence, both at night and during day in obese individuals along with carbon dioxide retention, hypoxia, polycythaemia and eventually right-sided heart failure (Mr Pickwick was a character, the fat boy, in Charles Dickens' *Pickwick Papers*. The term pickwickian syndrome was first used by Sir William Osler for the sleep-apnoea syndrome).

9. **Osteoarthritis** These individuals are more prone to develop degenerative joint disease due to wear and tear following trauma to joints as a result of large body weight.

10. **Cancer** Diet rich in fats, particularly derived from animal fats and meats, is associated with higher incidence of cancers of colon, breast, endometrium and prostate.

STARVATION

Starvation is a state of overall deprivation of nutrients. Its causes may be the following:

- i) deliberate fasting—religious or political;
- ii) famine conditions in a country or community; or
- iii) secondary undernutrition such as due to chronic wasting diseases (infections, inflammatory conditions, liver disease), cancer etc. Cancer results in malignant cachexia as a result of which cytokines are elaborated e.g. tumour necrosis factor- α , elastases, proteases etc.

A starved individual has lax, dry skin, wasted muscles and atrophy of internal organs.

METABOLIC CHANGES The following metabolic changes take place in starvation:

1. Glucose Glucose stores of the body are sufficient for one day's metabolic needs only. During fasting state, insulin-independent tissues such as the brain, blood cells and renal medulla continue to utilise glucose while insulin-dependent tissues like muscle stop taking up glucose. This results in release of glycogen stores of the liver to maintain normal blood glucose level. Subsequently, hepatic gluconeogenesis from other sources such as breakdown of proteins takes place.

2. Proteins Protein stores and the triglycerides of adipose tissue have enough energy for about 3 months in an individual. Proteins breakdown to release amino acids which are used as fuel for hepatic gluconeogenesis so as to maintain glucose needs of the brain. This results in nitrogen imbalance due to excretion of nitrogen compounds as urea.

3. Fats After about one week of starvation, protein breakdown is decreased while triglycerides of adipose tissue breakdown to form glycerol and fatty acids. The fatty acids are converted into ketone bodies in the liver which are used by most organs including brain in place of glucose. Starvation can then continue till all the body fat stores are exhausted following which death occurs.

PROTEIN-ENERGY MALNUTRITION

The inadequate consumption of protein and energy as a result of primary dietary deficiency or conditioned deficiency may

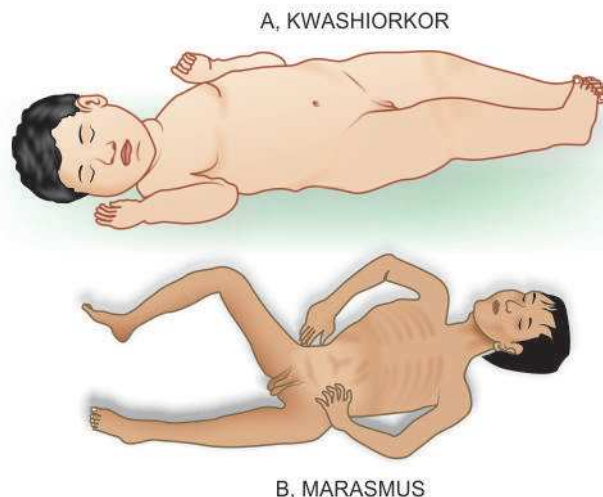

Figure 8.7 Two forms of PEM.

cause loss of body mass and adipose tissue, resulting in protein energy or protein calorie malnutrition (PEM or PCM). The primary deficiency is more frequent due to socioeconomic factors limiting the quantity and quality of dietary intake, particularly prevalent in the developing countries of Africa, Asia and South America. The impact of deficiency is marked in infants and children.

The spectrum of *clinical syndromes* produced as a result of PEM includes the following (Fig. 8.7):

1. *Kwashiorkor* which is related to protein deficiency though calorie intake may be sufficient.
2. *Marasmus* is starvation in infants occurring due to overall lack of calories.

The salient features of the two conditions are contrasted in Table 8.3. However, it must be remembered that mixed forms of kwashiorkor-marasmus syndrome may also occur.

METALS AND TRACE ELEMENTS

Several minerals in trace amounts are essential for health since they form components of enzymes and cofactors for metabolic functions. Besides *calcium* and *phosphorus* required for vitamin D manufacture, others include: *iron*, *copper*, *iodine*,

Table 8.3 Contrasting features of kwashiorkor and marasmus.

| FEATURE | KWASHIORKOR | MARASMUS |
|--------------------------|--|--|
| <i>Definition</i> | Protein deficiency with sufficient calorie intake | Starvation in infants with overall lack of calories |
| <i>Clinical features</i> | Occurs in children between 6 months and 3 years of age | Common in infants under 1 year of age |
| | Growth failure | Growth failure |
| | Wasting of muscles but preserved adipose tissues | Wasting of all tissues including muscles and adipose tissues |
| | Oedema, localised or generalised, present | Oedema absent |
| | Enlarged fatty liver | No hepatic enlargement |
| | Serum proteins low | Serum proteins low |
| | Anaemia present | Anaemia present |
| | 'Flag sign'—alternate bands of light (depigmented) and dark (pigmented) hair | Monkey-like face, protuberant abdomen, thin limbs |
| <i>Morphology</i> | Enlarged fatty liver | No fatty liver |
| | Atrophy of different tissues and organs but subcutaneous fat preserved | Atrophy of different tissues and organs including subcutaneous fat |

zinc, selenium, manganese, nickel, chromium, molybdenum, fluorine. However, out of these, the dietary deficiency of first five trace elements is associated with deficiency states which are discussed in detail in respective chapters later. These are as under:

- i) **Iron:** Microcytic hypochromic anaemia.
- ii) **Calcium:** Reduced bone mass, osteoporosis.
- iii) **Phosphorus:** Rickets, osteomalacia.
- iv) **Copper:** Muscle weakness, neurologic defect, anaemia, growth retardation.
- v) **Iodine:** Goitre and hyperthyroidism, cretinism.
- vi) **Zinc:** Growth retardation, infertility, alopecia.
- vii) **Selenium:** Cardiomyopathy, muscle degeneration.
- viii) **Fluoride:** Dental caries.
- ix) **Manganese:** Impaired growth and skeletal development.
- x) **Molybdenum:** Severe neurological abnormalities.

GIST BOX 8.4

Nutritional Diseases

- ☐ For good health, humans require energy-providing nutrients (proteins, fats and carbohydrates), vitamins, minerals, water and some non-essential nutrients.
- ☐ The nutritional deficiency may be *primary* due to either the lack or decreased amount of essential nutrients in diet, or *secondary* or conditioned deficiency occurring as a result of the various factors such as interference in ingestion, absorption, excretion, or increased nutritional demand.
- ☐ Dietary imbalance and overnutrition may lead to obesity. Effects of obesity are hyperinsulinaemia, type 2 diabetes, hypertension, atherosclerosis, non-alcoholic fatty liver disease, cholelithiasis, hyperventilation, and osteoarthritis.
- ☐ Starvation is a state of overall deprivation of nutrients i.e. glucose, proteins and fats.
- ☐ The inadequate consumption of protein and energy cause loss of body mass and adipose tissue, resulting in protein energy or protein calorie malnutrition (PEM or PCM). It is of 2 types: *kwashiorkor* which is related to protein deficiency though calorie intake may be sufficient, and *marasmus* which is starvation in infants occurring due to overall lack of calories.
- ☐ Besides calcium and phosphorus, several trace elements required in diet may produce deficiency states. Most important ones are due to iron, copper, iodine and zinc.

DISORDERS OF VITAMINS

Vitamins are organic substances which cannot be synthesised within the body and are essential for maintenance of normal structure and function of cells. Thus, these substances must be provided in the human diet. Most of the vitamins are of plant or animal origin so that they normally enter the body as constituents of ingested plant food or animal food. They are required in minute amounts in contrast to the relatively large amounts of essential amino acids and fatty acids. Vitamins do not play any part in production of energy.

ETIOLOGY OF VITAMIN DEFICIENCIES In the developing countries, *multiple deficiencies* of vitamins and other nutrients are common due to generalised malnutrition of dietary origin. In the developed countries, *individual vitamin deficiencies* are noted more often, particularly in children, adolescent, pregnant

and lactating women, and in some due to poverty. General secondary causes of conditioned nutritional deficiencies listed already (i.e. interference in ingestion, absorption, utilization, excretion) can result in vitamin deficiency in either case. Chronic alcoholism is a common denominator in many of vitamin deficiencies. A few other noteworthy features about vitamins are as under:

1. While vitamin deficiency as well as its excess may occur from another disease, the states of excess and deficiency themselves also cause disease.
2. Vitamins in high dose can be used as drugs.

CLASSIFICATION OF VITAMINS Vitamins are conventionally divided into 2 groups: fat-soluble and water-soluble.

1. Fat-soluble vitamins There are 4 fat-soluble vitamins: A, D, E and K. They are absorbed from intestine in the presence of bile salts and intact pancreatic function. Their deficiencies occur more readily due to conditioning factors (*secondary deficiency*). Beside the deficiency syndromes of these vitamins, a state of *hypervitaminosis* due to excess of vitamin A and D also occurs.

2. Water-soluble vitamins This group conventionally consists of vitamin C and members of B complex group. Besides, choline, biotin and flavonoids are new additions to this group. Water-soluble vitamins are more readily absorbed from small intestine. Deficiency of these vitamins is mainly due to *primary (dietary) factors*. Being water soluble, these vitamins are more easily lost due to cooking or processing of food.

Table 8.4 sums up the various clinical disorders produced by vitamin deficiencies.

FAT-SOLUBLE VITAMINS

Vitamin A (Retinol)

PHYSIOLOGY Vitamin A or retinol is a fat-soluble alcohol. It is available in diet in 2 forms:

- ◆ *As preformed retinol*, the dietary sources of which are animal-derived foods such as yolk of eggs, butter, whole milk, fish, liver, kidney.
- ◆ *As provitamin precursor carotenoid*, which is derived from β -carotene-containing foods such as yellow plants and vegetables e.g. carrots, potatoes, pumpkins, mangoes, spinach. β -carotene can be absorbed intact or converted in the intestinal mucosa to form retinaldehyde which is subsequently reduced to retinol.

Retinol is stored in the liver cells and released for transport to peripheral tissues after binding to retinol-binding protein found in blood.

The **physiologic functions** of retinol are as follows:

1. **Maintenance of normal vision in reduced light.** This involves formation of 2 pigments by oxidation of retinol: *rhodopsin*, a light sensitive pigment in reduced light synthesised in the rod cells, and *iodopsins* sensitive in bright light and formed in cone cells of retina. These pigments then transform the radiant energy into nerve impulses.
2. **Maintenance of structure and function of specialised epithelium.** Retinol plays an important role in the synthesis of glycoproteins of the cell membrane of specialised epithelium such as mucus-secreting columnar epithelium in glands and mucosal surfaces, respiratory epithelium and urothelium.

Table 8.4 Vitamin deficiencies.

| VITAMINS | DEFICIENCY DISORDERS |
|--|---|
| I. FAT-SOLUBLE VITAMINS | |
| <i>Vitamin A</i> (<i>Retinol</i>) | Ocular lesions (night blindness, xerophthalmia, keratomalacia, Bitot's spots, blindness) Cutaneous lesions (xeroderma) Other lesions (squamous metaplasia of respiratory epithelium, urothelium and pancreatic ductal epithelium, subsequent anaplasia; retarded bone growth) |
| <i>Vitamin D</i> (<i>Calcitriol</i>) | Rickets in growing children Osteomalacia in adults Hypocalcaemic tetany |
| <i>Vitamin E</i> (<i>α-Tocopherol</i>) | Degeneration of neurons, retinal pigments, axons of peripheral nerves; denervation of muscles Reduced red cell lifespan Sterility in male and female animals |
| <i>Vitamin K</i> | Hypoprothrombinaemia (in haemorrhagic disease of newborn, biliary obstruction, malabsorption, anticoagulant therapy, antibiotic therapy, diffuse liver disease) |
| II. WATER-SOLUBLE VITAMINS | |
| <i>Vitamin C</i> (<i>Ascorbic acid</i>) | Scurvy (haemorrhagic diathesis, skeletal lesions, delayed wound healing, anaemia, lesions in teeth and gums) |
| <i>Vitamin B Complex</i> | |
| (i) <i>Thiamine</i> (<i>Vitamin B₁</i>) | Beriberi ('dry' or peripheral neuritis, 'wet' or cardiac manifestations, 'cerebral' or Wernicke-Korsakoff's syndrome) |
| (ii) <i>Riboflavin</i> (<i>Vitamin B₂</i>) | Ariboflavinosis (ocular lesions, cheilosis, glossitis, dermatitis) |
| (iii) <i>Niacin/Nicotinic acid</i> (<i>Vitamin B₃</i>) | Pellagra (dermatitis, diarrhoea, dementia) |
| (iv) <i>Pyridoxine</i> (<i>Vitamin B₆</i>) | Vague lesions (convulsions in infants, dermatitis, cheilosis, glossitis, sideroblastic anaemia) |
| (v) <i>Folate/Folic acid</i> | Megaloblastic anaemia |
| (vi) <i>Cyanocobalamin</i> (<i>Vitamin B₁₂</i>) | Megaloblastic anaemia Pernicious anaemia |
| (vii) <i>Biotin</i> | Mental and neurological symptoms |
| <i>Choline</i> | Fatty liver, muscle damage |
| <i>Flavonoids</i> | Preventive of neurodegenerative disease, osteoporosis, diabetes |

- Maintenance of normal cartilaginous and bone growth.
- Increased immunity against infections in children.
- Anti-proliferative effect. β-carotene has anti-oxidant properties and may cause regression of certain non-tumorous skin diseases, premalignant conditions and certain cancers.

LESIONS IN VITAMIN A DEFICIENCY Nutritional deficiency of vitamin A is common in countries of South-East Asia, Africa, Central and South America whereas malabsorption syndrome may account for conditioned vitamin A deficiency in developed countries.

MORPHOLOGIC FEATURES Consequent to vitamin A deficiency, following pathologic changes are seen (Fig. 8.8):

1. Ocular lesions Lesions in the eyes are most obvious. *Night blindness* is usually the first sign of vitamin A deficiency. As a result of replacement metaplasia of mucus-secreting cells by squamous cells, there is dry and scaly scleral conjunctiva (*xerophthalmia*). The lacrimal duct also shows hyperkeratosis. Corneal ulcers may occur which may get infected and cause *keratomalacia*. *Bitot's spots* may

appear which are focal triangular areas of opacities due to accumulation of keratinised epithelium. If these occur on cornea, they impede transmission of light. Ultimately, infection, scarring and opacities lead to *blindness*.

2. Cutaneous lesions The skin develops papular lesions giving toad-like appearance (*xeroderma*). This is due to follicular hyperkeratosis and keratin plugging in the sebaceous glands.

3. Other lesions These are as under:

- Squamous metaplasia of respiratory epithelium* of bronchus and trachea may predispose to respiratory infections.
- Squamous metaplasia of pancreatic ductal epithelium* may lead to obstruction and cystic dilatation.
- Squamous metaplasia of urothelium* of the pelvis of kidney may predispose to pyelonephritis and perhaps to renal calculi.
- Long-standing metaplasia may cause progression to *anaplasia* under certain circumstances.
- Bone growth* in vitamin A deficient animals is retarded.

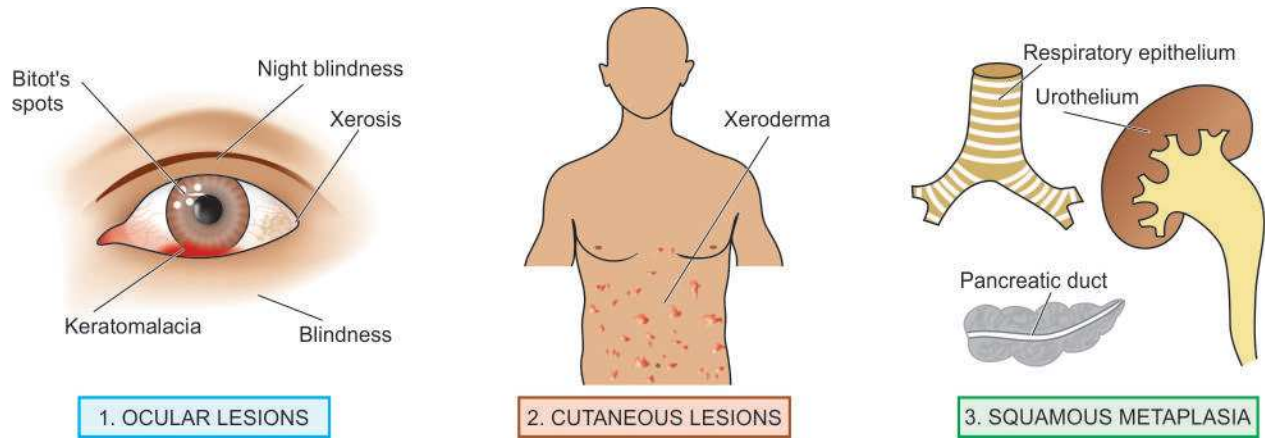

Figure 8.8 Lesions resulting from vitamin A deficiency.

vi) *Immune dysfunction* may occur due to damaged barrier epithelium and compromised immune defenses.

vii) *Pregnant women* may have increased risk of maternal infection, mortality and impaired embryonic development.

HYPERVITAMINOSIS A Very large doses of vitamin A can produce toxic manifestations in children as well as in adults. These may be *acute or chronic*.

Acute toxicity This results from a single large dose of vitamin A. The effects include neurological manifestations resembling brain tumour e.g. headache, vomiting, stupor, papilloedema.

Chronic toxicity The clinical manifestations of chronic vitamin A excess are as under:

- i) *Neurological* such as severe headache and disordered vision due to increased intracranial pressure.
- ii) *Skeletal pains* due to loss of cortical bone by increased osteoclastic activity as well as due to exostosis.
- iii) *Cutaneous involvement* may be in the form of pruritus, fissuring, sores at the corners of mouth and coarseness of hair.
- iv) *Hepatomegaly* with parenchymal damage and fibrosis.
- v) *Hypercarotenaemia* is yellowness of palms and skin due to excessive intake of β -carotene containing foods like carrots or due to inborn error of metabolism.

The effects of toxicity usually disappear on stopping excess of vitamin A intake.

Vitamin D (Calcitriol)

PHYSIOLOGY This fat-soluble vitamin exists in 2 activated *sterol forms*:

- ◆ Vitamin D₂ or *calciferol*; and
- ◆ Vitamin D₃ or *cholecalciferol*.

The material originally described as vitamin D₁ was subsequently found to be impure mixture of sterols. Since vitamin D₂ and D₃ have similar metabolism and functions, they are therefore referred to as vitamin D.

There are 2 *main sources* of vitamin D:

i) **Endogenous synthesis** 80% of body's need of vitamin D is met by endogenous synthesis from the action of ultraviolet light on 7-dehydrocholesterol widely distributed in oily secretions of the skin. The vitamin so formed by irradiation

enters the body directly through the skin. Pigmentation of the skin reduces the beneficial effects of ultraviolet light.

ii) **Exogenous sources** The other source of vitamin D is diet such as deep sea fish, fish oil, eggs, butter, milk, some plants and grains.

Irrespective of the source of vitamin D, it must be converted to its *active metabolites* (25-hydroxy vitamin D and 1,25-dihydroxy vitamin D or calcitriol) after its metabolism in the liver and kidney for being functionally active (**Fig. 8.9**).

1, 25-dihydroxy vitamin D (calcitriol) is 5-10 times more potent biologically than 25-hydroxy vitamin D. The production of calcitriol by the kidney is regulated by:

- i) plasma levels of calcitriol (hormonal feedback);
- ii) plasma calcium levels (hypocalcaemia stimulates synthesis); and
- iii) plasma phosphorus levels (hypophosphataemia stimulates synthesis).

The main storage site of vitamin D is the adipose tissue rather than the liver which is the case with vitamin A.

The main **physiologic functions** of the most active metabolite of vitamin D, calcitriol, are mediated by its binding

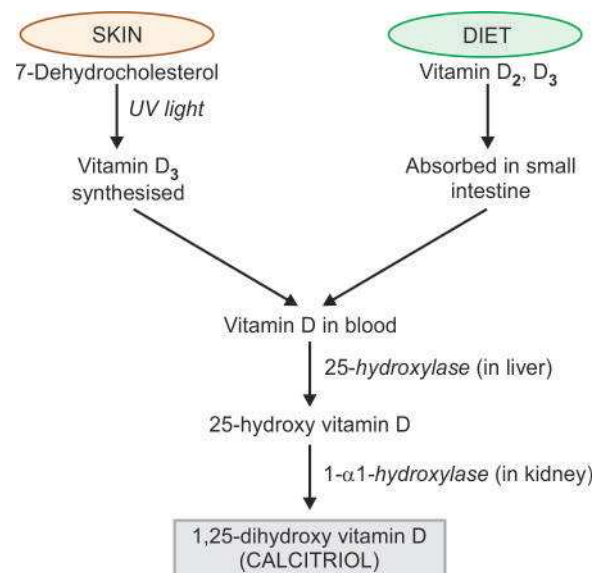

Figure 8.9 Normal metabolism of vitamin D.

to nuclear receptor superfamily, vitamin D receptor, expressed on a wide variety of cells. These actions are as under:

1. Maintenance of normal plasma levels of calcium and phosphorus The major essential function of vitamin D is to promote mineralisation of bone. This is achieved by the following actions of vitamin D:

i) *Intestinal absorption* of calcium and phosphorus is stimulated by vitamin D.

ii) *On bones* Vitamin D is normally required for mineralisation of epiphyseal cartilage and osteoid matrix. However, in hypocalcaemia, vitamin D collaborates with parathyroid hormone and causes osteoclastic resorption of calcium and phosphorus from bone so as to maintain the normal blood levels of calcium and phosphorus.

iii) *On kidneys* Vitamin D stimulates reabsorption of calcium at distal renal tubular level, though this function is also parathyroid hormone-dependent.

2. Antiproliferative effects Vitamin D receptor is expressed on the parathyroid gland cells by which active form of vitamin D causes antiproliferative action on parathyroid cells and suppresses the parathormone gene. Besides, vitamin D receptor is also expressed on cells of organs which do not have any role in mineral ion homeostasis and has antiproliferative effects on them e.g. in skin, breast cancer cells, prostate cancer cells.

LESIONS IN VITAMIN D DEFICIENCY Deficiency of vitamin D may result from:

- i) reduced endogenous synthesis due to inadequate exposure to sunlight;
- ii) dietary deficiency of vitamin D;
- iii) malabsorption of lipids due to lack of bile salts such as in intrahepatic biliary obstruction, pancreatic insufficiency and malabsorption syndrome;
- iv) derangements of vitamin D metabolism as occur in kidney disorders (chronic renal failure, nephrotic syndrome, uraemia), liver disorders (diffuse liver disease) and genetic disorders; and
- v) resistance of end-organ to respond to vitamin D.

Deficiency of vitamin D from any of the above mechanisms results in 3 types of lesions:

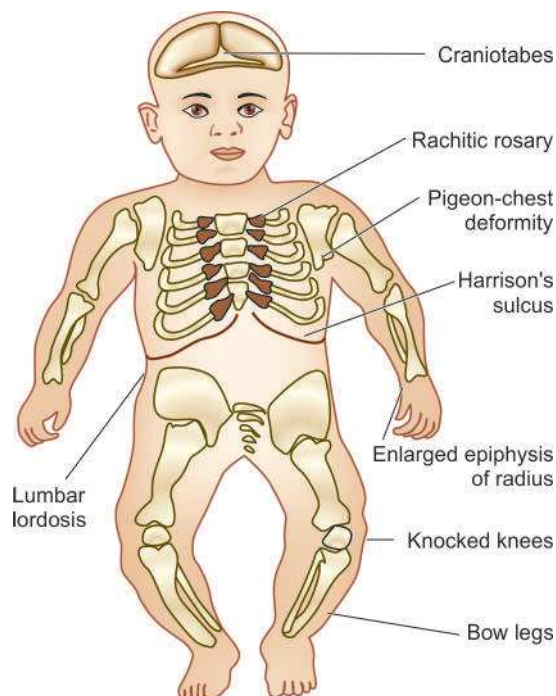

Figure 8.10 Lesions in rickets.

1. rickets in growing children;
2. osteomalacia in adults; and
3. hypocalcaemic tetany due to neuromuscular dysfunction.

RICKETS The primary defects in rickets are:

- ◆ interference with mineralisation of bone; and
- ◆ deranged endochondral and intramembranous bone growth.

The pathogenesis of lesions in rickets is better understood by contrasting them with sequence of changes in normal bone growth as outlined in **Table 8.5**.

MORPHOLOGIC FEATURES Rickets occurs in growing children from 6 months to 2 years of age. The disease has the following lesions and clinical characteristics (**Fig. 8.10**):

Table 8.5 Contrasting features of rickets with normal bone growth.

| NORMAL BONE GROWTH | RICKETS |
|--|--|
| <p>I. ENDOCHONDRAL OSSIFICATION (OCCURRING IN LONG TUBULAR BONES)</p> <ol style="list-style-type: none"> i. Proliferation of cartilage cells at the epiphyses followed by provisional mineralisation ii. Cartilage resorption and replacement by osteoid matrix iii. Mineralisation to form bone iv. Normal vascularisation of bone | <ol style="list-style-type: none"> i. Proliferation of cartilage cells at the epiphyses followed by inadequate provisional mineralisation ii. Persistence and overgrowth of epiphyseal cartilage; deposition of osteoid matrix on inadequately mineralised cartilage resulting in enlarged and expanded costochondral junctions iii. Deformed bones due to lack of structural rigidity iv. Irregular overgrowth of small blood vessels in disorganised and weak bone |
| <p>II. INTRAMEMBRANOUS OSSIFICATION (OCCURRING IN FLAT BONES)</p> <p>Mesenchymal cells differentiate into osteoblasts which develop osteoid matrix and subsequent mineralisation</p> | <p>Mesenchymal cells differentiate into osteoblasts with laying down of osteoid matrix which fails to get mineralised resulting in soft and weak flat bones</p> |

Skeletal changes These are as under:

- i) *Craniotabes* is the earliest bony lesion occurring due to small round unossified areas in the membranous bones of the skull, disappearing within 12 months of birth. The skull looks square and box-like.
- ii) *Harrison's sulcus* appears due to indrawing of soft ribs on inspiration.
- iii) *Rachitic rosary* is a deformity of chest due to cartilaginous overgrowth at costochondral junction.
- iv) *Pigeon-chest deformity* is the anterior protrusion of sternum due to action of respiratory muscles.
- v) *Bow legs* occur in ambulatory children due to weak bones of lower legs.
- vi) *Knocked knees* may occur due to enlarged ends of the femur, tibia and fibula.
- vii) *Lower epiphyses of radius may be enlarged*.
- viii) *Lumbar lordosis* is due to involvement of the spine and pelvis.

Biochemical changes These are as follows:

- i) Lowered levels of active metabolites of vitamin D (25-hydroxy vitamin D and 1, 25-dihydroxy vitamin D).
- ii) Plasma calcium levels are normal or slightly low.
- iii) Plasma phosphate levels are lowered.
- iv) Plasma alkaline phosphatase is usually raised due to osteoblastic activity.

Vitamin D-dependent rickets is an autosomal dominant disorder of vitamin D. The disease responds rapidly to administration of 1,25-dihydroxy vitamin D.

OSTEOMALACIA Osteomalacia is the adult counterpart of rickets in which there is failure of mineralisation of the osteoid matrix. It may occur following dietary deficiency, poor endogenous synthesis of vitamin D, or as a result of conditioned deficiency.

MORPHOLOGIC FEATURES Due to deficiency of vitamin D, osteoid matrix laid down fails to get mineralised. In H & E stained microscopic sections, this is identified by widened and thickened osteoid seams (stained pink) and decreased mineralisation at the borders between osteoid and bone (stained basophilic). *von Kossa's stain* for calcium may be employed to mark out the wide seams of unmineralised osteoid while the calcified bone is stained black. In addition, there may be increased osteoclastic activity and fibrosis of marrow.

Clinical features Osteomalacia is characterised by:

- i) muscular weakness;
- ii) vague bony pains;
- iii) fractures following trivial trauma;
- iv) incomplete or greenstick fractures; and
- v) looser's zones or pseudofractures at weak places in bones.

Biochemical changes These are:

- i) normal or low serum calcium levels;
- ii) plasma phosphate levels lowered; and
- iii) raised serum alkaline phosphatase due to increased osteoblastic activity.

It may be worthwhile to note here that another chronic disorder of skeleton seen in elderly, *osteoporosis*, is clinically similar but biochemically different disease (Chapter 26).

HYPERVITAMINOSIS D Very large excess of vitamin D may cause increased intestinal absorption of calcium and phosphorus, leading to hypercalcaemia, hyperphosphataemia and increased bone resorption. These changes may result in the following effects:

- i) increased urinary excretion of calcium and phosphate;
- ii) predisposition to renal calculi;
- iii) osteoporosis; and
- iv) widespread metastatic calcification, more marked in the renal tubules, arteries, myocardium, lungs and stomach.

Vitamin E (α -Tocopherol)

PHYSIOLOGY Out of many naturally-occurring tocoferols and tocotrienols, α -tocopherol is biologically the most active fat soluble compound for humans. Vitamin E is found in most of the ordinary foods such as vegetables, grains, nuts and oils. It is absorbed from the intestine and transported in blood in the form of chylomicrons. It is stored in fat depots, liver and muscle.

The main **physiologic functions** of vitamin E are as under:

1. *Anti-oxidant activity* Active form of vitamin E acts as an antioxidant and prevents the oxidative degradation of cell membranes containing phospholipids.
2. *Scavenger of free radicals* Vitamin E scavenges free radicals formed by redox reaction in the body (page 15) and thus maintains the integrity of the cell.
3. *Inhibits prostaglandin synthesis*.
4. *Activates protein kinase C and phospholipase A₂*.

LESIONS IN VITAMIN E DEFICIENCY The deficiency of vitamin E is mainly by conditioning disorders affecting its absorption and transport such as abetalipoproteinaemia, intra- and extrahepatic biliary cholestasis, cystic fibrosis of the pancreas and malabsorption syndrome. Low birth weight neonates, due to physiologic immaturity of the liver and bowel, may also develop vitamin E deficiency. Lesions of vitamin E deficiency are as follows:

1. *Neurons* with long axons develop degeneration in the posterior columns of spinal cord.
2. *Peripheral nerves* may also develop myelin degeneration in the axons.
3. *Skeletal muscles* may develop denervation.
4. *Retinal pigmentary degeneration* may occur.
5. *Red blood cells* deficient in vitamin E such as in premature infants have reduced lifespan.
6. In experimental animals, vitamin E deficiency can produce *sterility* in both male and female animals.

Vitamin K

PHYSIOLOGY Vitamin K (*K for Koagulations in Danish*) exists in nature in 2 forms:

- ◆ Vitamin K₁ or *phylloquinone*, obtained from exogenous dietary sources such as most green leafy vegetables; and
- ◆ Vitamin K₂ or *menaquinone*, produced endogenously by normal intestinal flora. Phylloquinone can be converted into menaquinone in some organs.

Like other fat-soluble vitamins, vitamin K is absorbed from the small intestine and requires adequate bile flow and intact pancreatic function.

The main **physiologic function** of vitamin K is in hepatic microsomal carboxylation reaction for vitamin K-dependent coagulation factors (most importantly factor II or prothrombin; others are factors VII, IX and X).

LESIONS IN VITAMIN K DEFICIENCY Since vitamin K is necessary for the manufacture of prothrombin, its deficiency leads of *hypoprothrombinaemia* (page 314). Estimation of plasma prothrombin, thus, affords a simple *in vitro* test for determining whether there is deficiency of vitamin K. Subjects with levels below 70% of normal should receive therapy with vitamin K.

Because most of the green vegetables contain vitamin K and that it can be synthesised endogenously, vitamin K deficiency is frequently a conditioned deficiency. The conditions which may bring about vitamin K deficiency are as follows:

1. Haemorrhagic disease of newborn The newborn infants are deficient in vitamin K because of minimal stores of vitamin K at birth, lack of established intestinal flora for endogenous synthesis and limited dietary intake since breast milk is a poor source of vitamin K. Hence the clinical practice is to routinely administer vitamin K at birth.

2. Biliary obstruction Bile is prevented from entering the bowel due to biliary obstruction which prevents the absorption of this fat-soluble vitamin. Surgery in patients of obstructive jaundice, therefore, leads to marked tendency to bleeding.

3. Due to malabsorption syndrome Patients suffering from malabsorption of fat develop vitamin K deficiency e.g. coeliac disease, sprue, pancreatic disease, hypermotility of bowel etc.

4. Due to anticoagulant therapy Patients on warfarin group of anticoagulants have impaired biosynthesis of vitamin K-dependent coagulation factors.

5. Due to antibiotic therapy The use of broad-spectrum antibiotics and sulfa drugs reduces the normal intestinal flora.

6. Diffuse liver disease Patients with diffuse liver disease (e.g. cirrhosis, amyloidosis of liver, hepatocellular carcinoma, hepatoblastoma) have hypoprothrombinaemia due to impaired synthesis of prothrombin. Administration of vitamin K to such patients is of no avail since liver, where prothrombin synthesis utilising vitamin K takes place, is diseased.

WATER-SOLUBLE VITAMINS

Vitamin C (Ascorbic Acid)

PHYSIOLOGY Vitamin C exists in natural sources as L-ascorbic acid closely related to glucose. The major sources of vitamin C are citrus fruits such as orange, lemon, grape fruit and some fresh vegetables like tomatoes and potatoes. It is present in small amounts in meat and milk. The vitamin is easily destroyed by heating so that boiled or pasteurised milk may lack vitamin C. It is readily absorbed from the small intestine and is stored in many tissues, most abundantly in adrenal cortex.

The **physiologic functions** of vitamin C are due to its ability to carry out *oxidation-reduction reactions*:

1. Vitamin C has been found to have *antioxidant* properties and can scavenge free radicals.
2. Ascorbic acid is required for hydroxylation of proline to form hydroxyproline which is an essential component of *collagen*.
3. Besides collagen, it is necessary for the *ground substance* of other mesenchymal structures such as osteoid, chondroitin sulfate, dentin and cement substance of vascular endothelium.
4. Vitamin C being a *reducing substance* has other functions such as:
 - ◆ hydroxylation of dopamine to norepinephrine;
 - ◆ maintenance of folic acid levels by preventing oxidation of tetrahydrofolate; and
 - ◆ role in iron metabolism in its absorption, storage and keeping it in reduced state.

LESIONS IN VITAMIN C DEFICIENCY Vitamin C deficiency in the food or as a conditioned deficiency results in scurvy. The lesions and clinical manifestations of scurvy are seen more commonly at two peak ages: in early childhood and in the very aged. These are as under (**Fig. 8.11**):

1. Haemorrhagic diathesis A marked tendency to bleeding is characteristic of scurvy. This may be due to deficiency of intercellular cement which holds together the cells of capillary endothelium. There may be haemorrhages in the skin, mucous membranes, gums, muscles, joints and underneath the periosteum.

2. Skeletal lesions These changes are more pronounced in growing children. The most prominent change is the *deranged formation of osteoid matrix and not deranged mineralisation* (c.f. the pathological changes underlying rickets already described). Growing tubular bones as well as flat bones are affected. The epiphyseal ends of growing long bones have cartilage cells in rows which normally undergo provisional mineralisation. However, due to vitamin C deficiency, the next step of laying down of osteoid matrix by osteoblasts is poor and results in failure of resorption of cartilage. Consequently,

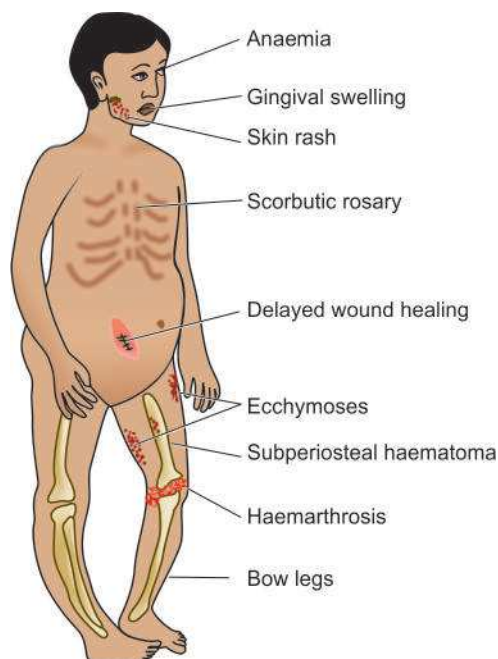

Figure 8.11 Lesions in scurvy.

mineralised cartilage under the widened and irregular epiphyseal plates project as *scorbutic rosary*. The skeletal changes are further worsened due to haemorrhages and haematomas under the periosteum and bleeding into the joint spaces.

3. Delayed wound healing There is delayed healing of wounds in scurvy due to following:

- ◆ deranged collagen synthesis;
- ◆ poor preservation and maturation of fibroblasts; and
- ◆ localisation of infections in the wounds.

4. Anaemia Anaemia is common in scurvy. It may be the result of haemorrhage, interference with formation of folic acid or deranged iron metabolism. Accordingly, anaemia is most often normocytic normochromic type; occasionally it may be megaloblastic or even iron deficiency type.

5. Lesions in teeth and gums Scurvy may interfere with development of dentin. The gums are soft and swollen, may bleed readily and get infected commonly.

6. Skin rash Hyperkeratotic and follicular rash may occur in scurvy.

VITAMIN B COMPLEX

The term vitamin B was originally coined for a substance capable of curing beriberi (B from beriberi). Now, vitamin B complex is commonly used for *a group of essential compounds which are biochemically unrelated but occur together in certain foods* such as green leafy vegetables, cereals, yeast, liver and milk. Most of the vitamins in this group are involved in metabolism of proteins, carbohydrates and fats.

The principal members of vitamin B complex are thiamine (vitamin B₁), riboflavin (vitamin B₂), niacin/nicotinic acid (vitamin B₃), pantothenic acid (vitamin B₅), pyridoxine (vitamin B₆), folate (folic acid), cyanocobalamin (vitamin B₁₂) and biotin. There is no definite evidence that any clinical disorder results from deficiency of pantothenic acid (vitamin B₅).

Thiamine (Vitamin B₁)

PHYSIOLOGY Thiamine was the first in the family of vitamin B complex group and hence named B₁. Thiamine hydrochloride is available in a variety of items of diet such as peas, beans, pulses, yeast, green vegetable roots, fruits, meat, pork, rice and wheat bran. The vitamin is lost in refined foods such as polished rice, white flour and white sugar. A few substances in the diet (strong tea, coffee) act as *anti-thiamines*. Since the vitamin is soluble in water, considerable amount of the vitamin is lost during cooking of vegetables. The vitamin is absorbed from the intestine either by passive diffusion or by energy-dependent transport. Reserves of vitamin B₁ are stored in the skeletal muscles, heart, liver, kidneys and bones.

The main **physiologic function** of thiamine is in carbohydrate metabolism. Thiamine after absorption is phosphorylated to form thiamine pyrophosphate which is functionally active compound. This compound acts as coenzyme for carboxylase so as to decarboxylate pyruvic acid, synthesises ATP and also participates in the synthesis of fat from carbohydrate. In addition, thiamin plays a role in peripheral nerve conduction by an unknown mechanism.

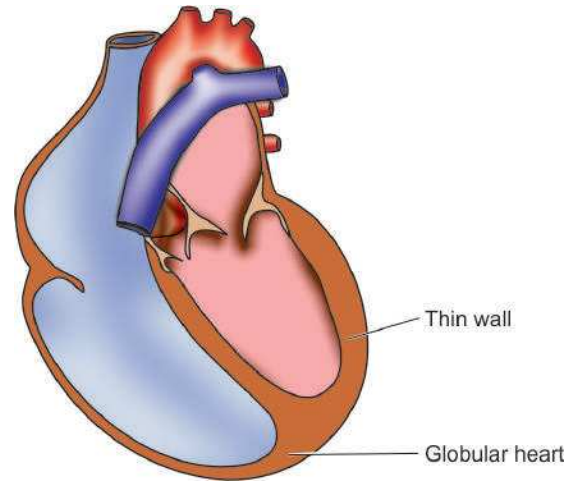

Figure 8.12 Wet (Cardiac) beriberi. Flabby, thin-walled, enlarged and globular appearance of the heart due to four-chamber dilatation.

LESIONS IN THIAMINE DEFICIENCY Thiamine deficiency can occur from primary or conditioned causes, chronic alcoholism being an important cause. The deficiency state leads to failure of complete combustion of carbohydrate and accumulation of pyruvic acid. This results in beriberi which produces lesions at 3 target tissues (peripheral nerves, heart and brain). Accordingly, beriberi is of 3 types:

- ◆ dry beriberi (*peripheral neuritis*);
- ◆ wet beriberi (*cardiac manifestations*), and
- ◆ cerebral beriberi (*Wernicke-Korsakoff's syndrome*).

It is worth-noting that lesions in beriberi are mainly located in the nervous system and heart. This is because the energy requirement of the brain and nerves is solely derived from oxidation of carbohydrates which is deranged in beriberi, while lesions in the heart appear to arise due to reduced ATP synthesis in beriberi which is required for cardiac functions.

The features of 3 forms of beriberi are as under:

1. Dry beriberi (peripheral neuritis) This is marked by neuromuscular symptoms such as weakness, paraesthesia and sensory loss. The nerves show polyneuritis, myelin degeneration and fragmentation of axons.

2. Wet beriberi (cardiac manifestations) This is characterised by cardiovascular involvement, generalised oedema, serous effusions and chronic passive congestion of viscera. The heart in beriberi is flabby (due to thin and weak myocardium), enlarged and globular in appearance due to 4-chamber dilatation (**Fig. 8.12**).

Microscopic examination of the heart shows hydropic degeneration of myocardial fibres, loss of striations, interstitial oedema and lymphocytic infiltration.

3. Cerebral beriberi (Wernicke-Korsakoff's syndrome) It consists of the following features:

i) *Wernicke's encephalopathy* occurs more often due to conditioned deficiencies such as in chronic alcoholism. It is characterised by degeneration of ganglia cells, focal demyelination and haemorrhage in the nuclei surrounding the region of ventricles and aqueduct.

Microscopic examination shows degeneration and necrosis of neurons, hypertrophy-hyperplasia of small blood vessels and haemorrhages.

ii) *Korsakoff's psychosis* results from persistence of psychotic features following brain haemorrhage in Wernicke's encephalopathy.

Riboflavin (Vitamin B₂)

PHYSIOLOGY Riboflavin used to be called 'yellow respiratory enzyme' (*flavus* = yellow), now known as 'cytochrome oxidase enzyme' which is important in view of its role as cellular respiratory coenzyme. The vitamin is usually distributed in plant and animal foods such as the liver, beef, mutton, pork, eggs, milk and green vegetables. Like other water-soluble vitamins, it is rapidly absorbed from the bowel and stored in tissues like liver.

LESIONS IN RIBOFLAVIN DEFICIENCY Lesions due to primary or conditioned deficiency of riboflavin (*aribo-flavinosis*) are as follows:

1. *Ocular lesions* consist of vascularisation of normally avascular cornea due to proliferation of capillaries from limbus. Subsequently, conjunctivitis, interstitial keratitis and corneal ulcers may develop.
2. *Cheilosis* and *angular stomatitis* are characterised by occurrence of fissures and cracks at the angles of mouth.
3. *Glossitis* is development of red, cyanosed and shiny tongue due to atrophy of mucosa of tongue ('*bald tongue*').
4. *Skin changes* appear in the form of scaly dermatitis resembling seborrheic dermatitis on nasolabial folds on the face, scrotum and vulva.
5. *Anaemia* may develop in some cases.

Niacin/Nicotinic Acid (Vitamin B₃)

PHYSIOLOGY As with thiamine and riboflavin, niacin or nicotinic acid or vitamin B₃ is also widely distributed in plant and animal foods such as the liver, kidney, meat, green vegetables and whole grain cereals. Niacin includes biologically active derivative *nicotinamide* which is essential for the formation of 2 oxidative coenzymes (*dehydrogenases*):

- ◆ NAD (nicotinamide adenine dinucleotide) which is required for dehydrogenation in the metabolism of fat, carbohydrates and proteins.
- ◆ NADP (nicotinamide adenine dinucleotide phosphate) which is essential for dehydrogenation in the hexose monophosphate shunt of glucose metabolism.

LESIONS IN NIACIN DEFICIENCY Deficiency of niacin causes pellagra, so named because of the rough skin of such patients (Italian *pelle agra* = rough skin). Pellagra may result from dietary deficiency in those who largely subsist on maize since niacin in maize is present in bound form and is hence not absorbable. Since niacin can be endogenously synthesised from tryptophan, a diet deficient in this amino acid or disorders of tryptophan metabolism such as in carcinoid syndrome or Hartnup syndrome results in niacin deficiency.

Lesions in pellagra are characterised by 3Ds:

1. *Dermatitis*: The sun-exposed areas of skin develop erythema resembling sunburn. This may progress to chronic type of dermatitis with blister formation.

2. *Diarrhoea*: Lesions similar to those seen in skin may develop in mucous membrane of the alimentary tract resulting in glossitis, lesions in the mouth, oesophagus, stomach and colon and cause diarrhoea, nausea, vomiting and burning sensation.

3. *Dementia*: Degeneration of neurons of the brain and of spinal tract results in neurological symptoms such as dementia, peripheral neuritis, ataxia and visual and auditory disturbances.

TOXICITY OF NIACIN Toxicity due to administration of high doses of niacin as therapy for dyslipidaemia has been observed but not due to dietary excess. It is characterised by flushing of skin and liver derangement.

Pyridoxine (Vitamin B₆)

PHYSIOLOGY Pyridoxine or vitamin B₆ is widely distributed in all animal and plant foods such as meat, liver, eggs, green vegetables and whole grain cereals. Pyridoxine exists in 3 closely related naturally-occurring substances—*pyridoxine*, *pyridoxal* and *pyridoxamine*. All of these can be converted into biologically active coenzyme, pyridoxal 5-phosphate.

The major **physiologic functions** of pyridoxine are related to:

- i) fat metabolism;
- ii) protein metabolism;
- iii) amino acid metabolism such as decarboxylation of amino acids, transmethylation of methionine, conversion of tryptophan to niacin;
- iv) steroid metabolism;
- v) neurotransmitter synthesis; and
- vi) haem synthesis.

LESIONS IN PYRIDOXINE DEFICIENCY Vitamin B₆ deficiency may result from inadequate dietary intake or may result from secondary deficiency such as increased demand in pregnancy and lactation, chronic alcoholism and intake of certain drugs (e.g. isoniazid in the treatment of tuberculosis, penicillamine, oestrogen in oral contraceptives etc).

The **lesions** of pyridoxine deficiency include the following:

1. Convulsions in infants born to mothers who had been administered large doses of vitamin B₆ for hyperemesis gravidarum (pyridoxine dependence)
2. Dermatitis and seborrhoea
3. Cheilosis and angular stomatitis
4. Glossitis (bald tongue)
5. Neuropathy
6. Depression, confusion
7. Sideroblastic anaemia.

Folate (Folic Acid) and Cyanocobalamin (Vitamin B₁₂)

Both these vitamins included in the B complex group are required for red cell formation. Their deficiency leads to megaloblastic anaemia which is discussed in Chapter 10.

BIOTIN

PHYSIOLOGY Biotin is a water-soluble vitamin and a member of vitamin B complex group. It is available in food sources such as organ meat, soya beans, egg yolk; however egg-white has a protein avidin which binds to biotin and blocks its bioavailability.

The major **physiologic functions** of biotin are as under:

1. In gene expression
2. In gluconeogenesis
3. In fatty acid synthesis
4. In catabolism of certain amino acids such as leucine
5. As carrier of CO₂ in carboxylase enzymes.

LESIONS IN BIOTIN DEFICIENCY Biotin deficiency is rare and develops due to inborn errors of metabolism and in patients on parenteral nutrients devoid of biotin. The lesions of biotin deficiency are as under:

1. Mental and neurologic symptoms such as hallucination, depression, paraesthesia
2. Anorexia
3. Nausea
4. Scaly, seborrhoeic dermatitis
5. In infants, hypotonia, alopecia and rash near ears.

In concluding the discussion of vitamin B complex, it must be mentioned that many of the animal and plant foods contain vitamin B complex group of vitamins. Their deficiency, whether primary from poverty, ignorance etc, or secondary from conditioning factors like chronic alcoholism, is more frequently *multiple vitamin deficiency*. Hence, the clinical practice is to administer combination of these members of vitamin B complex.

CHOLINE

PHYSIOLOGY Choline is precursor form of acetylcholine and betaine. Choline is widely distributed as lecithin in foods such as egg yolk, milk, wheat and organ meat. Choline is also synthesised in the liver.

The major **physiologic functions** of choline are as under:

1. In maintenance structural integrity of cell membranes
2. In transmembrane signalling pathways
3. In cholinergic neurotransmission
4. In metabolism of lipids and cholesterol.

LESIONS IN CHOLINE DEFICIENCY Choline deficiency develops in patients on choline-free parenteral nutrients. The lesions of choline deficiency are as under:

1. Fatty liver with deranged liver enzymes
2. Skeletal muscle damage with elevated CPK levels.

FLAVONOIDS

PHYSIOLOGY Flavonoids are a form of polyphenols present in several fruits and vegetables and are the constituents which impart colour, flavour and taste to these edible products. Particular food and vegetables rich in flavonoids are berries, grapes, apples, broccoli, onions, legumes etc.

The major **physiologic functions** of flavonoids are as under:

1. As antioxidants
2. In cell signaling pathways

LESIONS IN FLAVONOID DEFICIENCY Flavonoids have been a recent addition to the family of vitamins. Present data on animal experiments and human clinical studies indicates that they play a role in prevention of neurodegenerative diseases, osteoporosis and diabetes.

GIST BOX 8.5

Disorders of Vitamins

- ▣ There are 4 fat-soluble vitamins: A, D, E and K. Water-soluble vitamins consist of vitamin C and members of B complex group; in addition choline, biotin and flavonoids are newer members of this group.
- ▣ Vitamin A deficiency causes ocular lesions (night blindness, xerophthalmia, Bitot's spots), xeroderma, and squamous metaplasia of various specialised epithelia (respiratory, pancreatic ductal, urothelium). A state of hypervitaminosis A may produce an acute and chronic toxicity.
- ▣ Vitamin D is derived from endogenous (synthesis from UV light) and exogenous (sea fish, eggs, butter) sources. Its deficiency may produce rickets in growing children and osteomalacia in adults. Hypervitaminosis D may lead to hypercalcaemia, hyperphosphataemia and increased bone resorption.
- ▣ Vitamin E deficiency may cause degeneration of neurons, peripheral nerves and retinal pigment.
- ▣ Vitamin K deficiency causes hypoprothrombinaemia and may produce haemorrhagic disease of newborn.
- ▣ Vitamin C deficiency results in scurvy having lesions and clinical manifestations in early childhood and in the very aged. These are haemorrhagic diathesis, skeletal derangements and delayed healing.
- ▣ The principal members of vitamin B complex and their deficiency diseases are: thiamine (vitamin B₁) causing beriberi; riboflavin (vitamin B₂) causing lesions on cornea and angle of mouth; niacin/nicotinic acid (vitamin B₃) causing pellagra having 3 Ds (dermatitis, diarrhoea, dementia); pantothenic acid (vitamin B₅) not known to cause any deficiency state; pyridoxine (vitamin B₆) causing dermatitis and seborrhea; cyanocobalamin (vitamin B₁₂) and folate (folic acid) responsible for megaloblastic anaemia; and rare deficiency of biotin may cause mental and neurological symptoms.
- ▣ Besides, deficiency of choline may cause fatty liver and flavonoids act as antioxidants.

DIET AND CANCER

Before closing the discussion of nutritional pathology, it is worthwhile to sum up relationship of these factors to carcinogenesis discussed in previous chapter. There are three possible mechanisms on which the story of this relationship can be built up:

1. Dietary Content of Exogenous Carcinogens

i) The most important example in this mechanism comes from naturally-occurring carcinogen *aflatoxin* which is strongly associated with high incidence of hepatocellular carcinoma in those consuming grain contaminated with mould, *Aspergillus flavus*.

ii) *Artificial sweeteners* (e.g. saccharine cyclomates), food additives and pesticide contamination of food are implicated as carcinogens derived from diet.

2. Endogenous Synthesis of Carcinogens or Promoters

i) In the context of etiology of *gastric carcinoma*, nitrites, nitrates and amines from the digested food are transformed in the body to carcinogens—nitrosamines and nitrosamides.

ii) In the etiology of *colon cancer*, low fibre intake and high animal-derived fats are implicated. High fat diet results in rise in the level of bile acids and their intermediate metabolites produced by intestinal bacteria which act as carcinogens. The low fibre diet, on the other hand, does not provide adequate protection to the mucosa and reduces the stool bulk and thus increases the time the stools remain in the colon.

iii) In the etiology of *breast cancer*, epidemiologic studies have implicated the role of animal proteins, fats and obesity but the evidence is yet unsubstantiated.

3. Inadequate Protective Factors

As already mentioned, some components of diet such as *vitamin C, A, E, selenium*, and β -*carotenes* have protective role against cancer. These substances in normal amounts in the body act as antioxidants and protect the cells against free radical injury but their role of supplementation in diet as prevention against cancer is unproven.

GIST BOX 8.6

Diet and Cancer

- ☐ Diet plays an important role in health and disease.
- ☐ Mechanisms of components of diet acting in carcinogenesis are due to certain exogenous carcinogenic agents in diet, endogenous synthesis of carcinogens or their promoters, and dietary content poor in protective factors against cancer, mainly antioxidants.

GENETIC DISEASES

This chapter deals with the group of disorders affecting the foetus during intrauterine life (genetic as well as developmental) and paediatric age group. In the western countries, developmental and genetic birth defects constitute about 50% of total mortality in infancy and childhood, while in the developing and underdeveloped countries 95% of infant mortality is attributed to environmental factors such as poor sanitation and undernutrition. In this chapter, following groups of genetic diseases have been discussed:

1. Developmental defects
2. Cytogenetic (Karyotypic) defects
3. Single-gene defects (Mendelian disorders)
4. Multifactorial inheritance disorders
5. Storage diseases (Inborn errors of metabolism)

Though many of diseases included in the groups discussed below have been discussed along with relevant chapters later, broad overview of these disorders is presented here.

DEVELOPMENTAL DEFECTS

Developmental defects are a group of abnormalities during foetal life due to errors in morphogenesis. The branch of science dealing with the study of developmental anomalies is called *teratology*. Certain chemicals, drugs, physical and biologic agents are known to induce such birth defects and are called *teratogens*. The morphologic abnormality or defect in an organ or anatomic region of the body so produced is called *malformation*.

PATHOGENESIS

The teratogens may result in one of the following outcomes:

- i) Intrauterine death
- ii) Intrauterine growth retardation (IUGR)
- iii) Functional defects
- iv) Malformation

The effects of teratogens in inducing developmental defects are related to the following factors:

- i) *Variable individual susceptibility to teratogen*: All patients exposed to the same teratogen do not develop birth defect.
- ii) *Intrauterine stage at which patient is exposed to teratogen*: Most teratogens induce birth defects during the first trimester of pregnancy.
- iii) *Dose of teratogen*: Higher the exposure dose of teratogen, greater the chances of inducing birth defects.
- iv) *Specificity of developmental defect for specific teratogen*: A particular teratogen acts in a particular way and induces the same specific developmental defect.

CLASSIFICATION

Various developmental anomalies resulting from teratogenic effects are categorised as under:

Agenesis means the complete absence of an organ e.g. unilateral or bilateral agenesis of kidney.

Aplasia is the absence of development of an organ with presence of rudiment or anlage e.g. aplasia of lung with rudimentary bronchus.

Hypoplasia is incomplete development of an organ not reaching the normal adult size e.g. microglossia.

Atresia refers to incomplete formation of lumen in hollow viscus e.g. oesophageal atresia.

Developmental dysplasia is defective development of cells and tissues resulting in abnormal or primitive histogenetic structures e.g. renal dysplasia (*Developmental dysplasia* is quite different from *cellular dysplasia* in relation to precancerous lesions discussed earlier on page 41).

Dystraphic anomalies are the defects resulting from failure of fusion e.g. spina bifida.

Ectopia or heterotopia refers to abnormal location of tissue at ectopic site e.g. pancreatic heterotopia in the wall of stomach.

EXAMPLES OF DEVELOPMENTAL DEFECTS

A few common clinically important examples are given below:

1. Anencephaly-spina bifida complex This is the group of anomalies resulting from failure to fuse (dystraphy). While anencephaly results from failure of neural tube closure, spina bifida occurs from incomplete closure of the spinal cord and vertebral column, often in the lumbar region. The latter results in meningocele or meningomyelocele.

2. Thalidomide malformations Thalidomide is the best known example of teratogenic drug which was used as a sedative by pregnant women in 1960s in England and Germany and resulted in high incidence of limb-reduction anomalies (phocomelia) in the newborns.

3. Foetal hydantoin syndrome Babies born to mothers on anti-epileptic treatment with hydantoin have characteristic facial features and congenital heart defects.

4. Foetal alcohol syndrome Ethanol is another potent teratogen. Consumption of alcohol by pregnant mother in first trimester increases the risk of miscarriages, stillbirths, growth retardation and mental retardation in the newborn.

5. TORCH complex Infection with TORCH group of organisms (*Toxoplasma*, *Others*, *Rubella*, *Cytomegalovirus*, and *Herpes simplex*) during pregnancy is associated with multisystem anomalies and TORCH syndrome in the newborn (page 182).

6. Congenital syphilis As discussed in Chapter 5, vertical transmission of syphilis from mother to foetus is characterised by Hutchinson's triad: interstitial keratitis, sensorineural deafness and deformed Hutchinson's teeth, along with saddle-nose deformity.

**GIST BOX 9.1****Developmental Defects**

- ▣ Developmental defects are errors in morphogenesis during foetal life which occur from use of teratogens.
- ▣ The effects of teratogens are intrauterine death and growth retardation, defects in functions or malformations.
- ▣ Developmental defects may be of varying grades that include agenesis, aplasia, hypoplasia, atresia, developmental dysplasia, failure of fusion and ectopia.
- ▣ Some common examples are anencephaly, spina bifida, thalidomide malformations, foetal hydantoin and alcohol syndrome, TORCH complex, and lesions of congenital syphilis.

CYTOGENETIC (KARYOTYPIC) ABNORMALITIES

Human germ cells (ova and sperms) contain 23 chromosomes (haploid or 1N) while all the nucleated somatic cells of the human body contain 23 pairs of chromosomes (diploid or 2N)—44 autosomes and 2 sex chromosomes, being XX in females (46, XX) and XY in males (46, XY). The branch of science dealing with the study of human chromosomal abnormalities is called cytogenetics.

In a female, one of the two X chromosomes (paternal or maternal derived) is inactivated during embryogenesis as stated in *Lyon hypothesis*. This inactivation is passed to all the somatic cells while the germ cells in the female remain unaffected i.e. ovary will always have active X chromosome. Such an inactive X chromosome in the somatic cells in females lies condensed in the nucleus and is called as *sex chromatin* seen specifically in the somatic cells in females. *Nuclear sexing* can be done for genetic female testing by preparing and staining the smears of squamous cells scraped from oral cavity, or by identifying the *Barr body* in the circulating neutrophils as drumstick appendage attached to one of the nuclear lobes (**Fig. 9.1**). A minimum of 30% cells positive for sex chromatin is indicative of genetically female composition.

Though chromosomes can be studied in any human nucleated cells, circulating lymphocytes are more often used for this purpose. The study is done by arresting the dividing cells in metaphase by colchicine and then spreading them on glass slide and staining them with Giemsa stain.

Karyotype is the photographic representation of the stained preparation of chromosomes.

Each chromosome is composed of a pair of identical double helix of chromosomal DNA called *chromatids*. The chromosomes are classified based on their length and location of the *centromere*; centromere is the point where the two chromatids cross each other (**Fig. 9.2**). The distal end of each chromosome is called telomere.

Based on centromeric location, they are classified into 3 groups:

1. *Metacentric chromosomes* (numbers 1, 3, 16, 19, 20) are those in which the centromere is exactly in the middle.
2. *Submetacentric chromosomes* (numbers 1, 3) in which the centromere divides the chromosomes into short arm (*p* arm;

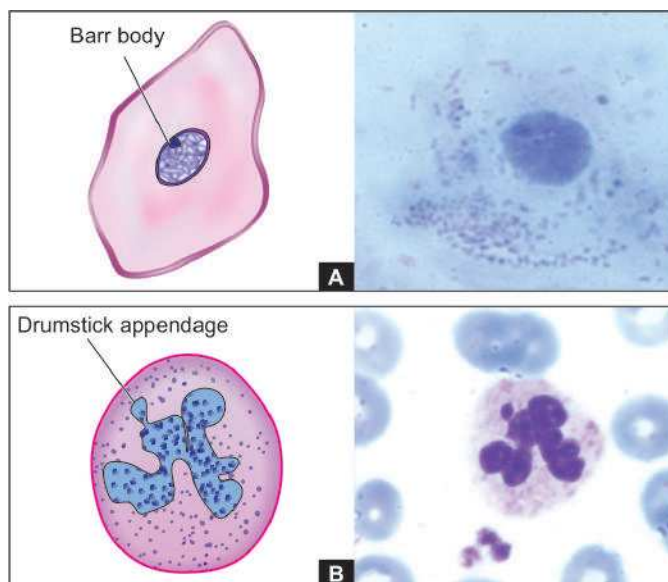

Figure 9.1 Nuclear sexing. A, Sex chromatin as seen in scraped squamous cells from oral cavity. B, Barr body seen as drumstick appendage attached to a lobe of a circulating neutrophil.

petit means short in French) and long arm (*q* arm; for alphabet next to *p*).

3. *Acrocentric chromosomes* (numbers 13, 14, 15, 21, 22, and Y) have very short arm and the centromere is eccentrically located.

Based on length of chromosomes, they are divided into 7 groups—A to G, called *Denver classification* adopted at a meeting in Denver, Colorado in US.

Chromosomal banding techniques are employed for study of classes of chromosomes. Chromosomal bands are unique alternate dark and light staining patterns. Banding techniques include:

- i) G-banding (Giemsa stain);
- ii) Q-banding (quinacrine fluorescence stain);
- iii) R-banding (reverse Giemsa staining); and
- iv) C-banding (constitutive heterochromatin demonstration).

With these brief introductory comments, we can now turn to abnormalities of chromosomes which can be divided into 2 types:

1. Numerical abnormalities; and
2. Structural abnormalities.

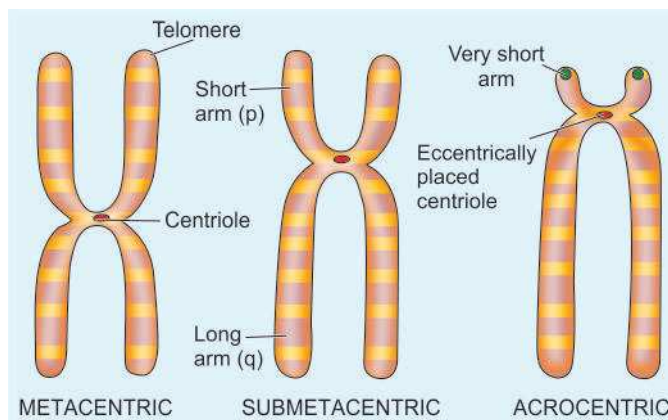

Figure 9.2 Classification of chromosomes based on size and location of centromere.

NUMERICAL ABNORMALITIES

As mentioned above, normal karyotype of a human nucleated somatic cell is diploid or $2N$ (46 chromosomes) while the germ cells have haploid or $1N$ (23 chromosomes).

1. Polyploidy is the term used for the number of chromosomes which is a multiple of haploid number e.g. triploid or $3N$ (69 chromosomes), tetraploid or $4N$ (92 chromosomes). Polyploidy occurs normally in megakaryocytes and dividing liver cells. Polyploidy in somatic cells of conceptus results in spontaneous abortions.

2. Aneuploidy is the number of chromosomes which is not an exact multiple of haploid number e.g. hypodiploid or $2N-1$ (45 chromosomes) monosomy, hyperdiploid or $2N+1$ (47 chromosomes) trisomy.

The most common mechanism of aneuploidy is **nondisjunction**. Nondisjunction is the failure of chromosomes to separate normally during cell division during first or second stage of meiosis, or in mitosis.

i) *Nondisjunction during first meiotic division* stage will result in two gametes from both the parental chromosomes due to failure to separate while the other two gametes will have no chromosomes (nullisomic).

ii) *Nondisjunction during second meiotic division* stage results in one gamete with two identical copies of the same chromosome, one nullisomic gamete, and two gametes with normal chromosome number.

iii) *Nondisjunction during mitosis* results in mosaicism, meaning thereby that the individual has two or more types of cell lines derived from the same zygote. Mosaicism of mitotic nondisjunction of chromosomes occurs in cancers.

iv) *Anaphase lag* is a form of nondisjunction involving single pair of chromosomes in which one chromosome in meiosis or a chromatid in mitosis fails to reach the pole of dividing cell at

the same time (i.e. it lags behind) and is left out of the nucleus of daughter cell. This results in one normal daughter cell and the other monosomic for the missing chromosome.

Three clinically important syndromes resulting from numerical aberrations of chromosomes due to nondisjunction are as under and their main clinical features are illustrated in **Fig. 9.3**:

◆ **Down's syndrome** There is trisomy 21 in about 95% cases of Down's syndrome due to nondisjunction during meiosis in one of the parents. Down's syndrome is the most common chromosomal disorder and is the commonest cause of mental retardation. The incidence of producing offspring with Down's syndrome rises in mothers over 35 years of age.

◆ **Klinefelter's syndrome** Klinefelter's syndrome is the most important example of sex chromosome trisomy. About 80% cases have 47, XXY karyotype while others are mosaics. Typically, these patients have testicular dysgenesis. In general, sex chromosome trisomies are more common than trisomies of autosomes.

◆ **Turner's syndrome** Turner's syndrome is an example of monosomy ($45, X0$) most often due to loss of X chromosome in paternal meiosis.

STRUCTURAL ABNORMALITIES

During cell division (meiosis as well as mitosis), certain structural abnormalities of chromosomes may appear. These may occur during gametogenesis and then transmitted to all somatic cells and cause hereditary transmissible disorders, or may produce somatic cell mutations and result in changes varying from no effect to some forms of cancers. Structural abnormalities may be balanced or unbalanced.

i) *Balanced structural alteration* means no change in total number of genes or genetic material.

ii) *Unbalanced structural alteration* refers to gene rearrangement resulting in loss or gain of genetic material.

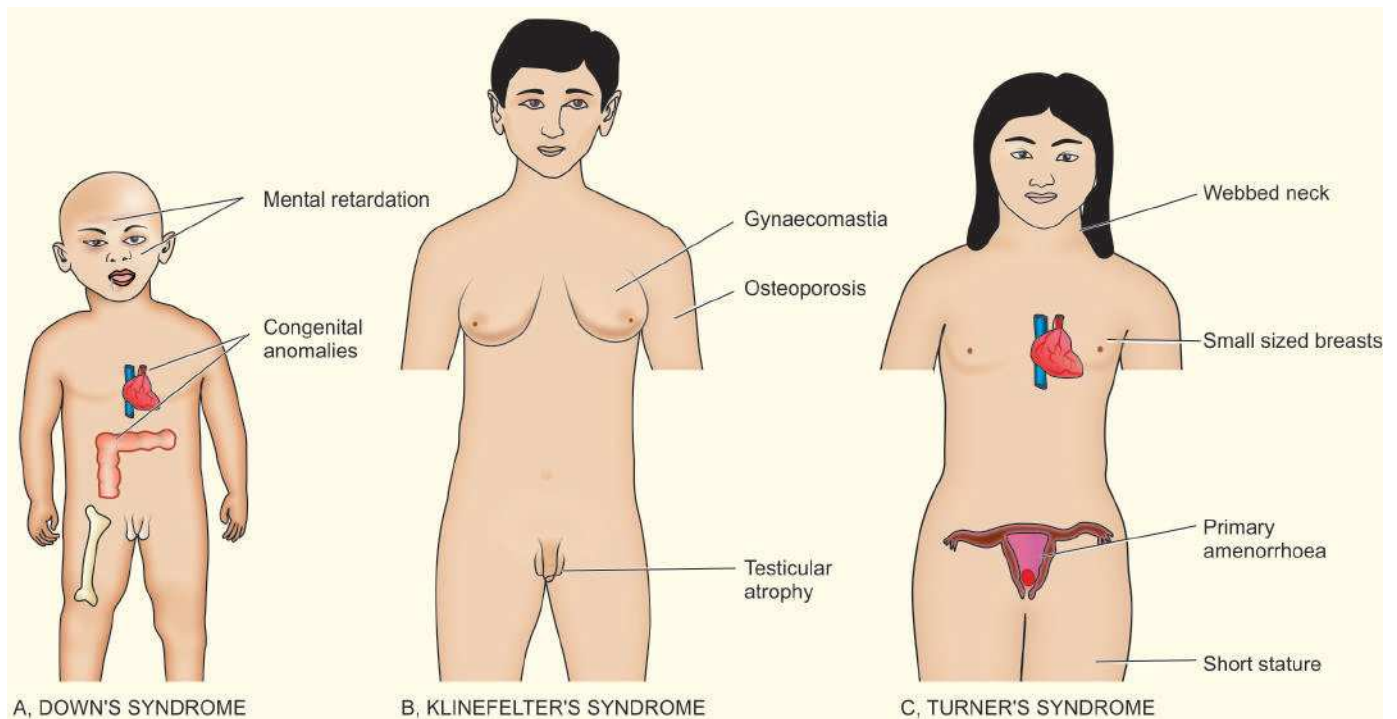

Figure 9.3 Clinical features of important forms of numerical chromosomal abnormalities.

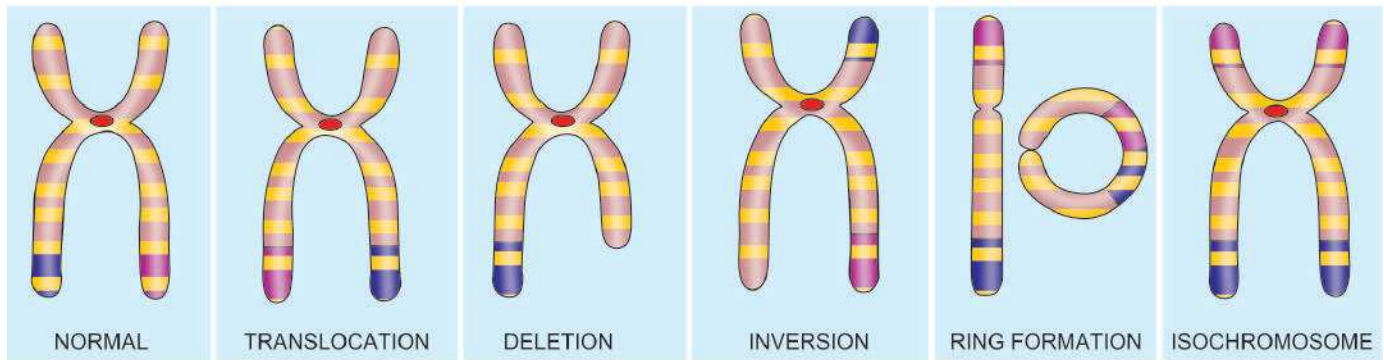

Figure 9.4 Common structural abnormalities of human chromosomes.

Some common forms of structural abnormalities are as under (**Fig. 9.4**):

1. TRANSLOCATIONS Translocation means crossing over or exchange of fragment of chromosome which may occur between non-homologous or homologous chromosomes. There are two main types of translocations: reciprocal in about two-third and Robertsonian in one-third cases:

◆ **Reciprocal translocation** is the exchange of genetic material between two non-homologous (heterologous) chromosomes without involving centromere (acentric). Such translocations occur due to single breaks in both the chromosomes and the exchange is detected by banding techniques. Reciprocal translocation may be balanced (without any loss of genetic material during the exchange) or unbalanced (with some loss of genetic material).

i) *Balanced reciprocal translocation* is more common and the individual is phenotypically normal e.g. translocation between long arm (q) of chromosomes 22 and long arm (q) of chromosome 9 written as t(9;22). This translocation is termed Philadelphia chromosome seen in most cases of chronic myeloid leukaemia (page 335).

ii) *Unbalanced reciprocal translocations* are less common and account for repeated abortions and malformed children.

◆ **Robertsonian translocation** is less common than reciprocal translocation. In this, there is fusion of two acrocentric chromosomes (having very short arms) at the centromere (centric fusion) with loss of short arms. The result of this fusion is one very large chromosome and the other very small one. Individuals born with Robertsonian translocation may be phenotypically normal but suffer from infertility and are at higher risk of producing malformed children in the next progeny.

2. DELETIONS Loss of genetic material from the chromosome is called deletion. Deletion may be from the terminal or middle portion of the chromosome. The examples of deletion are: *cri du chat* (named after cry of infant like that of a cat) syndrome (deletion of short arm of chromosome 5) and several cancers with hereditary basis (e.g. retinoblastoma with deletion of long arm of chromosome 13, Wilms' tumour with deletion of short arm of chromosome 11).

3. INVERSION Inversion is a form of rearrangement involving breaks of a single chromosome at two points. Inversion

may be pericentric or paracentric, depending upon whether the rotation occurs at the centromere or at the acentric portion of the arm of chromosome. Inversions are not associated with any abnormality.

4. RING CHROMOSOME A ring of chromosome is formed by a break at both the telomeric (terminal) ends of a chromosome followed by deletion of the broken fragment and then end-to-end fusion. The consequences of ring chromosome depend upon the amount of genetic material lost due to break.

5. ISOCHROMOSOME When centromere, rather than dividing parallel to the long axis, instead divides transverse to the long axis of chromosome, it results in either two short arms only or two long arms only called isochromosomes. The example involving isochromosome of X-chromosome is seen in some cases (15%) of Turner's syndrome.

GIST BOX 9.2

Cytogenetic (Karyotypic) Abnormalities

- ▣ Abnormalities of chromosomes may be numerical or structural.
- ▣ Numerical abnormalities may be due to polyploidy (i.e. multiple of haploid number) or aneuploidy (i.e. which is not a multiple of haploid number).
- ▣ A few common examples of numerical aberrations of chromosomes due to nondisjunction are Down's syndrome (trisomy 21), Klinefelter's syndrome (47,XXY) and Turner's syndrome (45,XO).
- ▣ Common structural abnormalities are translocations (reciprocal or Robertsonian) and deletions; others are inversion, ring chromosome, and isochromosome.

SINGLE-GENE DEFECTS (MENDELIAN DISORDERS)

In order to unravel causes of disease at genetic level, spectacular advances have been made in human genetics. With mapping of human genome consisting of about 30,000 genes, it is possible to perform molecular profiling of diseases at genetic level.

The classic laws of inheritance of characteristics or traits were outlined by Austrian monk Gregor Mendel in 1866 based on his observations of cross-breeding of red and white garden peas. Single-gene defects follow the classic mendelian patterns of inheritance and are also called mendelian disorders. These

disorders are the result of mutation of a single gene of large effect.

MUTATIONS The term mutation is applied to permanent change in the DNA of the cell. Mutations affecting germ cells are transmitted to the next progeny producing *inherited diseases*, while the mutations affecting somatic cells give rise to *various cancers* and *congenital malformations*. Presently, following types of mutations have been described:

i) Point mutation is the result of substitution of a single nucleotide base by a different base i.e. replacement of an amino acid by another e.g. in sickle cell anaemia there is point mutation by substitution of glutamic acid by valine in the polypeptide chain.

ii) Stop codon or nonsense mutation refers to a type of mutation in which the protein chain is prematurely terminated or truncated.

iii) Frameshift mutation occurs when there is insertion or deletion of one or two base pairs in the DNA sequence e.g. in cystic fibrosis of pancreas.

iv) Trinucleotide repeat mutation is characterised by amplification of a sequence of three nucleotides.

Thus, it can be summed up from above that single-gene defects are synonymous with various types of heritable mutations. Currently, approximately 5000 single-gene defects have been described—some major and others of minor consequence. While most of these disorders are discussed in relevant chapters later, the group of storage diseases (inborn errors of metabolism) is considered below.

INHERITANCE PATTERN The inheritance pattern of genetic abnormalities may be *dominant or recessive, autosomal or sex-linked*:

A *dominant gene** produces its effects, whether combined with similar dominant or recessive gene. *Recessive genes* are effective only if both genes are similar. However, when both alleles of a gene pair are expressed in heterozygous state, it is called *codominant inheritance*. A single gene may express in multiple allelic forms known as *polymorphism*. *Autosomal diseases* are due to defect in any of 1 to 22 autosomes while *sex-linked disorders* are mostly X-linked.

◆ **Autosomal dominant inheritance** pattern is characterised by one faulty copy of gene (i.e. mutant allele) in any autosome and one copy of normal allele; disease phenotype is seen in all such individuals. Patients having autosomal dominant inheritance disease have 50% chance of passing on the disease to the next generation.

◆ In **autosomal recessive inheritance**, both copies of genes are mutated. Usually, it occurs when both parents are carriers of the defective gene, i.e. having one normal allele and one defective allele in each parent, and each parent passes on their defective gene to the next progeny causing disease. There is 25% chance of transmission of autosomal recessive disease when both parents are carriers.

*A particular characteristic of an individual is determined by a pair of single genes, located at the same specific site termed *locus*, on a pair of homologous chromosomes. These paired genes are called *alleles* which may be *homozygous* when alike, and *heterozygous* if dissimilar. *Genotype* is the genetic composition of an individual while *phenotype* is the effect of genes produced.

◆ **X-linked disorders** are caused by mutations in genes on X-chromosome, derived from either one of the two X-chromosomes in females, or from the single X-chromosome of the male.

◆ There are much fewer genes on Y-chromosome and are determinant for testis. **Y-linked diseases** are rare and include male infertility, excessive hair on pinna, retinitis pigmentosa, colour blindness and XYY syndrome.

Table 9.1 lists important examples of groups of genetic disorders: *autosomal* recessive (the largest group), codominant (intermediate), and dominant, and *sex-(X-) linked* recessive and dominant disorders.

Table 9.1 Important examples of Mendelian disorders (single gene defects).

MULTIFACTORIAL INHERITANCE

Some normal phenotypic characteristics have also multifactorial inheritance e.g. colour of hair, eye, skin, height and intelligence. Multifactorial disorders are those disorders which result from the combined effect of genetic composition and environmental influences. Some common examples of such disorders in which environmental influences mask the mutant genes are as under:

1. Cleft lip and cleft palate
2. Pyloric stenosis
3. Diabetes mellitus
4. Hypertension
5. Congenital heart disease
6. Coronary heart disease.

GIST BOX 9.3

Single Gene Defects, Multifactorial Inheritance

- ▣ Mutation is permanent change in the DNA of the cell. Mutations are of different types: point, stop codon (nonsense), frameshift and trinucleotide repeat.
- ▣ The inheritance pattern of genetic abnormalities may be *dominant or recessive, autosomal or sex-linked*. Most sex-linked diseases are actually X-linked since Y chromosome has very few functional genes.
- ▣ Multifactorial inheritance is responsible for several normal phenotypic characters. Hypertension and pyloric stenosis are common examples.

STORAGE DISEASES (INBORN ERRORS OF METABOLISM)

Storage diseases or inborn errors of metabolism are biochemically distinct groups of disorders occurring due to genetic defect in the metabolism of carbohydrates, lipids, and proteins resulting in intracellular accumulation of metabolites. These substances may collect within the cells throughout the body but most commonly affected organ or site is the one where the stored material is normally found and degraded. Since lysosomes comprise the chief site of intracellular digestion (autophagy as well as heterophagy), the material is naturally stored in the lysosomes, and hence the generic name 'lysosomal storage diseases'. Cells of mononuclear-phagocyte system are particularly rich in lysosomes; therefore, reticuloendothelial organs containing numerous phagocytic cells like the liver and spleen are most commonly involved in storage disease.

Based on the biochemical composition of the accumulated material within the cells, storage diseases are classified into distinct groups, each group containing a number of diseases depending upon the specific enzyme deficiency. A summary of major groups of storage diseases along with their respective enzyme deficiencies, major accumulating metabolites and the organs involved is presented in **Table 9.2**. A few general comments can be made about all storage diseases:

- ◆ All the storage diseases occur either as a result of autosomal recessive, or sex-(X-) linked recessive genetic transmission.

Table 9.2 Storage diseases (inborn errors of metabolism).

| DISEASE | ENZYME DEFICIENCY | ACCUMULATING METABOLITE | ORGANS INVOLVED |
|---|--|---|---|
| GLYCOGEN STORAGE DISEASE | | | |
| <i>Type I (von Gierke's disease)</i> | Glucose-6-phosphatase | Glycogen | Liver, kidney |
| <i>Type II (Pompe's disease)</i> | Acid- α -glucosidase (acid maltase) | Glycogen | Heart, skeletal muscle |
| <i>Type III (Forbes'/Cori's disease)</i> | Amyloglucosidase (debrancher) | Limit dextrin | Heart, skeletal muscle |
| <i>Type IV (Anderson's disease)</i> | Amylotransglucosidase (brancher) | Amylopectin | Liver |
| <i>Type V (McArdle's disease)</i> | Muscle phosphorylase | Glycogen | Skeletal muscle |
| <i>Type VI (Hers' disease)</i> | Liver phosphorylase | Glycogen | Liver |
| <i>Type VII</i> | Phosphofructokinase | Glycogen | Muscle |
| <i>Type VIII</i> | Phosphorylase kinase | Glycogen | Liver |
| MUCOPOLYSACCHARIDOSES (MPS) | | | |
| <i>Type I to type VI MPS syndromes</i> | Different lysosomal enzymes | Chondroitin sulphate, dermatan sulphate, heparan sulphate, keratan sulphate | Connective tissue, liver, spleen, bone marrow, lymph nodes, kidneys, heart, brain |
| SPHINGOLIPIDOSES (GANGLIOSIDOSES) | | | |
| <i>GM1-gangliosidosis (infantile and juvenile types)</i> | GM1 ganglioside-galactose | GM1-ganglioside | Liver, kidney, spleen, heart, brain |
| <i>GM2-gangliosidosis (Tay-Sachs, Sandhoff's disease)</i> | Hexosaminidase | GM2-ganglioside | Liver, kidney, spleen, heart, brain |
| SULFATIDOSES | | | |
| <i>Metachromatic leucodystrophy</i> | Aryl sulfatase A | Sulfatide | Brain, liver, spleen, heart, kidney |
| <i>Krabbe's disease</i> | Galactocerebrosidase | Galactocerebroside | Nervous system, kidney |
| <i>Fabry's disease</i> | α -Galactosidase | Ceramide | Skin, kidney, heart, spleen |
| <i>Gaucher's disease</i> | Glucocerebrosidase | Glucocerebroside | Spleen, liver, bone marrow |
| <i>Niemann-Pick disease</i> | Sphingomyelinase | Sphingomyelin | Spleen, liver, bone marrow, lymph nodes, lung |

◆ Most, but not all, of the storage diseases are lysosomal storage diseases. However, out of the glycogen storage diseases, type II (Pompe's disease) is the only example of lysosomal storage disease.

A few important forms of storage diseases are described below:

GLYCOGEN STORAGE DISEASES (GLYCOGENOSES)

These are a group of inherited disorders in which there is defective glucose metabolism resulting in excessive intracellular accumulation of glycogen in various tissues. Based on specific enzyme deficiencies, glycogen storage diseases are divided into 8 main types designated by Roman numerals I to VIII. However, based on pathophysiology, glycogen storage diseases can be divided into 3 main subgroups:

1. Hepatic forms are characterised by inherited deficiency of hepatic enzymes required for synthesis of glycogen for storage (e.g. von Gierke's disease or type I glycogenosis) or due to lack of hepatic enzymes necessary for breakdown of glycogen into glucose (e.g. type VI glycogenosis).

2. Myopathic forms on the other hand, are those disorders in which there is genetic deficiency of glycolysis to form lactate in the striated muscle resulting in accumulation of glycogen in the muscles (e.g. McArdle's disease or type V glycogenosis, type VII disease).

3. Other forms are those in which glycogen storage does not occur by either hepatic or myopathic mechanisms. In Pompe's disease or type II glycogenosis, there is lysosomal storage of glycogen, while in type IV there is deposition of abnormal metabolites of glycogen in the brain, heart, liver and muscles.

The prototypes of these three forms are briefly considered below.

VON GIERKE'S DISEASE (TYPE I GLYCOGENOSIS) This condition is inherited as an autosomal recessive disorder due to deficiency of enzyme, glucose-6-phosphatase. In the absence of glucose-6-phosphatase, excess of normal type of glycogen accumulates in the liver and also results in hypoglycaemia due to reduced formation of free glucose from glycogen. As a result, fat is metabolised for energy requirement leading to hyperlipoproteinaemia and ketosis. Other changes due to deranged glucose metabolism are hyperuricaemia and accumulation of pyruvate and lactate.

The disease manifests clinically in infancy with failure to thrive and stunted growth. Most prominent feature is enormous hepatomegaly with intracytoplasmic and intranuclear glycogen. The kidneys are also enlarged and show intracytoplasmic glycogen in tubular epithelial cells. Other features include gout, skin xanthomas and bleeding tendencies due to platelet dysfunction.

POMPE'S DISEASE (TYPE II GLYCOGENOSIS) This is also an autosomal recessive disorder due to deficiency of a lysosomal enzyme, acid maltase, and is the only example of *lysosomal* storage disease amongst the various types of glycogenoses. Acid maltase is normally present in most cell types and is responsible for the degradation of glycogen. Its deficiency, therefore, results in accumulation of glycogen in many tissues, most often in the heart and skeletal muscle, leading to cardiomegaly and hypotonia.

McARDLE'S DISEASE (TYPE V GLYCOGENOSIS) The condition occurs due to deficiency of muscle phosphorylase

resulting in accumulation of glycogen in the muscle (deficiency of liver phosphorylase results in type VI glycogenosis). The disease is common in 2nd to 4th decades of life and is characterised by painful muscle cramps, especially after exercise, and detection of myoglobinuria in half the cases.

MUCOPOLYSACCHARIDOSES (MPS)

Mucopolysaccharidoses are a group of six inherited syndromes numbered from MPS I to MPS VI. Each of these result from deficiency of specific lysosomal enzyme involved in the degradation of mucopolysaccharides or glycosaminoglycans, and are, therefore, a form of lysosomal storage diseases. Mucopolysaccharides which accumulate in the MPS are: chondroitin sulphate, dermatan sulphate, heparan sulphate and keratan sulphate. All these syndromes are autosomal recessive disorders except MPS II (Hunter's syndrome) which has X-linked recessive transmission.

Syndrome of MPS manifests in infancy or early childhood and involves multiple organs and tissues, chiefly connective tissues, liver, spleen, bone marrow, lymph nodes, kidneys, heart and brain. The mucopolysaccharides accumulate in mononuclear phagocytic cells, endothelial cells, intimal smooth muscle cells and fibroblasts. The material is finely granular and PAS-positive by light microscopy. By electron microscopy, it appears in the swollen lysosomes and can be identified biochemically as mucopolysaccharide.

GAUCHER'S DISEASE

This is an autosomal recessive disorder in which there is mutation in lysosomal enzyme, acid β -glucosidase (earlier called glucocerebrosidase), which normally cleaves glucose from ceramide. This results in lysosomal accumulation of glucocerebroside (ceramide-glucose) in phagocytic cells of the body and sometimes in the neurons. The main sources of glucocerebroside in phagocytic cells are the membrane glycolipids of old leucocytes and erythrocytes, while the deposits in the neurons consist of gangliosides.

Clinically, 3 subtypes of Gaucher's disease are identified based on neuronopathic involvement:

◆ **Type I or classic form** is the adult form of disease in which there is storage of glucocerebroside in the phagocytic cells of the body, principally involving the spleen, liver, bone marrow, and lymph nodes. This is the most common type comprising 80% of all cases of Gaucher's disease.

◆ **Type II** is the infantile form in which there is progressive involvement of the central nervous system.

◆ **Type III** is the juvenile form of the disease having features in between type I and type II i.e. they have systemic involvement like in type I and progressive involvement of the CNS as in type II.

Clinical features depend upon the clinical subtype of Gaucher's disease. In addition to involvement of different organs and systems (splenomegaly, hepatomegaly, lymphadenopathy, bone marrow and cerebral involvement), a few other features include pancytopenia, or thrombocytopenia secondary to hypersplenism, bone pains and pathologic fractures.

Microscopy shows large number of characteristically distended and enlarged macrophages called *Gaucher cells*

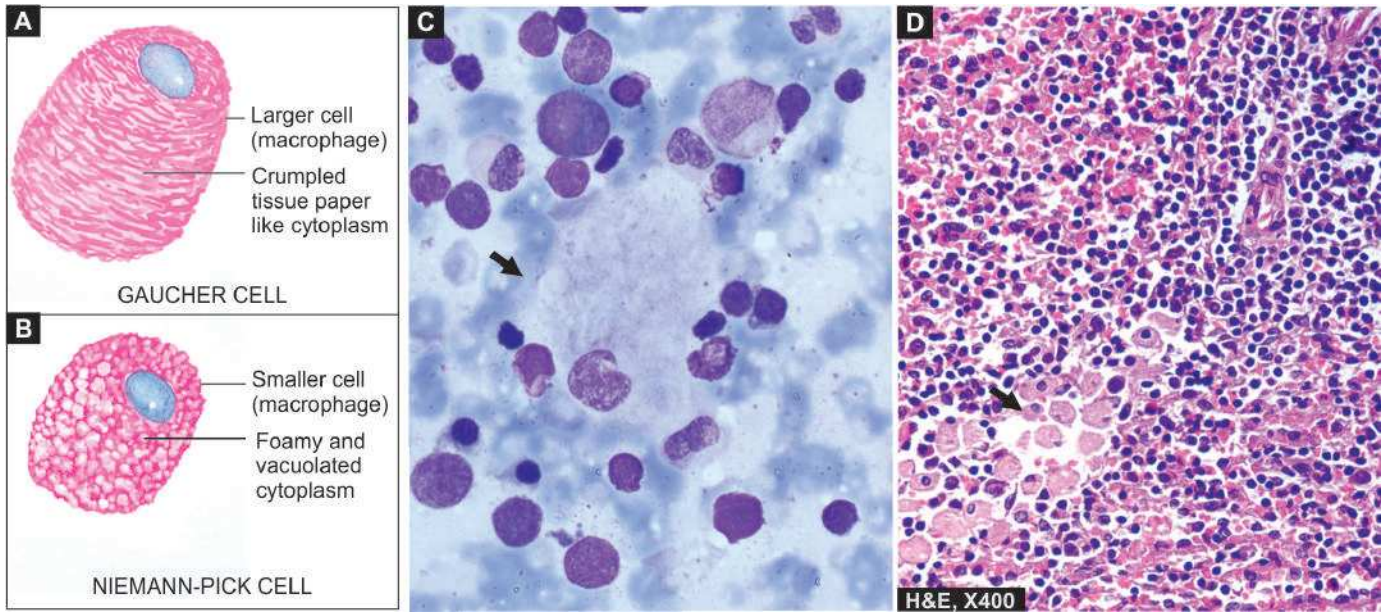

Figure 9.5 Diagrammatic view of comparative features of typical Gaucher cell (A) and typical macrophage in Niemann-Pick disease (B). C, A Gaucher cell (arrow) in bone marrow aspirate smear. D, Infiltration by Gaucher cells in red pulp of splenic parenchyma

which are found in the spleen, liver, bone marrow and lymph nodes, and in the case of neuronal involvement, in the Virchow-Robin space. The cytoplasm of these cells is abundant, granular and fibrillar resembling crumpled tissue paper. They have mostly a single nucleus but occasionally may have two or three nuclei (Fig. 9.5, A, C, D). Gaucher cells are positive with PAS, oil red O, and Prussian-blue reaction indicating the nature of accumulated material as glycolipids admixed with haemosiderin. These cells often show erythrophagocytosis and are rich in acid phosphatase.

NIEMANN-PICK DISEASE

This is also an autosomal recessive disorder characterised by accumulation of sphingomyelin and cholesterol due to defect in acid sphingomyelinase.

Two types have been described: type A and B.

◆ **Type A** is more common and typically presents in infancy and is characterised by hepatosplenomegaly, lymphadenopathy, rapidly progressive deterioration of CNS and physical underdevelopment. About a quarter of patients present with familial amaurotic idiocy with characteristic cherry-red spots in the macula of the retina (*amaurosis* = loss of vision without apparent lesion of the eye).

◆ **Type B** develops later and has a progressive hepatosplenomegaly with development of cirrhosis due to replacement of the liver by foam cells, and impaired lung function due to infiltration in lung alveoli.

Microscopy shows storage of sphingomyelin and cholesterol within the lysosomes, particularly in the cells of mononuclear phagocyte system. The cells of Niemann-Pick disease are somewhat smaller than Gaucher cells and their cytoplasm is not wrinkled but is instead foamy and vacuolated which stains positively with fat stains (Fig. 9.5, B). These cells are widely distributed in the spleen, liver, lymph nodes, bone marrow, lungs, bowel and brain.

GIST BOX 9.4

Storage Diseases

- Storage diseases or inborn errors of metabolism are biochemically distinct disorders occurring due to genetic defect in the metabolism of carbohydrates, lipids, and proteins resulting in intracellular accumulation of metabolites.
- Most of the storage diseases are lysosomal storage diseases. Out of the glycogen storage diseases, type II (Pompe's disease) is the only example of lysosomal storage disease.
- Mucopolysaccharidoses are inherited syndromes resulting from deficiency of specific lysosomal enzyme involved in the degradation of mucopolysaccharides or glycosaminoglycans.
- Gaucher's disease is an autosomal recessive disorder due to mutation in lysosomal enzyme, acid β -glucosidase (earlier called glucocerebrosidase), which normally cleaves glucose from ceramide.
- Niemann-Pick disease is also an autosomal recessive disorder characterised by accumulation of sphingomyelin and cholesterol due to defect in acid sphingomyelinase.

OTHER PAEDIATRIC DISEASES

As mentioned in the foregoing discussion, many diseases affecting infancy and childhood are genetic or developmental in origin. Here, other diseases affecting the period from birth to puberty are discussed under the heading of paediatric diseases. This period is conventionally subdivided into 4 stages:

- i) *Neonatal period*: birth to first 4 weeks
- ii) *Infancy*: first year of life
- iii) *Early childhood*: 1-4 years
- iv) *Late childhood*: 5-14 years

Each of these four stages has distinct anatomic, physiologic and immunologic development compared to adults and, therefore, has different groups of diseases unique to particular

age groups. Before discussing these diseases affecting different age groups, a few general comments about these stages can be made:

1. Neonatal period is the period of continuation of dependent intrauterine foetal life to independent postnatal period. Therefore, this is the period of maximum risk to life due to perinatal causes (e.g. prematurity, low birth weight, perinatal infections, respiratory distress syndrome, birth asphyxia, birth trauma etc) and congenital anomalies. If adequate postnatal medical care is not provided, neonatal mortality is high. Neonatal mortality in first week after birth is about 10-times higher compared to second week, and shows improvement with every passing week at this stage.

2. In infancy, the major health problems are related to congenital anomalies, infections of lungs and bowel, and sudden infant death syndrome (often during sleep).

3. Young children from 1-4 years are exposed to higher risk of sustaining injuries, and manifest certain congenital anomalies. Some malignant tumours are peculiar to this age group.

4. Older children from 5-14 years too have higher risk of injuries from accidents and have other problems related to congenital anomalies and certain malignant tumours at this age.

Thus, hazardous effects of congenital anomalies are a common denominator for all age groups from birth to adolescence. Specific tumours peculiar to infants and children are discussed along with discussion in related chapters of Systemic Pathology. However, a short note on general aspects of this subject is given below.

TUMOURS OF INFANCY AND CHILDHOOD

Tumours of infancy and childhood comprise 2% of all malignant tumours but they are the leading cause of death in this age group exceeded only by accidents. Benign tumours are more common than malignant neoplasms but they are generally of little immediate consequence. Another aspect requiring consideration here is the difficulty in differentiating benign tumours from tumour-like lesions.

HISTOGENESIS Histogenetic evolution of tumours at different age groups takes place as under:

1. Some tumours have probably evolved *in utero* and are apparent at birth or in immediate postnatal period. Such tumours are termed *developmental tumours*.

2. Many other tumours originate in abnormally developed organs and organ rests; they become apparent subsequently and are termed *embryonic tumours*.

3. In embryonic tumours, proliferation of embryonic cells occurs which *have not reached the differentiation stage* essential for specialised functions i.e. the cells proliferate as *undifferentiated or as partially differentiated* stem cells and an embryonal tumour (embryoma or blastoma) is formed.

4. Tumours of infancy and childhood have *some features of normal embryonic or foetal cells* in them which proliferate under growth promoting influence of oncogenes and suffer from mutations which make them appear morphologically malignant.

5. Under appropriate conditions, these malignant embryonal cells may *cease to proliferate* and transform into non-proliferating mature differentiated cells e.g. a neonatal neuroblastoma may mature and differentiate into benign ganglioneuroma; tissues in foetal sacrococcygeal teratoma may mature with age to adult tissues and is assigned better prognosis.

Thus, normal somatic cell maturation and neoplastic development in embryonal tumours represent two opposite ends of *ontogenesis*, with capability of some such tumours to mature and differentiate to turn benign from malignant.

BENIGN TUMOURS AND TUMOUR-LIKE CONDITIONS

Many of the benign tumours seen in infancy and childhood are actually growth of displaced cells and masses of tissues and their proliferation takes place along with the growth of the child. Some of these tumours undergo a phase of spontaneous regression subsequently—a feature usually not seen in true benign tumours. While some consider such lesions as mere *'tumour-like lesions or malformations'*, others call them benign tumours. A few such examples are as under:

Table 9.3 Common paediatric benign tumours and tumour-like lesions.

| NOMENCLATURE | MAIN FEATURES |
|---|--|
| BENIGN TUMOURS | |
| i. <i>Haemangioma</i> | <ul style="list-style-type: none"> • Most common in infancy • Commonly on skin (e.g. port-wine stain) • May regress spontaneously |
| ii. <i>Lymphangioma</i> | <ul style="list-style-type: none"> • Cystic and cavernous type common • Located in skin or deeper tissues • Tends to increase in size after birth |
| iii. <i>Sacrococcygeal teratoma</i> | <ul style="list-style-type: none"> • Often accompanied with other congenital malformations • Majority (75%) are benign; rest are immature or malignant |
| iv. <i>Fibromatosis</i> | <ul style="list-style-type: none"> • Solitary (which generally behaves as benign) to multifocal (aggressive lesions) |
| TUMOUR-LIKE LESIONS/BENIGN TUMOURS | |
| i. <i>Naevocellular naevi</i> | <ul style="list-style-type: none"> • Very common lesion on the skin |
| ii. <i>Liver cell adenoma</i> | <ul style="list-style-type: none"> • Most common benign tumour of liver |
| iii. <i>Rhabdomyoma</i> | <ul style="list-style-type: none"> • Rare foetal and cardiac tumour |

Table 9.4 Common paediatric malignant tumours.

| SYSTEM | AGE < 4 YRS | AGE 5-9 YRS | AGE 10-14 YRS |
|--------------------------|---|---|--------------------------|
| 1. <i>Haematopoietic</i> | Acute leukaemia | Acute leukaemia Lymphoma | Hodgkin's |
| 2. <i>Blastomas</i> | Neuroblastoma Hepatoblastoma Retinoblastoma Nephroblastoma (Wilms' tumour) Pleuropulmonary blastoma | Neuroblastoma Hepatocellular carcinoma | Hepatocellular carcinoma |
| 3. <i>Soft tissues</i> | Rhabdomyosarcoma | Soft tissue sarcoma | Soft tissue sarcoma |
| 4. <i>Bony</i> | — | Ewing's sarcoma | Osteogenic sarcoma |
| 5. <i>Neural</i> | CNS tumours | CNS tumours | — |
| 6. <i>Others</i> | Teratoma | — | Thyroid cancer |

1. Hamartomas Hamartomas are focal accumulations of cells normally present in that tissue but are arranged in an abnormal manner i.e. though present at normal site they do not reproduce normal architecture identical to adjacent tissues (page 185).

2. Choristoma (heterotopia) Choristoma or heterotopia is collection of normal cells and tissues at aberrant locations e.g. heterotopic pancreatic tissue in the wall of small bowel or stomach.

A list of common benign tumours and tumour-like lesions is presented in **Table 9.3**.

MALIGNANT TUMOURS

Cancers of infancy and childhood differ from those in adults in the following respects:

1. Sites Cancers of this age group more commonly pertain to haematopoietic system, neural tissue and soft tissues compared to malignant tumours in adults at sites such as the lung, breast, prostate, colon and skin.

2. Genetic basis Many of paediatric malignant tumours have underlying genetic abnormalities.

3. Regression Foetal and neonatal malignancies have a tendency to regress spontaneously or to mature.

4. Histologic features These tumours have unique histologic features in having primitive or embryonal appearance rather than pleomorphic-anaplastic histologic appearance.

5. Management Many of paediatric malignant tumours are curable by chemotherapy and/or radiotherapy but may develop second malignancy.

A few *generalisations* can be drawn about paediatric cancers:

- ◆ In infants and children under 4 years of age: the most common malignant tumours are various types of *blastomas*.
- ◆ Children between 5 to 9 years of age: *haematopoietic malignancies* are more common.
- ◆ In the age range of 10-14 years (prepubertal age): *soft tissue and bony sarcomas* are the prominent tumours.

Based on these broad guidelines, classification of common paediatric malignant tumours at different age groups is presented in **Table 9.4**. These have been discussed in related chapters later.

GIST BOX 9.5 Other Paediatric Diseases

- ☐ Tumours of infancy and childhood may evolve during intrauterine life (developmental tumours), or may be embryonic tumours arising from fully or partially differentiated stage or undifferentiated stem cells.
- ☐ Common examples of benign paediatric tumours are haemangioma, lymphangioma, sacrococcygeal teratoma and fibromatosis, besides a few possible tumours (naevi, liver cell adenoma).
- ☐ Common malignant tumours in children under 4 years of age are acute leukaemias, blastomas/embryomas (neuroblastoma, hepatoblastoma, retinoblastoma, nephroblastoma or Wilms' tumour), gliomas and teratomas.
- ☐ Common malignant tumours in older children (beyond 4 and under 14 years of age) are lymphomas, soft tissue sarcomas, osteogenic sarcoma, Ewing's sarcoma and thyroid cancer.

Section II

HAEMATOLOGY AND
LYMPHORETICULAR TISSUES

10

Introduction to Haematopoietic
System and Disorders of
Erythroid Series

The section on disorders of the haematopoietic system is concerned with diseases of the blood and the bone marrow. Conventionally, it includes study of constituents of circulating blood and blood-forming organs and thus comprises of discussion on diseases of red blood cells, white blood cells, platelets and bleeding disorders, besides an account of blood groups and blood transfusion.

However, currently the WHO classification of malignancies of haematopoietic system and lymphoreticular tissues has been widely accepted and has superseded previous FAB (French-American-British) Cooperative Group classifications. While the criteria for the FAB group classification system was the location of leucocytes (in blood and in tissues), the WHO classification takes into consideration both 'circulating' leucocytes and 'fixed' leucocytes present anywhere in the tissues together since these diseases may disseminate from one pool to the other.

Based on these modifications in classification systems, the section on diseases of blood, bone marrow and lymphoreticular tissues was restructured rationally in the last edition; the same distribution of this section into three chapters has been retained in the present edition too. These are: introduction to haematopoietic system and disorders of erythroid series (Chapter 10), disorders of platelets, bleeding disorders and basic transfusion medicine (Chapter 11) and disorders of leucocytes (myeloid and lymphoid series) and disorders of lymphoreticular tissues (Chapter 12).

It may also be mentioned here that since study and understanding of diseases of haematopoietic system involves two phases—laboratory haematology and clinical haematology, learning broad principles of management of common haematological diseases is as desirable for a student of pathology as is the need for a physician to know basic laboratory haematology.

In this chapter, following topics have been covered:

1. Bone marrow and haematopoiesis
2. Erythropoiesis
3. Anaemias—general considerations
4. Hypochromic anaemias
5. Megaloblastic anaemias—Vitamin B₁₂ and folate deficiency
6. Haemolytic anaemias and anaemia due to blood loss
7. Aplastic anaemia and other primary bone marrow disorders.

BONE MARROW AND HAEMATOPOIESIS

Haematopoiesis is production of formed elements of the blood. Normally, it takes place in the bone marrow. Circulating blood normally contains 3 main types of mature blood cells—the red cells (erythrocytes), the white cells (leucocytes) and the platelets (thrombocytes). These blood cells perform their respective major physiologic functions: *erythrocytes* largely concerned with oxygen transport, *leucocytes* play various roles in body defense against infection and tissue injury, while *thrombocytes* are primarily involved in maintaining integrity of blood vessels and in preventing blood loss. The lifespan of these cells in circulating blood is variable—neutrophils have a short lifespan of 8-12 hours, followed by platelets with a lifespan of 8-10 days, while the RBCs have the longest lifespan of 90-120 days. The rates of production of these blood cells are normally regulated in healthy individuals in such a way so as to match the rate at which they are lost from circulation. Their concentration is normally maintained within well-defined limits unless the balance is disturbed due to some pathologic processes.

HAEMATOPOIETIC ORGANS

In the human embryo, the *yolk sac* is the main site of haematopoiesis in the first few weeks of gestation. By about 3rd month, however, the *liver and spleen* are the main sites of blood cell formation and continue to do so until about 2 weeks after birth. Haematopoiesis commences in the *bone marrow* by 4th and 5th month and becomes fully active by 7th and 8th month so that at birth practically all the bones contain active marrow. During normal childhood and adult life, therefore, the marrow is the only source of new blood cells. However, during childhood, there is progressive fatty replacement throughout the long bones so that by adult life the haematopoietic marrow is confined to the central skeleton (vertebrae, sternum, ribs, skull, sacrum and pelvis) and proximal ends of femur, tibia and humerus (**Fig. 10.1**). Even in these haematopoietic areas, about 50% of the marrow consists of fat (**Fig. 10.2**). Non-haematopoietic marrow in the adult is, however, capable of reverting to active haematopoiesis in certain pathologic conditions. The spleen and liver can also resume their foetal haematopoietic role in certain pathologic conditions and is called *extramedullary haematopoiesis*.

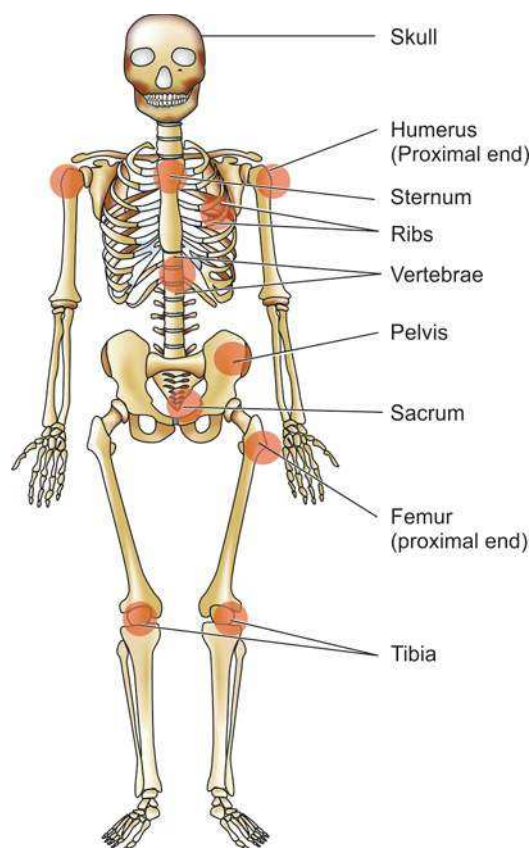

Figure 10.1 Sites of haematopoiesis in the bone marrow in the adult.

In the bone marrow, developing blood cells are situated outside the marrow sinuses, from where after maturation they enter the marrow sinuses, the marrow microcirculation and then released into circulation.

HAEMATOPOIETIC STEM CELLS

Haematopoiesis involves two stages: mitotic division or proliferation, and differentiation or maturation.

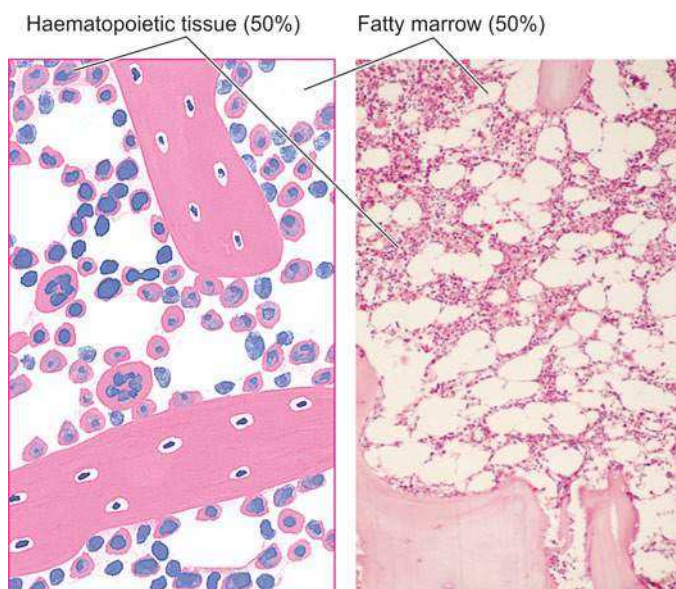

Figure 10.2 A normal bone marrow in an adult as seen in a section after trephine biopsy. Bony trabeculae support the marrow-containing tissue. Approximately 50% of the soft tissue of the bone consists of haematopoietic tissue and 50% is fatty marrow.

It is known for a few decades that blood cells develop from a small population of common multipotent haematopoietic stem cells (HSC). HSC express a variety of cell surface proteins such as CD34 and adhesion proteins which help these cells to “home” to the bone marrow when infused. HSC have the appearance of small or intermediate-sized lymphocytes and their presence in the marrow can be demonstrated by cell culture techniques by the growth of colony-forming units (CFU) pertaining to different cell lines. HSC have the capability of maintaining their progeny by self-replication. The bone marrow provides a suitable environment for growth and development of HSC. For instance, if HSC are infused intravenously into a suitably-prepared recipient, they seed the marrow successfully but do not thrive at other sites. This principle forms the basis of bone marrow (or HSC) transplantation performed for various haematologic diseases.

After a series of divisions, HSC differentiate into two types of progenitors—*lymphoid* (immune system) stem cells, and *non-lymphoid or myeloid* (trilineage) stem cells. The former develop into T, B and NK cells while the latter differentiate into 3 types of cell lines—granulocyte-monocyte progenitors (producing neutrophils, eosinophils, basophils and monocytes), erythroid progenitors (producing red cells), and megakaryocytes (as the source of platelets). Monocytes on entering the tissues form a variety of phagocytic macrophages, both of which together constitute mononuclear-phagocyte system (page 46). Lymphopoietic cells in the marrow undergo differentiation to form B, T and natural killer (NK) cells of the immune system. The development of mature cells (*i.e. poiesis*)—red cells (erythropoiesis), granulocytes (granulopoiesis), monocytes, lymphocytes (lymphopoiesis) and platelets (thrombopoiesis) are considered in detail later under relevant headings.

Two cardinal functions of HSC are self-renewal and differentiation of their progenitor cells to produce leucocytes, erythroid cells and platelets (**Fig. 10.3**). Haematopoiesis or myelopoiesis is regulated by certain endogenous glycoproteins called haematopoietic growth factors, cytokines and hormones. For example:

- i) Erythropoietin: for red cell formation
- ii) Granulocyte colony-stimulating factor (G-CSF): for production of granulocytes
- iii) Granulocyte-macrophage colony-stimulating factor (GM-CSF): for production of granulocytes and monocyte-macrophages
- iv) Thrombopoietin; for production of platelets

Each of these growth factors acts on their specific receptors to initiate further cell events as discussed under respective topics later.

BONE MARROW EXAMINATION

Examination of the bone marrow provides an invaluable diagnostic help in some cases, while in others it is of value in confirming a diagnosis suspected on clinical examination or on the blood film. A peripheral blood smear examination, however, must always precede bone marrow examination.

Bone marrow examination may be performed by two methods—*aspiration* and *trephine biopsy*. A comparison of the two methods is summarised in **Table 10.1**.

BONE MARROW ASPIRATION The method involves suction of marrow via a strong, wide bore, short-bevelled needle fitted with a stylet and an adjustable guard in order to prevent excessive penetration; for instance Salah bone marrow aspiration needle (**Fig. 10.4,A**). Smears are prepared immediately from the bone

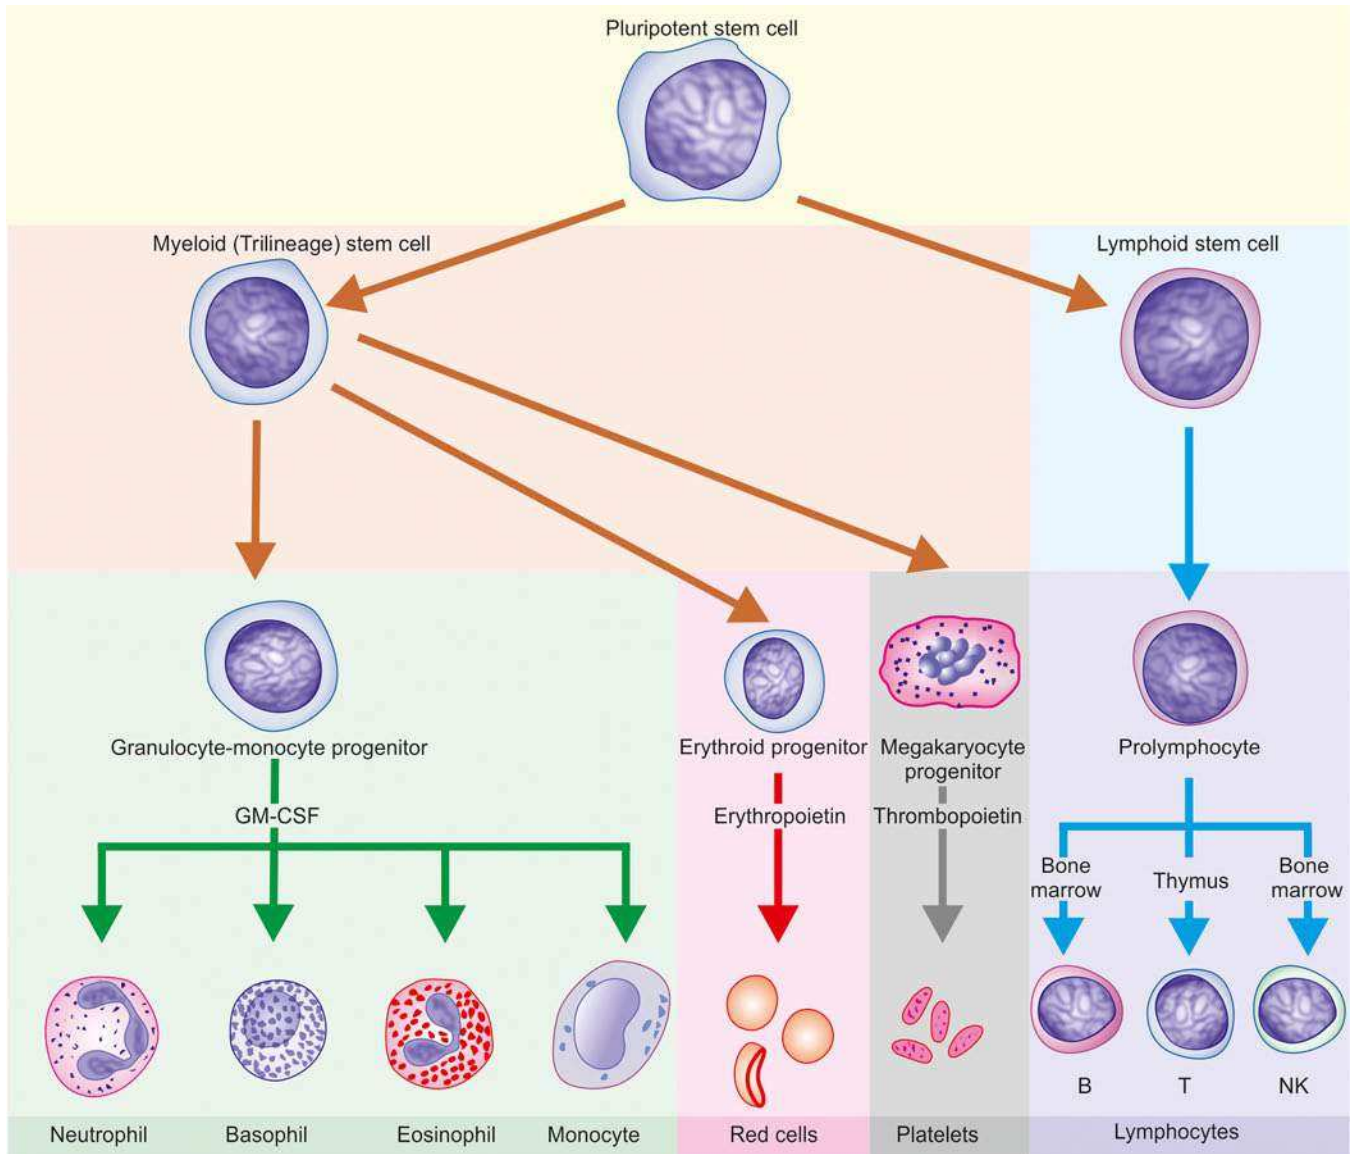

Figure 10.3 Schematic representation of differentiation of multipotent stem cells into blood cells.

marrow aspirate and are fixed in 95% methanol after air-drying. The usual Romanowsky technique is employed for staining and a stain for iron is performed routinely so as to assess the reticuloendothelial stores of iron.

The marrow film provides assessment of cellularity, details of developing blood cells (i.e. normoblastic or megaloblastic, myeloid, lymphoid, macrophages and megakaryocytic), ratio between erythroid and myeloid cells, storage diseases,

Table 10.1 Comparison of bone marrow aspiration and trephine biopsy.

| FEATURE | ASPIRATION | TREPINE |
|-----------------------|--|---|
| 1. <i>Site</i> | Sternum, posterior iliac crest; tibial head in infants | Posterior iliac crest |
| 2. <i>Instrument</i> | Salah BM aspiration needle | Jamshidi trephine needle |
| 3. <i>Stains</i> | Romanowsky, Perls' reaction for iron on smears | Haematoxylin and eosin, reticulin on tissue sections |
| 4. <i>Time</i> | Within 1-2 hours | Within 1-7 days |
| 5. <i>Morphology</i> | Better cellular morphology of aspiration smears but marrow architecture is indistinct | Better marrow architectural pattern but cell morphology is not as distinct since tissue sections are examined and not smears |
| 6. <i>Indications</i> | Anaemias, suspected leukaemias, neutropenia thrombocytopenia, polycythaemia, myeloma, lymphomas, carcinomatosis, lipid storage diseases, granulomatous conditions, parasites, fungi, and unexplained enlargements of liver, spleen or lymph nodes. | Additional indications are: myelosclerosis, aplastic anaemia and in cases with 'dry tap' on aspiration, immunohistochemical stains. |

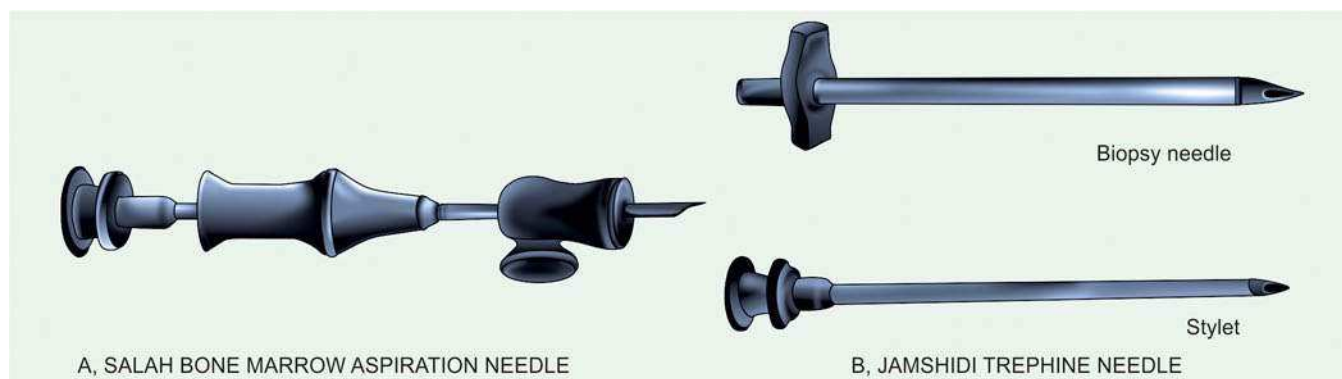

Figure 10.4 The Salah bone marrow aspiration needle (A), Jamshidi trephine needle (B).

and for the presence of cells foreign to the marrow such as secondary carcinoma, granulomatous conditions, fungi (e.g. histoplasmosis) and parasites (e.g. malaria, leishmaniasis, trypanosomiasis). Estimation of the proportion of cellular components in the marrow, however, can be provided by doing a differential count of at least 500 cells (myelogram, **Table 10.2**). In some conditions, the marrow cells can be used for more detailed special tests such as cytogenetics, microbiological culture, biochemical analysis, and immunological and cytological markers.

TREPHINE BIOPSY Trephine biopsy is performed by a simple *Jamshidi trephine needle* by which a core of tissue from periosteum to bone marrow cavity is obtained (**Fig. 10.4,B**). The tissue is then fixed, soft decalcified and processed for histological sections and stained with haematoxylin and eosin and for reticulin. Trephine biopsy is useful over aspiration since it provides an excellent view of the overall marrow architecture, cellularity, and presence or absence of infiltrates, but is less valuable than aspiration as far as individual cell morphology is concerned.

GIST BOX 10.1 Bone Marrow and Haematopoiesis

- Haematopoiesis commences in the bone marrow by 4th and 5th month and becomes fully active by 7th and 8th month. During normal childhood and adult life, the marrow is the only source of new blood cells.
- Haematopoietic stem cells (HSC) in the bone marrow give rise to two types of multipotent stem cells: *non-lymphoid* which differentiate into committed cell lineage, and *lymphoid stem cells* which differentiate in the bone marrow and then migrate to the lymphoid tissues.
- HSC are regulated by a few factors such as erythropoietin, granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor and thrombopoietin.
- Examination of the bone marrow provides an invaluable diagnostic help and confirming a suspected diagnosis.
- Bone marrow examination may be performed by two methods—*aspiration* and *trephine biopsy*.
- Major indications of bone marrow aspiration are typing of anaemias, leukaemias, neutropenia and marrow infiltrations, while trephine has additional advantages in dry aspiration, myelofibrosis and aplastic anaemia.

Table 10.2 Normal adult bone marrow counts (myelogram).

| Reticulum cells: 0.1-2% |

ERYTHROPOIESIS

Erythropoiesis is production of mature erythrocytes of the peripheral blood which takes place in the bone marrow from morphologically unrecognisable HSC. Red cell production is influenced by growth factors and hormones, notably erythropoietin.

ERYTHROPOIETIN

Erythropoietic activity in the body is regulated by erythropoietin, which is produced in response to anoxia. The principal site of erythropoietin production is the kidney though there is evidence of its extra-renal production in certain unusual circumstances. Its levels are, therefore, lowered in chronic renal diseases, while a case of renal cell carcinoma may be associated with its increased production and erythrocytosis. Erythropoietin acts on the marrow at the various stages of morphologically unidentifiable as well as identifiable erythroid precursors.

Immunoassay of erythropoietin in plasma or serum can be done by sensitive techniques (ELISA and radioimmunoassay) due to its quite low values; normal values are 10-25 U/L.

Significance

1. There is an increased production of erythropoietin in most types of anaemias. However, in anaemia of chronic diseases (e.g. in infections and neoplastic conditions) there is no such enhancement of erythropoietin.
2. In polycythaemia rubra vera, there is erythrocytosis but depressed production of erythropoietin. This is because

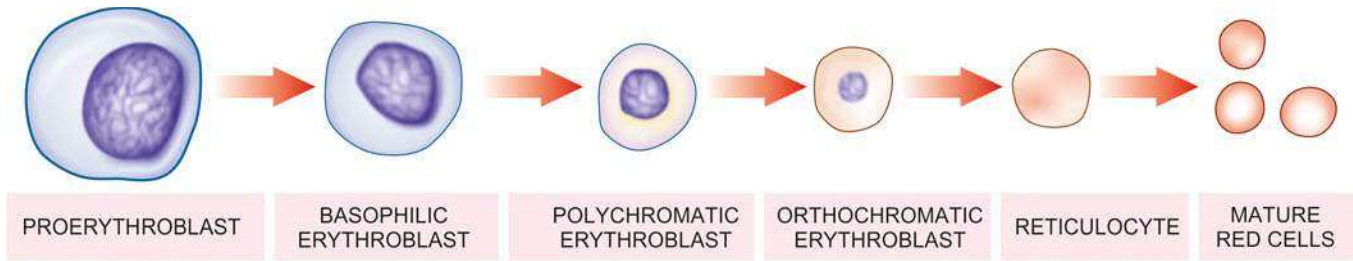

Figure 10.5 The erythroid series. There is progressive condensation of the nuclear chromatin which is eventually extruded from the cell at the late erythroblast stage. The cytoplasm contains progressively less RNA and more haemoglobin.

of an abnormality of HSC class which is not under erythropoietin control.

Besides erythropoietin, androgens and thyroxine also appear to be involved in the red cell production.

ERYTHROID SERIES

Erythroid series are a well-defined and readily recognisable lineage of nucleated red cells normally confined to the marrow. These are as under (Fig. 10.5):

1. PROERYTHROBLAST The earliest recognisable cell in the marrow is a proerythroblast or pronormoblast. It is a large cell, 15-20 μm in diameter having deeply basophilic cytoplasm and a large central nucleus containing nucleoli. The deep blue colour of the cytoplasm is due to high content of RNA which is associated with active protein synthesis. As the cells mature, the nuclei lose their nucleoli and become smaller and denser, while the cytoplasm on maturation leads to replacement of dense blue colour progressively by pink-staining haemoglobin. Each proerythroblast undergoes 4-5 replications and forms 16-32 mature RBCs.

2. BASOPHILIC (EARLY) ERYTHROBLAST It is a round cell having a diameter of 12-16 μm with a large nucleus which is slightly more condensed than the proerythroblast and contains basophilic cytoplasm. Basophilic erythroblast undergoes rapid proliferation.

3. POLYCHROMATIC (INTERMEDIATE) ERYTHROBLAST Next maturation stage has a diameter of 12-14 μm . The nucleus at this stage is coarse and deeply basophilic. The cytoplasm is characteristically polychromatic i.e. contains admixture of basophilic RNA and acidophilic haemoglobin. The cell at this stage ceases to undergo proliferative activity.

4. ORTHOCHROMATIC (LATE) ERYTHROBLAST The final stage in the maturation of nucleated red cells is the orthochromatic or late erythroblast. The cell at this stage is smaller, 8-12 μm in diameter, containing a small and pyknotic nucleus with dark nuclear chromatin. The cytoplasm is characteristically acidophilic with diffuse basophilic hue due to the presence of large amounts of haemoglobin.

5. RETICULOCYTE The nucleus is finally extruded from the late erythroblast within the marrow and a reticulocyte results. The reticulocytes are juvenile red cells devoid of nuclei but contain ribosomal RNA so that they are still able to synthesise haemoglobin. A reticulocyte spends 1-2 days in the marrow and circulates for 1-2 days in the peripheral blood before maturing in the spleen, to become a biconcave red cell. The reticulocytes

in the peripheral blood are distinguished from mature red cells by slightly basophilic hue in the cytoplasm similar to that of an orthochromatic erythroblast. Reticulocytes can be counted in the laboratory by *vital staining* with dyes such as new methylene blue or brilliant cresyl blue. The reticulocytes by either of these staining methods contain deep blue reticulofilamentous material (Fig. 10.6). While erythroblasts are not normally present in human peripheral blood, reticulocytes are found normally in the peripheral blood. Normal range of reticulocyte count in health is 0.5-2.5% in adults and 2-6% in infants. Their percentage in the peripheral blood is a fairly accurate reflection of erythropoietic activity. Their proportion is increased in conditions of rapid red cell regeneration e.g. after haemorrhage, haemolysis and haematopoietic response of anaemia to treatment.

THE RED CELL

The mature erythrocytes of the human peripheral blood are non-nucleated cells and lack the usual cell organelles. The normal human erythrocyte is a biconcave disc, 7.2 μm in diameter, and has a thickness of 2.4 μm at the periphery and 1 μm in the centre. The biconcave shape renders the red cells quite flexible so that they can pass through capillaries whose minimum diameter is 3.5 μm . More than 90% of the weight of erythrocyte consists of haemoglobin. The lifespan of red cells is 120 ± 30 days.

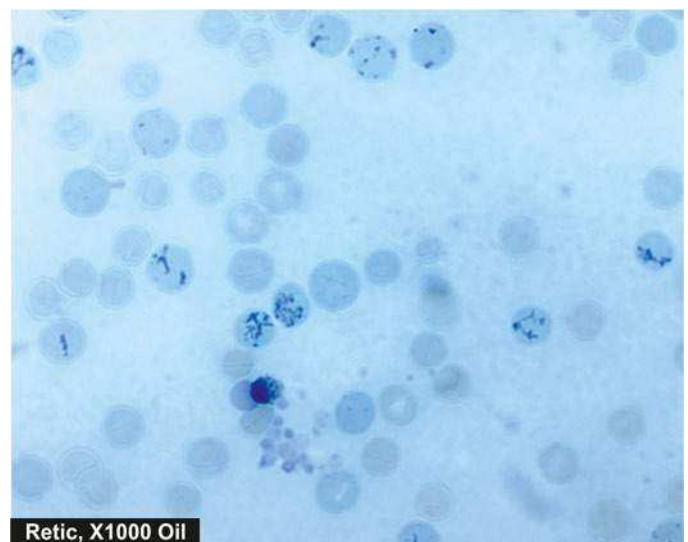

Figure 10.6 Reticulocytes in blood as seen in blood stained by supravital dye, new methylene blue.

RED CELL MEMBRANE The red cell membrane is a trilaminar structure having a bimolecular lipid layer interposed between two layers of proteins.

◆ Important *proteins* in red cell membrane are band 3 protein (named on the basis of the order in which it migrates during electrophoresis), glycophorin and spectrin.

◆ Important *lipids* are glycolipids, phospholipids and cholesterol.

◆ *Carbohydrates* form skeleton of erythrocytes having a lattice-like network which is attached to the internal surface of the membrane and is responsible for biconcave form of the erythrocytes.

A number of inherited disorders of the red cell membrane and cytoskeletal components produce abnormalities of the shape such as: *spherocytosis* (spherical shape from loss of part of the membrane), *ovalocytosis* (oval shape from loss of elasticity of cytoskeleton), *echinocytosis* (spiny processes from external surface due to metabolic abnormalities of red cells), and *stomatocytosis* (bowl-shaped red cells from expansion of inner membrane on one side).

NUTRITIONAL REQUIREMENTS FOR ERYTHROPOIESIS

New red cells are being produced each day for which the marrow requires certain essential substances. These substances are as under:

1. Metals Iron is essential for red cell production because it forms part of the haem molecule in haemoglobin. Its deficiency leads to iron deficiency anaemia. Cobalt and manganese are certain other metals required for red cell production.

2. Vitamins Vitamin B₁₂ and folate are essential for biosynthesis of nucleic acids. Deficiency of B₁₂ or folate causes megaloblastic anaemia. Vitamin C (ascorbic acid) plays an indirect role by facilitating the iron turnover in the body. Vitamin B₆ (pyridoxine), vitamin E (tocopherol) and riboflavin are the other essential vitamins required in the synthesis of red cells.

3. Amino acids Amino acids comprise the globin component of haemoglobin. Severe amino acid deficiency due to protein deprivation causes depressed red cell production.

HAEMOGLOBIN Haemoglobin consists of a basic protein, *globin*, and the iron-porphyrin complex, *haem*. The molecular weight of haemoglobin is 68,000. Normal adult haemoglobin (*HbA*) constitutes 96-98% of the total haemoglobin content and consists of four polypeptide chains, $\alpha_2\beta_2$. Small quantities of 2 other haemoglobins present in adults are: *HbF* containing $\alpha_2\gamma_2$ globin chains comprising 0.5-0.8% of total haemoglobin, and *HbA₂* having $\alpha_2\delta_2$ chains and constituting 1.5-3.5% of total haemoglobin. Most of the haemoglobin (65%) is synthesised by the nucleated red cell precursors in the marrow, while the remainder (35%) is synthesised at the reticulocyte stage.

Synthesis of haem occurs largely in the mitochondria by a series of biochemical reactions summarised in **Fig. 10.7**. Coenzyme, pyridoxal-6-phosphate, derived from pyridoxine (vitamin B₆) is essential for the synthesis of amino levulinic acid (ALA) which is the first step in the biosynthesis of protoporphyrin. The reaction is stimulated by erythropoietin and inhibited by haem. Ultimately, protoporphyrin combines with iron supplied from circulating transferrin to form haem. Each molecule of haem combines with a globin chain synthesised by polyribosomes. A tetramer of 4 globin chains, each having its own haem group, constitutes the haemoglobin molecule (**Fig. 10.8, A**).

RED CELL FUNCTIONS The essential function of the red cells is to carry oxygen from the lungs to the tissue and to transport carbon dioxide to the lungs. In order to perform these functions, the red cells have the ability to generate energy as ATP by an anaerobic glycolytic pathway (Embden-Meyerhof pathway). This pathway also generates reducing power as NADH and NADPH by the hexose monophosphate (HMP) shunt.

1. Oxygen carrying The normal adult haemoglobin, HbA, is an extremely efficient oxygen-carrier. The four units of tetramer of haemoglobin molecule take up oxygen in succession, which, in turn, results in stepwise rise in affinity of haemoglobin for oxygen. This is responsible for the *sigmoid shape* of the oxygen dissociation curve.

The oxygen affinity of haemoglobin is expressed in term of P₅₀ value which is the oxygen tension (pO₂) at which 50% of the haemoglobin is saturated with oxygen. Pulmonary capillaries have high pO₂ and, thus, there is virtual saturation of available oxygen-combining sites of haemoglobin. The tissue capillaries, however, have relatively low pO₂ and, thus, part of

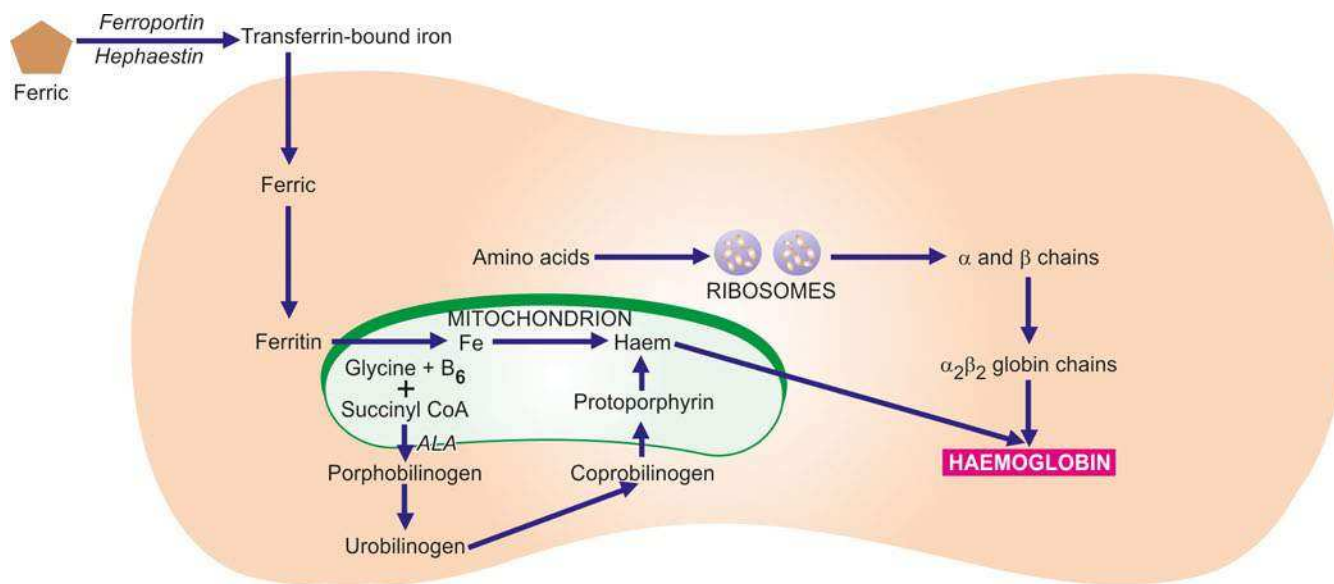

Figure 10.7 Schematic diagram of haemoglobin synthesis in the developing red cell.

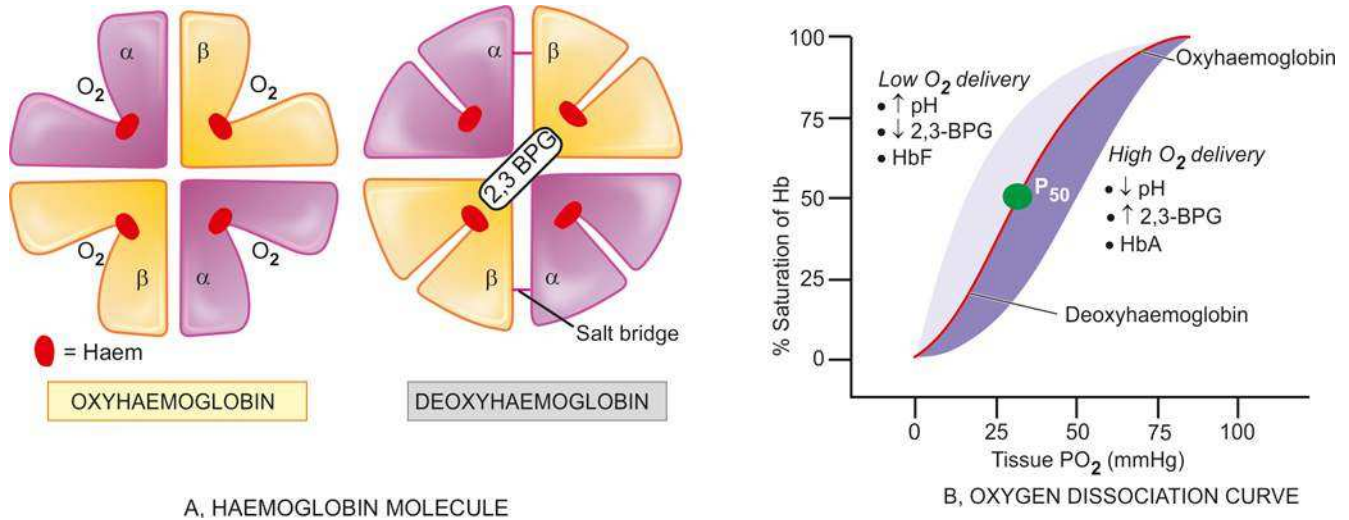

Figure 10.8 A, Normal adult haemoglobin molecule (HbA) consisting of $\alpha_2 \beta_2$ globin chains, each with its own haem group in oxy and deoxy state. The haemoglobin tetramer can bind up to four molecules of oxygen in the iron containing sites of the haem molecules. As oxygen is bound, salt bridges are broken, and 2,3-BPG and CO_2 are expelled. B, Hb-dissociation curve. On dissociation of oxygen from Hb molecule i.e. on release of oxygen to the tissues, salt bridges are formed again, and 2,3-BPG and CO_2 are bound. The shift of the curve to higher oxygen delivery is affected by acidic pH, increased 2,3-BPG and HbA molecule while oxygen delivery is less with high pH, low 2,3-BPG and HbF.

haemoglobin is in deoxy state. The extent to which oxygen is released from haemoglobin at $p\text{O}_2$, in tissue capillaries depends upon 3 factors—the nature of globin chains, the pH, and the concentration of 2,3-bisphosphoglycerate (2,3-BPG) as follows (Fig. 10.8, B):

- Normal adult haemoglobin (HbA) has *lower affinity for oxygen* than foetal haemoglobin and, therefore, releases greater amount of bound oxygen at $p\text{O}_2$ of tissue capillaries.
- A *fall in the pH* (acidic pH) lowers affinity of oxyhaemoglobin for oxygen, so called the Bohr effect, thereby causing enhanced release of oxygen from erythrocytes at the lower pH in tissue capillaries.
- A *rise in red cell concentration of 2,3-BPG*, an intermediate product of Embden-Meyerhof pathway, as occurs in anaemia and hypoxia, causes decreased affinity of HbA for oxygen. This, in turn, results in enhanced supply of oxygen to the tissue.

2. CO_2 transport Another important function of the red cells is the CO_2 transport. In the tissue capillaries, the $p\text{CO}_2$ is high so that CO_2 enters the erythrocytes where much of it is converted into bicarbonate ions which diffuse back into the plasma. In the pulmonary capillaries, the process is reversed and bicarbonate ions are converted back into CO_2 . Some of the CO_2 produced by tissues is bound to deoxyhaemoglobin forming carbamino-haemoglobin. This compound dissociates in the pulmonary capillaries to release CO_2 .

RED CELL DESTRUCTION Red cells have a mean lifespan of 120 days, after which red cell metabolism gradually deteriorates as the enzymes are not replaced. The destroyed red cells are removed mainly by the macrophages of the reticuloendothelial (RE) system of the marrow, and to some extent by the macrophages in the liver and spleen (Fig. 10.9). The breakdown of red cells liberates iron for recirculation via plasma transferrin to marrow erythroblasts, and protoporphyrin which is broken down to bilirubin. Bilirubin circulates to the liver where it is conjugated to its diglucuronide which is excreted in the gut via bile and converted to stercobilinogen and stercobilin excreted in the faeces. Part of stercobilinogen and stercobilin is reabsorbed and excreted in the urine as urobilinogen and urobilin. A small fragment of protoporphyrin is converted to

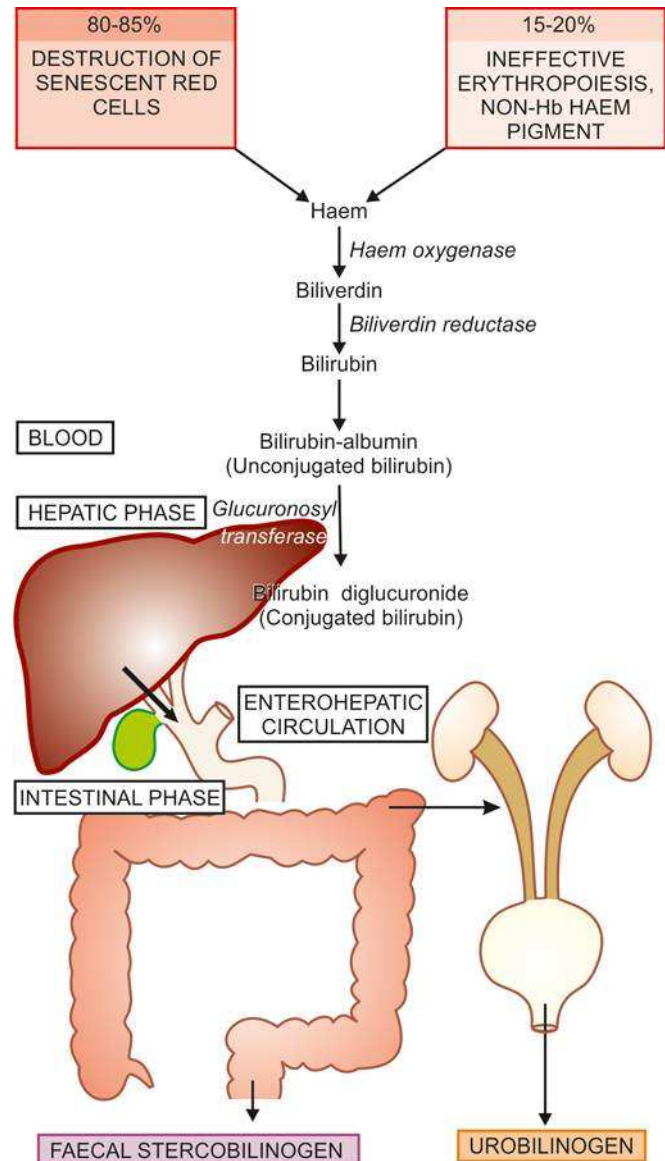

Figure 10.9 Normal red cell destruction in the RE system.

carbon monoxide and excreted in exhaled air from the lungs. Globin chains are broken down to amino acids and reused for protein synthesis in the body.

NORMAL VALUES AND RED CELL INDICES Range of normal red cell count in health is $5.5 \pm 1.0 \times 10^{12}/L$ in men and $4.8 \pm 1.0 \times 10^{12}/L$ in women. The packed cell volume (PCV) or haematocrit is the volume of erythrocytes per litre of whole blood indicating the proportion of plasma and red cells and ranges $0.47 \pm 0.07 L/L$ (40-54%) in men and $0.42 \pm 0.05 L/L$ (37-47%) in women. The haemoglobin content in health is $15.5 \pm 2.5 g/dl$ (13-18 g/dl) in men and $14.0 \pm 2.5 g/dl$ (11.5-16.5 g/dl) in women. Based on these normal values, a series of absolute values or red cell indices can be derived which have diagnostic importance. These are as under:

1. Mean corpuscular volume (MCV)

$$\frac{\text{PCV in L/L}}{\text{RBC count/L}}$$

The normal value is $85 \pm 8 \text{ fl}$ (77-93 fl)*.

2. Mean corpuscular haemoglobin (MCH)

$$\frac{\text{Hb/L}}{\text{RBC count/L}}$$

The normal range is $29.5 \pm 2.5 \text{ pg}$ (27-32 pg)*.

3. Mean corpuscular haemoglobin concentration (MCHC)

$$\frac{\text{Hb/dl}}{\text{PCV in L/L}}$$

The normal value is $32.5 \pm 2.5 g/dl$ (30-35 g/dl).

Since MCHC is independent of red cell count and size, it is considered to be of greater clinical significance as compared to other absolute values. It is low in iron deficiency anaemia but is usually normal in macrocytic anaemia.

4. Red cell distribution width (RDW) RDW is an assessment of varying volume of red cells based on size of red cells. For example, fragmented red cells have a tiny size while the macrocytes and reticulocytes have large size.

GIST BOX 10.2 Erythropoiesis

- Erythropoietic activity in the body is regulated by erythropoietin, which is produced, mainly from kidneys, in response to anoxia. Its levels are increased in most forms of anaemias.
- Erythroid series are a series of recognisable nucleated red cells normally seen in the marrow and include proerythroblast, polychromatic erythroblast, orthochromatic erythroblast and reticulocytes.
- The mature erythrocytes of the human peripheral blood are non-nucleated cells. Red cell membrane is a trilaminar structure having a bimolecular lipid layer interposed between two layers of proteins.
- Erythropoiesis requires various nutrients, namely iron, vitamins and amino acids.
- Haemoglobin consists of a basic protein, globin, and the iron-porphyrin complex, haem.
- Essential functions performed by red cells are oxygen carrying and carbon dioxide transport.
- At the end of lifespan, red cells are destroyed and phagocytosed by macrophages.

*For conversions, the multiples used are as follows: 'deci (d) = 10^{-1} , milli (m) = 10^{-3} , micro (μ) = 10^{-6} , nano (n) = 10^{-9} , pico (p) = 10^{-12} , femto (f) = 10^{-15}

ANAEMIA—GENERAL CONSIDERATIONS

Anaemia is defined as reduced haemoglobin concentration in blood below the lower limit of the normal range for the age and sex of the individual. In adults, the lower extreme of the normal haemoglobin is taken as 13.0 g/dl for males and 11.5 g/dl for females. Newborn infants have higher haemoglobin level and, therefore, 15 g/dl is taken as the lower limit at birth, whereas at 3 months the normal lower level is 9.5 g/dl. Although haemoglobin value is employed as the major parameter for determining whether or not anaemia is present, the red cell counts, haematocrit (PCV) and absolute values (MCV, MCH and MCHC) provide alternate means of assessing anaemia.

PATHOPHYSIOLOGY

Subnormal level of haemoglobin causes lowered oxygen-carrying capacity of the blood. This, in turn, initiates compensatory physiologic adaptations such as follows:

- i) Increased release of oxygen from haemoglobin
- ii) Increased blood flow to the tissues
- iii) Maintenance of the blood volume
- iv) Redistribution of blood flow to maintain the cerebral blood supply.

Eventually, however, tissue hypoxia develops causing impaired functions of the affected tissues. The degree of functional impairment of individual tissues is variable depending upon their oxygen requirements. Tissues with high oxygen requirement such as the heart, CNS and the skeletal muscle during exercise, bear the brunt of clinical effects of anaemia.

GENERAL CLINICAL FEATURES

The haemoglobin level at which symptoms and signs of anaemia develop depends upon 4 main factors:

1. *The speed of onset of anaemia:* Rapidly progressive anaemia causes more symptoms than anaemia of slow-onset as there is less time for physiologic adaptation.
2. *The severity of anaemia:* Mild anaemia produces no symptoms or signs but a rapidly developing severe anaemia (haemoglobin below 6.0 g/dl) may produce significant clinical features.
3. *The age of the patient:* The young patients due to good cardiovascular compensation tolerate anaemia quite well as compared to the elderly. The elderly patients develop cardiac and cerebral symptoms more prominently due to associated cardiovascular disease.
4. *The haemoglobin dissociation curve:* In anaemia, the affinity of haemoglobin for oxygen is depressed as 2,3-BPG in the red cells increases. As a result, oxyhaemoglobin is dissociated more readily to release free oxygen for cellular use, causing a shift of the oxyhaemoglobin dissociation curve to the right.

SYMPTOMS In symptomatic cases of anaemia, the presenting features are: tiredness, easy fatigability, generalised muscular weakness, lethargy and headache. In older patients, there may be symptoms of cardiac failure, angina pectoris, intermittent claudication, confusion and visual disturbances.

SIGNS A few general signs common to all types of anaemias are as under:

1. Pallor Pallor is the most common and characteristic sign which may be seen in the mucous membranes, conjunctivae and skin.

2. Cardiovascular system A hyperdynamic circulation may be present with tachycardia, collapsing pulse, cardiomegaly, midsystolic flow murmur, dyspnoea on exertion, and in the case of elderly, congestive heart failure.

3. Central nervous system The older patients may develop symptoms referable to the CNS such as attacks of faintness, giddiness, headache, tinnitus, drowsiness, numbness and tingling sensations of the hands and feet.

4. Ocular manifestations Retinal haemorrhages may occur if there is associated vascular disease or bleeding diathesis.

5. Reproductive system Menstrual disturbances such as amenorrhoea and menorrhagia and loss of libido are some of the manifestations involving the reproductive system in anaemic subjects.

6. Renal system Mild proteinuria and impaired concentrating capacity of the kidney may occur in severe anaemia.

7. Gastrointestinal system Anorexia, flatulence, nausea, constipation and weight loss may occur.

In addition to the general features, specific signs may be associated with particular types of anaemia which are described later together with discussion of specific types of anaemias.

GENERAL SCHEME OF INVESTIGATIONS OF ANAEMIA

After obtaining the full medical history pertaining to different general and specific signs and symptoms, the patient is examined for evidence of anaemia. Special emphasis is placed on colour of the skin, conjunctivae, sclerae and nails. Changes in the retina, atrophy of the papillae of the tongue, rectal examination for evidence of bleeding, and presence of hepatomegaly, splenomegaly, lymphadenopathy and bony tenderness are looked for.

In order to confirm or deny the presence of anaemia, its type and its cause, the following plan of investigations is generally followed, of which complete blood counts (CBC) with reticulocyte count is the basic test.

A. HAEMOGLOBIN ESTIMATION The first and foremost investigation in any suspected case of anaemia is to carry out a haemoglobin estimation. Several methods are available but most reliable and accurate is the cyanmethaemoglobin (HiCN) method employing Drabkin's solution and a spectrophotometer. If the haemoglobin value is below the lower limit of the normal range for particular age and sex, the patient is said to be anaemic. In pregnancy, there is haemodilution and, therefore, the lower limit in normal pregnant women is less (10.5 g/dl) than in the non-pregnant state.

B. PERIPHERAL BLOOD FILM EXAMINATION The haemoglobin estimation is invariably followed by examination of a peripheral blood film for morphologic features after staining it with the Romanowsky dyes (e.g. Leishman's stain, May-Grünwald-Giemsa's stain, Jenner-Giemsa's stain, Wright's stain etc). The blood smear is evaluated in an area where there is neither Rouleaux formation nor so thin as to cause red cell distortion. Such an area can usually be found at junction of the body with the tail of the film, but not actually at the tail. The following abnormalities in erythroid series of cells are particularly looked for in a blood smear:

1. Variation in size (Anisocytosis) Normally, there is slight variation in diameter of the red cells from 6.7-7.7 μm (mean value 7.2 μm). Increased variation in size of the red cell is

termed anisocytosis. Anisocytosis may be due to the presence of cells larger than normal (*macrocytosis*) or cells smaller than normal (*microcytosis*). Sometimes both microcytosis and macrocytosis are present (*dimorphic*).

i) *Macrocytes* are classically found in megaloblastic anaemia; other causes are aplastic anaemia, other dyserythropoietic anaemias, chronic liver disease and in conditions with increased erythropoiesis.

ii) *Microcytes* are present in iron deficiency anaemia, thalassaemia and spherocytosis. They may also result from fragmentation of erythrocytes such as in haemolytic anaemia.

2. Variation in shape (Poikilocytosis) Increased variation in shape of the red cells is termed poikilocytosis. The nature of the abnormal shape determines the cause of anaemia. Poikilocytes are produced in various types of abnormal erythropoiesis e.g. in megaloblastic anaemia, iron deficiency anaemia, thalassaemia, myelofibrosis and microangiopathic haemolytic anaemia.

3. Inadequate haemoglobin formation (Hypochromasia) Normally, the intensity of pink staining of haemoglobin in a Romanowsky-stained blood smear gradually decreases from the periphery to the centre of the cell. Increased central pallor is referred to as *hypochromasia*. It may develop either from lowered haemoglobin content (e.g. in iron deficiency anaemia, chronic infections), or due to thinness of the red cells (e.g. in thalassaemia, sideroblastic anaemia). Unusually deep pink staining of the red cells due to increased haemoglobin concentration is termed *hyperchromasia* and may be found in megaloblastic anaemia, spherocytosis and in neonatal blood.

4. Compensatory erythropoiesis A number of changes are associated with compensatory increase in erythropoietic activity. These are as under:

i) *Polychromasia* is defined as the red cells having more than one type of colour. Polychromatic red cells are slightly larger, generally stained bluish-grey and represent reticulocytes and, thus, correlate well with reticulocyte count.

ii) *Erythroblastaemia* is the presence of nucleated red cells in the peripheral blood film. A small number of erythroblasts (or normoblasts) may be normally found in cord blood at birth. They are found in large numbers in haemolytic disease of the newborn, other haemolytic disorders and in extramedullary erythropoiesis. They may also appear in the blood in various types of severe anaemias except in aplastic anaemia. Erythroblastaemia may also occur after splenectomy.

iii) *Punctate basophilia* or *basophilic stippling* is diffuse and uniform basophilic granularity in the cell which does not stain positively with Perls' reaction (in contrast to Pappenheimer bodies which stain positively). Classical punctate basophilia is seen in aplastic anaemia, thalassaemia, myelodysplasia, infections and lead poisoning.

iv) *Howell-Jolly bodies* are purple nuclear remnants, usually found singly, and are larger than basophilic stippling. They are present in megaloblastic anaemia and after splenectomy.

5. Miscellaneous changes In addition to features of red cells described above, several morphologic abnormalities of red cells may be found in different haematological disorders. Some of these are as follows (**Fig. 10.10**):

i) *Spherocytosis* is characterised by presence of spheroidal rather than biconcave disc-shaped red cells. Spherocytes are seen in hereditary spherocytosis, autoimmune haemolytic anaemia and in ABO haemolytic disease of the newborn.

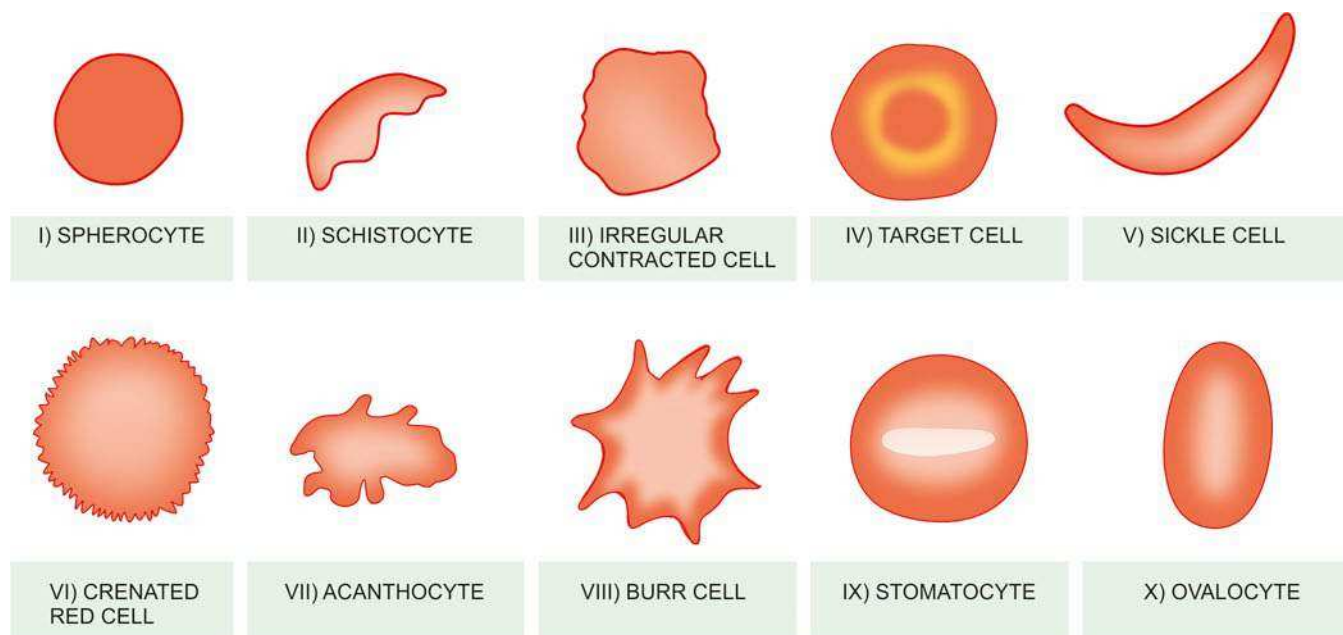

Figure 10.10 Some of the common morphologic abnormalities of red cells (The serial numbers in the illustrations correspond to the order in which they are described in the text).

ii) *Schistocytosis* is identified by fragmentation of erythrocytes. Schistocytes are found in thalassaemia, hereditary elliptocytosis, megaloblastic anaemia, iron deficiency anaemia, microangiopathic haemolytic anaemia and in severe burns.

iii) *Irregularly contracted red cells* are found in drug and chemical induced haemolytic anaemia and in unstable haemoglobinopathies.

iv) *Leptocytosis* is the presence of unusually thin red cells. Leptocytes are seen in severe iron deficiency and thalassaemia. *Target cell* is a form of leptocyte in which there is central round stained area and a peripheral rim of haemoglobin. Target cells are found in iron deficiency, thalassaemia, chronic liver disease, and after splenectomy.

v) *Sickle cells or drepanocytes* are sickle-shaped red cells found in sickle cell disease.

vi) *Crenated red cells* are the erythrocytes which develop numerous projections from the surface. They are present in blood films due to alkaline pH, presence of traces of fatty substances on the slides and in cases where the film is made from blood that has been allowed to stand overnight.

vii) *Acanthocytosis* is the presence of coarsely crenated red cells. Acanthocytes are found in large number in blood film made from splenectomised subjects, and in chronic liver disease.

viii) *Burr cells* are cell fragments having one or more spines. They are particularly found in uraemia.

ix) *Stomatocytosis* is the presence of stomatocytes which have central area having slit-like or mouth-like appearance. They are found in hereditary stomatocytosis, or may be seen in chronic alcoholism.

x) *Ovalocytosis or elliptocytosis* is the oval or elliptical shape of red cells. Their highest proportion (79%) is seen in hereditary ovalocytosis and elliptocytosis; other conditions showing such abnormal shapes of red cells are megaloblastic anaemia and hypochromic anaemia.

C. RED CELL INDICES An alternative method to diagnose and detect the severity of anaemia is by measuring the red cell indices:

1. In iron deficiency and thalassaemia, MCV, MCH and MCHC are reduced. In early stage of iron deficiency, RDW is increased while in thalassaemia trait RDW is normal (with low MCV) and can be distinguished from iron deficiency.
2. In anaemia due to acute blood loss and haemolytic anaemias, MCV, MCH and MCHC are all within normal limits.
3. In megaloblastic anaemias, MCV is raised above the normal range.

D. LEUCOCYTE AND PLATELET COUNT Measurement of leucocyte and platelet count helps to distinguish pure anaemia from pancytopenia in which red cells, granulocytes and platelets are all reduced. In anaemias due to haemolysis or haemorrhage, the neutrophil count and platelet counts are often elevated. In infections and leukaemias, the leucocyte counts are high and immature leucocytes appear in the blood.

E. RETICULOCYTE COUNT Reticulocyte count (normal 0.5-2.5%) is done in each case of anaemia to assess the marrow erythropoietic activity. In acute haemorrhage and in haemolysis, the reticulocyte response is indicative of impaired marrow function.

F. ERYTHROCYTE SEDIMENTATION RATE The ESR is a non-specific test used as a screening test for anaemia. It usually gives a clue to the underlying organic disease but anaemia itself may also cause rise in the ESR.

G. BONE MARROW EXAMINATION Bone marrow aspiration is done in cases where the cause for anaemia is not obvious. The procedures involved for marrow aspiration and trephine biopsy and their relative advantages and disadvantages have already been discussed (page 263).

In addition to these general tests, certain specific tests are done in different types of anaemias which are described later under the discussion of specific anaemias.

CLASSIFICATION OF ANAEMIAS

Several types of classifications of anaemias have been proposed. Two of the widely accepted classifications are based on the pathophysiology and morphology (Table 10.3).

PATHOPHYSIOLOGIC CLASSIFICATION Depending upon the pathophysiological mechanism, anaemias are classified into 3 groups:

I. Anaemia due to blood loss This is further of 2 types:

- A. Acute post-haemorrhagic anaemia
- B. Anaemia of chronic blood loss

II. Anaemia due to impaired red cell formation A disturbance due to impaired red cell production from various causes may produce anaemia. These are as under:

- A. *Cytoplasmic maturation defects*
 1. Deficient haem synthesis: iron deficiency anaemia
 2. Deficient globin synthesis: thalassaemic syndromes
- B. *Nuclear maturation defects*
Vitamin B₁₂ and/or folic acid deficiency: megaloblastic anaemia
- C. *Haematopoietic stem cell proliferation and differentiation abnormality* e.g.
 1. Aplastic anaemia
 2. Pure red cell aplasia
- D. *Bone marrow failure due to systemic diseases* (anaemia of chronic disorders) e.g.
 1. Anaemia of inflammation/infections, disseminated malignancy

2. Anaemia in renal disease
 3. Anaemia due to endocrine and nutritional deficiencies (hypometabolic states)
 4. Anaemia in liver disease
- E. *Bone marrow infiltration* e.g.
 1. Leukaemias
 2. Lymphomas
 3. Myelosclerosis
 4. Multiple myeloma
 - F. *Congenital anaemia* e.g.
 1. Sideroblastic anaemia
 2. Congenital dyserythropoietic anaemia.

The term *hypoproliferative anaemias* is also used to denote impaired marrow proliferative activity and includes 2 main groups: hypoproliferation due to iron deficiency and that due to other hypoproliferative disorders; the latter category includes anaemia of chronic inflammation/infection, renal disease, hypometabolic states, and causes of bone marrow failure.

III. Anaemia due to increased red cell destruction (haemolytic anaemias) This is further divided into 2 groups:

- A. Intracorporeal defect (hereditary and acquired).
- B. Extracorporeal defect (acquired haemolytic anaemias).

MORPHOLOGIC CLASSIFICATION Based on the red cell size, haemoglobin content and red cell indices, anaemias are classified into 3 types:

1. **Microcytic, hypochromic** MCV, MCH, MCHC are all reduced e.g. in iron deficiency anaemia and in certain non-iron deficient anaemias (sideroblastic anaemia, thalassaemia, anaemia of chronic disorders).
2. **Normocytic, normochromic** MCV, MCH, MCHC are all normal e.g. after acute blood loss, haemolytic anaemias, bone marrow failure, anaemia of chronic disorders.
3. **Macrocytic** MCV is raised e.g. in megaloblastic anaemia due to deficiency of vitamin B₁₂ or folic acid.

With these general comments on anaemias, a discussion of the specific types of anaemias is given in the following pages.

Table 10.3 Classification of anaemias.

| | |

GIST BOX 10.3 Anaemias: General Considerations

- ☐ Anaemia is reduced haemoglobin concentration in blood below the lower limit of the normal for the age and sex of the individual.
- ☐ Anaemia causes lowered oxygen-carrying capacity and eventually tissue hypoxia and impaired function.
- ☐ Major symptoms of anaemia are tiredness, weakness and lethargy, and main signs are pallor, hyperdynamic circulation, and impaired functions of CNS and kidneys.
- ☐ A suspected case of anaemia is investigated by haemoglobin estimation, peripheral blood smear examination, and complete blood counts including reticulocyte count and ESR.
- ☐ Bone marrow aspiration and trephine biopsy are done to confirm and type the anaemia.
- ☐ Anaemias are classified based on pathophysiology (into anaemia due to blood loss, impaired red cell production, increased red cell destruction) or morphology (into microcytic hypochromic, macrocytic, normocytic normochromic).

HYPOCHROMIC ANAEMIAS

Hypochromic anaemia due to iron deficiency is the commonest cause of anaemia the world over. It is estimated that about 20% of women in child-bearing age group are iron deficient, while the overall prevalence in adult males is about 2%. It is the most important, though not the sole, cause of microcytic hypochromic anaemia in which all the three red cell indices (MCV, MCH and MCHC) are reduced and occurs due to defective haemoglobin synthesis. Hypochromic anaemias, therefore, are classified into 2 groups:

- I. Hypochromic anaemia due to iron deficiency.
- II. Hypochromic anaemias other than iron deficiency.

The latter category includes 3 groups of disorders—sideroblastic anaemia, thalassaemia and anaemia of chronic disorders.

IRON DEFICIENCY ANAEMIA

The commonest nutritional deficiency disorder present throughout the world is iron deficiency but its prevalence is

higher in the developing countries. The factors responsible for iron deficiency in different populations are variable and are best understood in the context of normal iron metabolism.

IRON METABOLISM

The amount of iron obtained from the diet should replace the losses from the skin, bowel and genitourinary tract. These losses together are about 1 mg daily in an adult male or in a non-menstruating female, while in a menstruating woman there is an additional iron loss of 0.5-1 mg daily. The iron required for haemoglobin synthesis is derived from 2 primary sources—ingestion of foods containing iron (e.g. leafy vegetables, beans, meats, liver etc) and recycling of iron from senescent red cells (Fig. 10.11).

ABSORPTION The average Western diet contains 10-15 mg of iron, out of which only 5-10% is normally absorbed. In pregnancy and in iron deficiency, the proportion of absorption is raised to 20-30%. Iron is absorbed mainly in the duodenum and proximal jejunum. The absorption is regulated by *mucosal*

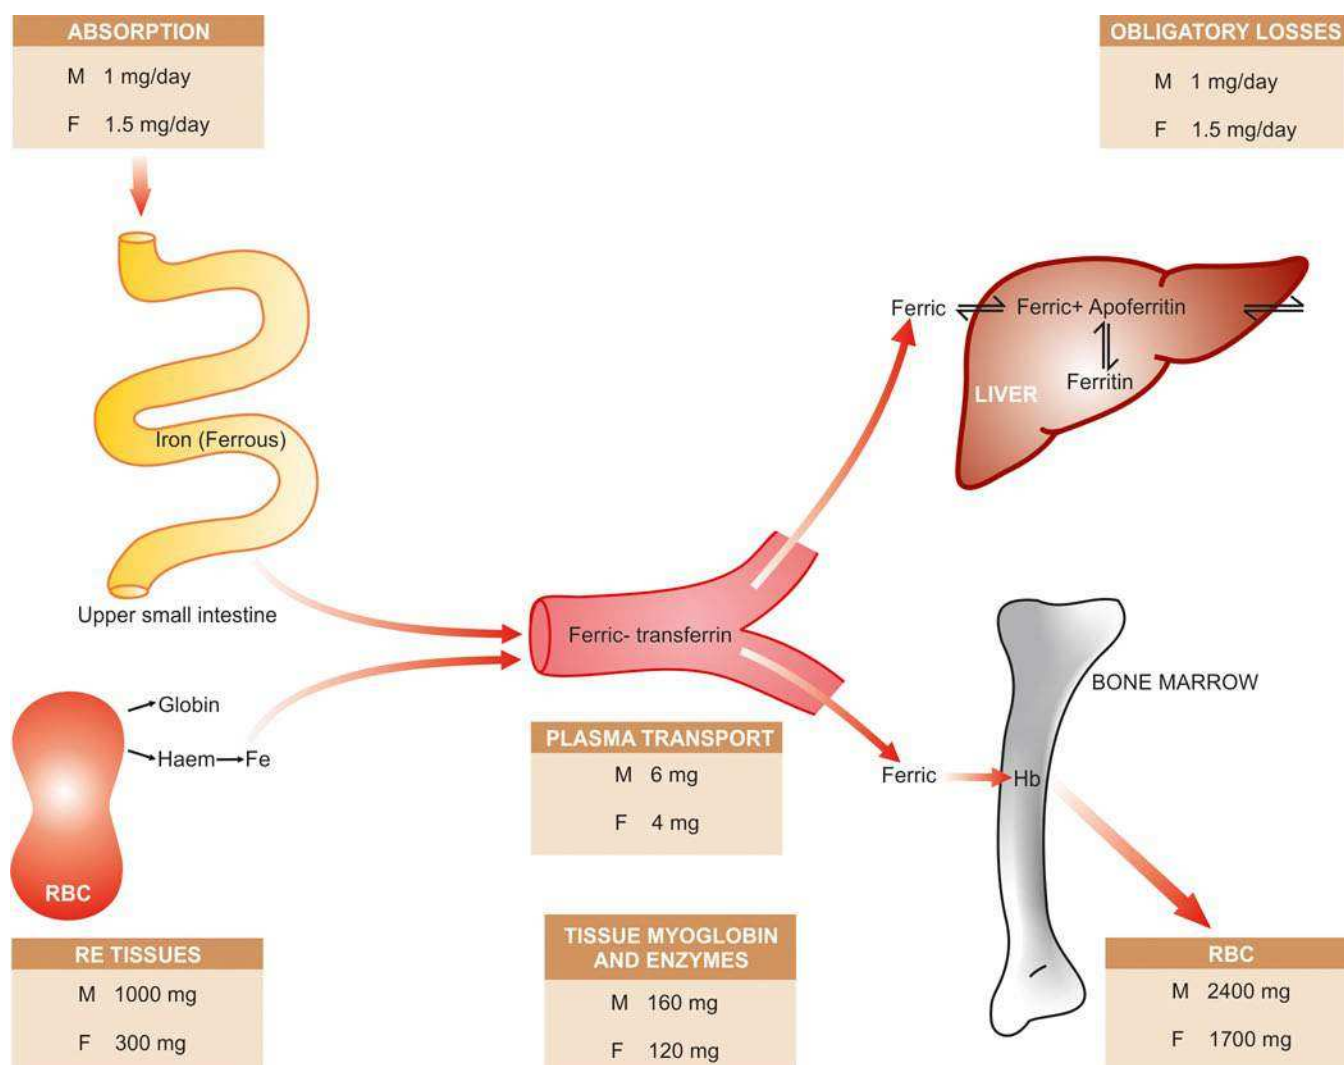

Figure 10.11 Daily iron cycle. Iron on absorption from upper small intestine circulates in plasma bound to transferrin and is transported to the bone marrow for utilisation in haemoglobin synthesis. The mature red cells are released into circulation, which on completion of their lifespan of 120 days, die. They are then phagocytosed by RE cells and iron stored as ferritin and haemosiderin. Stored iron is mobilised in response to increased demand and used for haemoglobin synthesis, thus completing the cycle (M = males; F = females).

block mechanism—when iron stores are low (e.g. during pregnancy, menstruation, periods of growth and various diseases) absorption is enhanced, and when iron stores are increased (e.g. in haemosiderosis) little iron is absorbed or transported. *Iron from diet containing haem is better absorbed than non-haem iron:*

◆ Absorption of **non-haem iron** is enhanced by factors such as ascorbic acid (vitamin C), citric acid, amino acids, sugars, gastric secretions and hydrochloric acid of the stomach. Iron absorption is impaired by factors like medicinal antacids, milk, pancreatic secretions, phytates, phosphates, ethylene diamine tetra-acetic acid (EDTA) and tannates contained in tea. Non-haem iron is released as ferrous or ferric form but is absorbed almost exclusively as ferrous form; reduction of ferric to ferrous form when required takes place at the intestinal brush border by *ferric reductase*. Transport across the membrane is accomplished by divalent metal transporter 1 (DMT 1). Once inside the gut cells, ferric iron may be either stored as ferritin or further transported to transferrin by two vehicle proteins—*ferroportin* and *hephaestin*. The function of ferroportin is inversely regulated by hepcidin released from the liver and is the main iron regulating hormone.

◆ The mechanism of dietary **haem iron** absorption is not clearly understood yet but it is through a different transport than DMT 1.

After absorption of both non-haem and haem forms of iron, it comes into mucosal pool (**Fig. 10.12,A**).

TRANSPORT Iron is transported in plasma bound to a β -globulin, *transferrin*, synthesised in the liver. Transferrin-bound iron is made available to the marrow where the developing erythroid cells having *transferrin receptors* utilise

iron for haemoglobin synthesis. It may be mentioned here that transferrin receptors are present on cells of many tissues of the body but their number is greatest in the developing erythroblasts. Transferrin is reutilised after iron is released from it. A small amount of transferrin iron is delivered to other sites such as parenchymal cells of the liver. Normally, transferrin is about one-third saturated. But in conditions where transferrin-iron saturation is increased, parenchymal iron uptake is increased. Virtually, no iron is deposited in the mononuclear-phagocyte cells (RE cells) from the plasma transferrin-iron but instead these cells derive most of their iron from phagocytosis of senescent red cells. Storage form of iron (ferritin and haemosiderin) in RE cells is normally not functional but can be readily mobilised in response to increased demands for erythropoiesis. However, conditions such as malignancy, infection and inflammation interfere with the release of iron from iron stores causing ineffective erythropoiesis.

EXCRETION The body is unable to regulate its iron content by excretion alone. The amount of iron lost per day is 0.5-1 mg which is independent of iron intake. This loss is nearly twice more (i.e. 1-2 mg/day) in menstruating women. Iron is lost from the body in both sexes as a result of desquamation of epithelial cells from the gastrointestinal tract, from excretion in the urine and sweat, and loss via hair and nails. Iron excreted in the faeces mainly consists of unabsorbed iron and desquamated mucosal cells.

DISTRIBUTION In an adult, iron is distributed in the body as under:

1. **Haemoglobin**—present in the red cells, contains most of the body iron (65%).

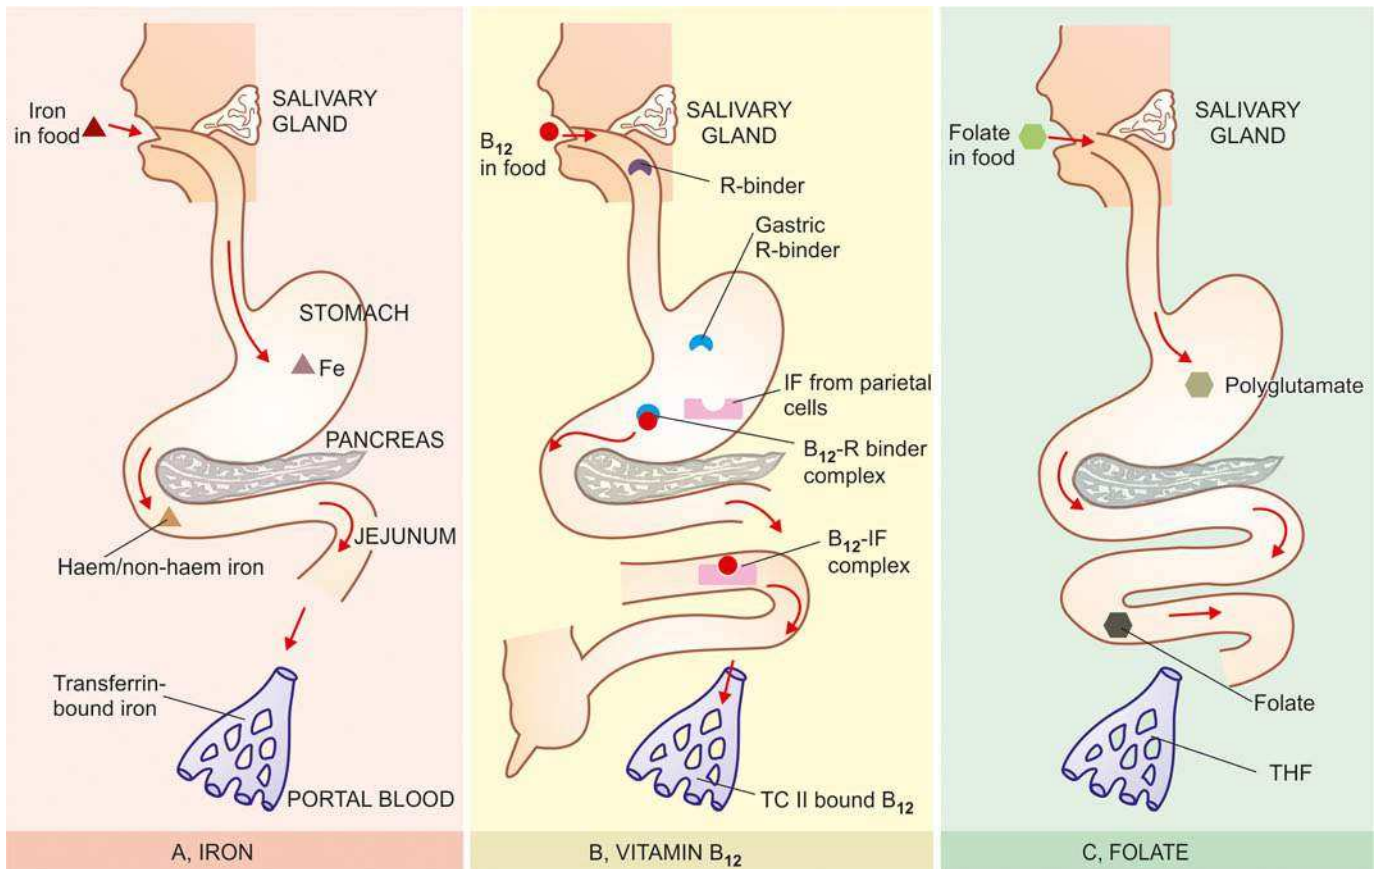

Figure 10.12 Contrasting pathways of absorption and transport of iron, vitamin B₁₂ and folic acid.

2. Myoglobin—comprises a small amount of iron in the muscles (3.5%).

3. Haem and non-haem enzymes—e.g. cytochrome, catalase, peroxidases, succinic dehydrogenase and flavoproteins constitute a fraction of total body iron (0.5%).

4. Transferrin-bound iron—circulates in the plasma and constitutes another fraction of total body iron (0.5%).

All these forms of iron are in *functional form*.

5. Ferritin and haemosiderin—are the *storage forms* of excess iron (30%). They are stored in the mononuclear-phagocyte cells of the spleen, liver and bone marrow and in the parenchymal cells of the liver.

PATHOGENESIS

Iron deficiency anaemia develops when the supply of iron is inadequate for the requirement of haemoglobin synthesis. Initially, negative iron balance is covered by mobilisation from the tissue stores so as to maintain haemoglobin synthesis. It is only after the tissue stores of iron are exhausted that the supply of iron to the marrow becomes insufficient for haemoglobin formation and thus a state of iron deficiency anaemia develops. The development of iron deficiency depends upon one or more of the following factors:

1. Increased blood loss
2. Increased requirements
3. Inadequate dietary intake
4. Decreased intestinal absorption.

The relative significance of these factors varies with the age and sex of the patient (Table 10.4). Accordingly, certain groups of individuals at increased risk of developing iron deficiency can be identified (*see below*). In general, in developed countries the mechanism of iron deficiency is usually due to chronic occult blood loss, while in the developing countries poor intake of iron or defective absorption are responsible for iron deficiency anaemia.

ETIOLOGY

Iron deficiency anaemia is always secondary to an underlying disorder. Correction of the underlying cause, therefore, is essential part of its treatment. Based on the above-mentioned pathogenetic mechanisms, following etiologic factors are involved in development of iron deficiency anaemia at different age and sex (Table 10.4):

1. FEMALES IN REPRODUCTIVE PERIOD OF LIFE The highest incidence of iron deficiency anaemia is in women during their reproductive years of life. It may be from one or more of the following causes:

- i) *Blood loss* This is the most important cause of anaemia in women during child-bearing age group. Commonly, it is due to persistent and heavy menstrual blood loss such as occurs in various pathological states and due to insertion of IUCDs. Young girls at the onset of menstruation may develop mild anaemia due to blood loss. Significant blood loss may occur as a result of repeated miscarriages.
- ii) *Inadequate intake* Inadequate intake of iron is prevalent in women of lower economic status. Besides diet deficient in iron, other factors such as anorexia, impaired absorption and diminished bioavailability may act as contributory factors.
- iii) *Increased requirements* During pregnancy and adolescence, the demand of body for iron is increased. During a

Table 10.4 Etiology of iron deficiency anaemia.

| | |
|------|--|
| I. | INCREASED BLOOD LOSS |
| 1. | <i>Uterine</i> e.g. excessive menstruation in reproductive years, repeated miscarriages, at onset of menarche, post-menopausal uterine bleeding |
| 2. | <i>Gastrointestinal</i> e.g. peptic ulcer, haemorrhoids hookworm infestation, cancer of stomach and large bowel, oesophageal varices, hiatus hernia, chronic aspirin ingestion, ulcerative colitis, diverticulosis |
| 3. | <i>Renal tract</i> e.g. haematuria, haemoglobinuria |
| 4. | <i>Nose</i> e.g. repeated epistaxis |
| 5. | <i>Lungs</i> e.g. haemoptysis |
| II. | INCREASED REQUIREMENTS |
| 1. | Spurts of growth in infancy, childhood and adolescence |
| 2. | Prematurity |
| 3. | Pregnancy and lactation |
| III. | INADEQUATE DIETARY INTAKE |
| 1. | Poor economic status |
| 2. | Anorexia e.g. in pregnancy |
| 3. | Elderly individuals due to poor dentition, apathy and financial constraints |
| IV. | DECREASED ABSORPTION |
| 1. | Partial or total gastrectomy |
| 2. | Achlorhydria |
| 3. | Intestinal malabsorption such as in coeliac disease |

normal pregnancy, about 750 mg of iron may be siphoned off from the mother—about 400 mg to the foetus, 150 mg to the placenta, and 200 mg is lost at parturition and lactation. If several pregnancies occur at short intervals, iron deficiency anaemia certainly follows.

2. POST-MENOPAUSAL FEMALES Though the physiological demand for iron decreases after cessation of menstruation, iron deficiency anaemia may develop in post-menopausal women due to chronic blood loss. Following are among the important causes during these years:

- i) *Post-menopausal uterine bleeding* due to carcinoma of the uterus.
- ii) *Bleeding from the alimentary tract* such as due to carcinoma of stomach and large bowel and hiatus hernia.

3. ADULT MALES It is uncommon for adult males to develop iron deficiency anaemia in the presence of normal dietary iron content and iron absorption. The vast majority of cases of iron deficiency anaemia in adult males are due to chronic blood loss. The cause for chronic haemorrhage may lie at one of the following sites:

- i) *Gastrointestinal tract* is the usual source of bleeding which may be due to peptic ulcer, haemorrhoids, hookworm infestation, carcinoma of stomach and large bowel, oesophageal varices, hiatus hernia, chronic aspirin ingestion and ulcerative colitis. Other causes in the GIT are malabsorption and following gastrointestinal surgery.
- ii) *Urinary tract* e.g. due to haematuria and haemoglobinuria.
- iii) *Nose* e.g. in repeated epistaxis.
- iv) *Lungs* e.g. in haemoptysis from various causes.

4. INFANTS AND CHILDREN Iron deficiency anaemia is fairly common during infancy and childhood with a peak incidence at 1-2 years of age. The principal cause for anaemia at this age is increased demand of iron which is not met by the inadequate intake of iron in the diet. Normal full-term infant has sufficient iron stores for the first 4-6 months of life, while

premature infants have inadequate reserves because iron stores from the mother are mainly laid down during the last trimester of pregnancy. Therefore, unless the infant is given supplemental feeding of iron or iron-containing foods, iron deficiency anaemia develops.

CLINICAL FEATURES

As already mentioned, iron deficiency anaemia is much more common in women between the age of 20 and 45 years than in men; at periods of active growth in infancy, childhood and adolescence; and is also more frequent in premature infants. Initially, there are usually no clinical abnormalities. But subsequently, in addition to features of the underlying disorder causing the anaemia, the clinical consequences of iron deficiency manifest in 2 ways—anaemia itself and epithelial tissue changes.

1. ANAEMIA The onset of iron deficiency anaemia is generally slow. The usual symptoms are weakness, fatigue, dyspnoea on exertion, palpitations and pallor of the skin, mucous membranes and sclerae. Older patients may develop angina and congestive cardiac failure. Patients may have unusual dietary cravings such as pica. Menorrhagia is a common symptom in iron deficient women.

2. EPITHELIAL TISSUE CHANGES Long-standing chronic iron deficiency anaemia causes epithelial tissue changes in some patients. The changes occur in the nails (koilonychia or spoon-shaped nails), tongue (atrophic glossitis), mouth (angular stomatitis), and oesophagus causing dysphagia from development of thin, membranous webs at the postcricoid area (Plummer-Vinson syndrome).

LABORATORY FINDINGS

The development of anaemia progresses in 3 stages:

◆ Firstly, *storage iron depletion* occurs during which iron reserves are lost without compromise of the iron supply for erythropoiesis.

◆ The next stage is *iron deficient erythropoiesis* during which the erythroid iron supply is reduced without the development of anaemia.

◆ The final stage is the development of *frank iron deficiency anaemia* when the red cells become microcytic and hypochromic.

The following laboratory tests can be used to assess the varying degree of iron deficiency (**Fig. 10.13**):

1. BLOOD PICTURE AND RED CELL INDICES The degree of anaemia varies. It is usually mild to moderate but occasionally it may be marked (haemoglobin less than 6 g/dl) due to persistent and severe blood loss. The salient haematological findings in these cases are as under.

i) Haemoglobin The essential feature is a fall in haemoglobin concentration up to a variable degree.

ii) Red cells The red cells in the blood film are hypochromic and microcytic, and there is anisocytosis and poikilocytosis (**Fig. 10.14,A**). Hypochromia generally precedes microcytosis. Hypochromia is due to poor filling of the red cells with haemoglobin so that there is increased central pallor. In severe cases, there may be only a thin rim of pink staining at the periphery. Target cells, elliptical forms and polychromatic cells are often present. Normoblasts are uncommon. RBC count is below normal but is generally not proportionate to the fall in haemoglobin value. When iron deficiency is associated with severe folate or vitamin B₁₂ deficiency, a *dimorphic* blood picture occurs with dual population of red cells—macrocytic as well as microcytic hypochromic.

iii) Reticulocyte count The reticulocyte count is normal or reduced but may be slightly raised (2-5%) in cases after haemorrhage.

iv) Absolute values The red cell indices reveal a diminished MCV (below 50 fl), diminished MCH (below 15 pg), and diminished MCHC (below 20 g/dl).

v) Leucocytes The total and differential white cell counts are usually normal.

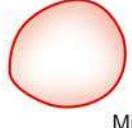

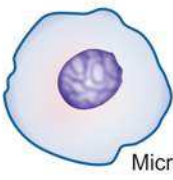

| LABORATORY FINDINGS | | NORMAL | IRON-DEFICIENCY ANAEMIA |
|---------------------|-----------------------|---|---|
| BLOOD | RED CELL MORPHOLOGY |  Normal red cell |  Microcytic hypochromic red cell |
| | RED CELL INDICES | MCV, MCH, MCHC all normal | MCV ↓, MCH ↓, MCHC ↓ |
| BONE MARROW | MARROW ERYTHROPOIESIS |  Normoblastic |  Micronormoblastic |
| | MARROW IRON STORES |  Normal |  Deficient |

Figure 10.13 Laboratory findings in iron deficiency anaemia.

vi) **Platelets** Platelet count is usually normal but may be slightly to moderately raised in patients who have had recent bleeding.

2. BONE MARROW FINDINGS Bone marrow examination is not essential in such cases routinely but is done in complicated cases so as to distinguish from other hypochromic anaemias. The usual findings are as follows (**Fig. 10.14,B**):

i) **Marrow cellularity** The marrow cellularity is increased due to erythroid hyperplasia (myeloid-erythroid ratio decreased).

ii) **Erythropoiesis** There is normoblastic erythropoiesis with predominance of small polychromatic normoblasts (micronormoblasts). These normoblasts have a thin rim of cytoplasm around the nucleus and a ragged and irregular cell border. The *cytoplasmic maturation lags behind* so that the late normoblasts have pyknotic nucleus but persisting polychromatic cytoplasm (compared from megaloblastic anaemia in which the nuclear maturation lags behind, page 284).

iii) **Other cells** Myeloid, lymphoid and megakaryocytic cells are normal in number and morphology.

iv) **Marrow iron** Iron staining (Prussian blue reaction) on bone marrow aspirate smear shows deficient reticuloendothelial iron stores and absence of siderotic iron granules from developing normoblasts.

3. BIOCHEMICAL FINDINGS In addition to blood and bone marrow examination, the following biochemical tests are of value:

i) The *serum iron* level is low (normal 40-140 µg/dl); it is often under 50 µg/dl. When serum iron falls below 15 µg/dl, marrow iron stores are absent.

ii) *Total iron binding capacity (TIBC)* is high (normal 250-450 µg/dl) and rises to give less than 10% saturation (normal 33%). In anaemia of chronic disorders, however, serum iron as well as TIBC are reduced.

iii) *Serum ferritin* is very low (normal 30-250 ng/ml) indicating poor tissue iron stores. The serum ferritin is

raised in iron overload and is normal in anaemia of chronic disorders.

iv) *Red cell protoporphyrin* is very low (normal 20-40 µg/dl) as a result of insufficient iron supply to form haem.

v) *Serum transferrin receptor protein* which is normally present on developing erythroid cells and reflects total red cell mass, is raised in iron deficiency due to its release in circulation (normal level 4-9 µg/L as determined by immunoassay).

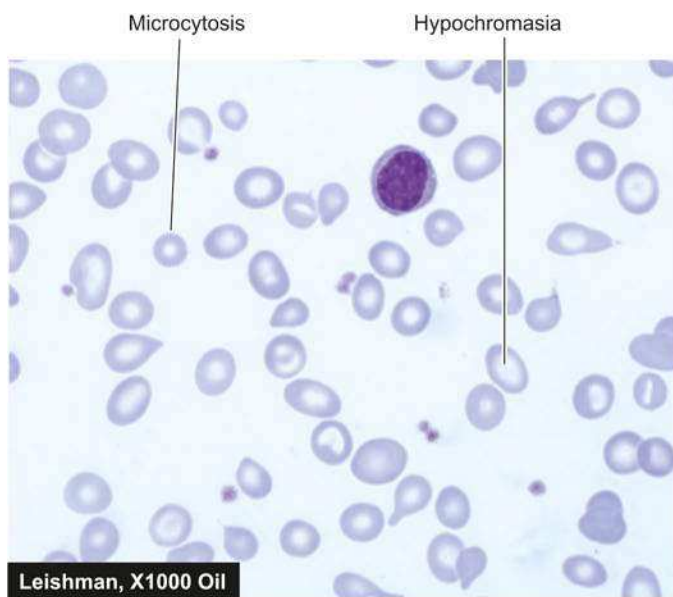

PRINCIPLES OF TREATMENT

The management of iron deficiency anaemia consists of 2 essential principles: correction of disorder causing the anaemia, and correction of iron deficiency.

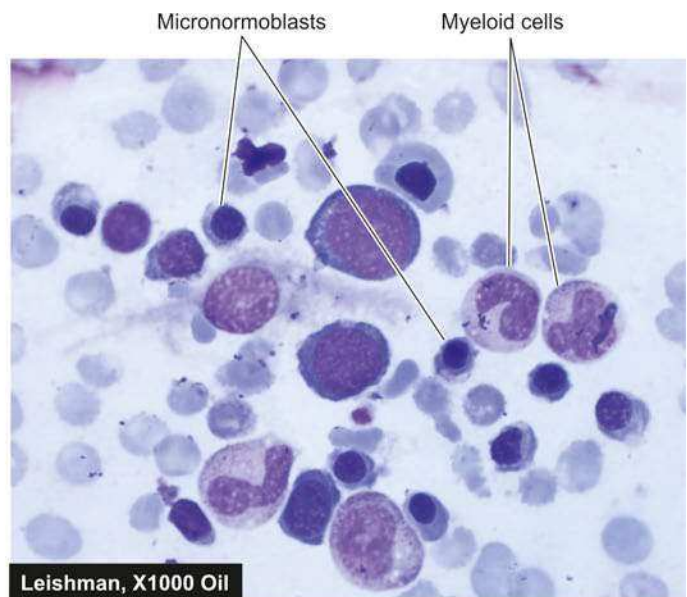

1. CORRECTION OF THE DISORDER The underlying cause of iron deficiency is established after thorough check-up and investigations. Appropriate surgical, medical or preventive measures are instituted to correct the cause of blood loss.

2. CORRECTION OF IRON DEFICIENCY The lack of iron is corrected with iron therapy as under:

i) **Oral therapy** Iron deficiency responds very effectively to the administration of oral iron salts such as ferrous sulfate, ferrous fumarate, ferrous gluconate and polysaccharide iron. These preparations have varying amount of elemental iron in each tablet ranging from 39 mg to 105 mg. Optimal absorption is obtained by giving iron fasting, but if side-effects occur (e.g. nausea, abdominal discomfort, diarrhoea) iron can be given with food or by using a preparation of lower iron content (e.g. ferrous gluconate containing 39 mg elemental iron). Oral iron therapy is continued long enough, both to correct the anaemia and to replenish the body iron stores. The response to oral iron therapy is observed by reticulocytosis which begins to appear in 3-4 days with a peak in about 10 days. Poor response to iron replacement may occur from various causes such as: incorrect diagnosis, non-compliance, continuing blood loss, bone marrow suppression by tumour or chronic inflammation, and malabsorption.

A, PERIPHERAL BLOOD SMEAR

B, BONE MARROW ASPIRATE SMEAR

Figure 10.14 Iron deficiency anaemia. A, PBF showing microcytic hypochromic anaemia. There is moderate microcytosis and hypochromia. B, Examination of bone marrow aspirate showing micronormoblastic erythropoiesis.

ii) **Parenteral therapy** Parenteral iron therapy is indicated in following types of cases:

- Intolerance to oral iron therapy
- In GIT disorders such as malabsorption
- Post-operative cases
- Cases requiring a rapid replenishment of iron stores e.g. in women with severe anaemia a few weeks before expected date of delivery.

Parenteral iron therapy is hazardous and expensive when compared with oral administration. The haematological response to parenteral iron therapy is no faster than the administration of adequate dose of oral iron but the stores are replenished much faster. Before giving the parenteral iron, total dose is calculated by a simple formula by multiplying the grams of haemoglobin below normal with 250 (250 mg of elemental iron is required for each gram of deficit haemoglobin), plus an additional 500 mg is added for building up iron stores. A common preparation is iron dextran which may be given as a single intramuscular injection, or as intravenous infusion after dilution with dextrose or saline. The adverse effects with iron dextran include hypersensitivity or anaphylactoid reactions, haemolysis, hypotension, circulatory collapse, vomiting and muscle pain. Newer iron complexes such as sodium ferric gluconate and iron sucrose can be administered as repeated intravenous injections with much lesser side effects.

SIDEROBLASTIC ANAEMIA

The sideroblastic anaemias comprise a group of disorders of diverse etiology in which the nucleated erythroid precursors in the bone marrow, show characteristic 'ringed sideroblasts.'

SIDEROCYTES AND SIDEROBLASTS

Siderocytes and sideroblasts are erythrocytes and normoblasts respectively which contain cytoplasmic granules of iron (Fig. 10.15).

SIDEROCYTES These are red cells containing granules of non-haem iron. These granules stain positively with Prussian blue reaction as well as stain with Romanowsky dyes when they are referred to as *Pappenheimer bodies*. Siderocytes are normally not present in the human peripheral blood but a small number may appear following splenectomy. This is because the reticulocytes on release from the marrow are finally sequestered in the spleen to become mature red cells. In the absence of spleen, the final maturation step takes place in the peripheral blood and hence siderocytes make their appearance in the blood after splenectomy.

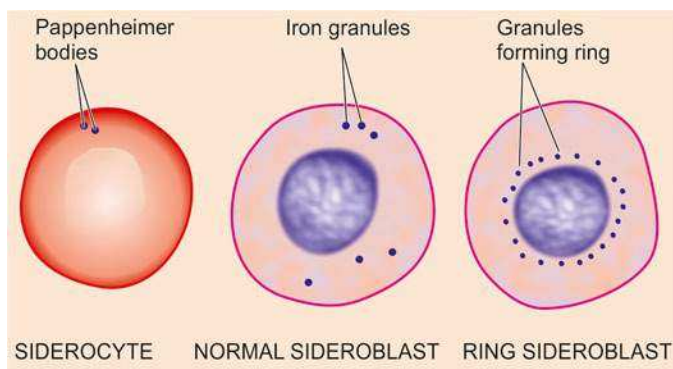

Figure 10.15 A siderocyte containing Pappenheimer bodies, a normal sideroblast and a ring sideroblast.

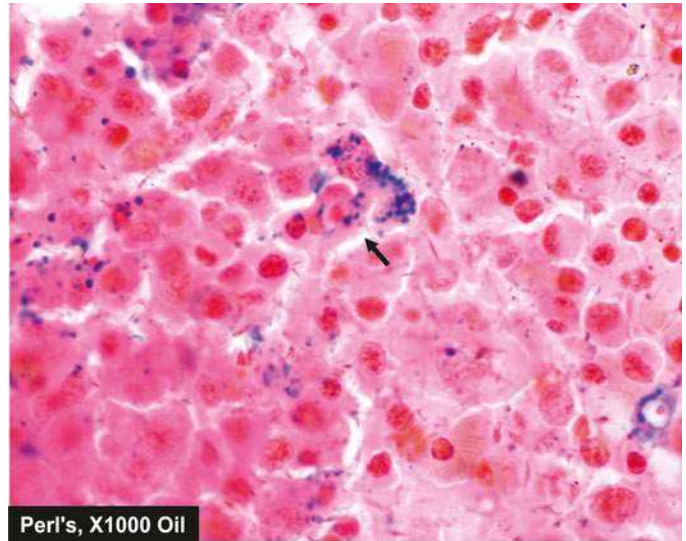

Figure 10.16 Sideroblastic anaemia. Bone marrow aspirate smear in Perl's stain shows marked excess of reticular iron and a ringed sideroblast (arrow) showing Prussian blue granules in the cytoplasm.

SIDEROBLASTS These are nucleated red cells (normoblasts) containing siderotic granules which stain positively with Prussian blue reaction. Depending upon the number, size and distribution of siderotic granules, sideroblasts may be normal or abnormal (Fig. 10.16):

Normal sideroblasts contain a few fine, scattered cytoplasmic granules representing iron which has not been utilised for haemoglobin synthesis. These cells comprise 30-50% of normoblasts in the normal marrow but are reduced or absent in iron deficiency.

Abnormal sideroblasts are further of 2 types:

- ◆ *One type* is a sideroblast containing numerous, diffusely scattered, coarse cytoplasmic granules and are seen in conditions such as dyserythropoiesis and haemolysis. In this type, there is no defect of haem or globin synthesis but the percentage saturation of transferrin is increased.
- ◆ The other type is *ringed sideroblast* in which haem synthesis is disturbed as occurs in sideroblastic anaemias. Ringed sideroblasts contain numerous large granules, often forming a complete or partial ring around the nucleus. The ringed arrangement of these granules is due to the presence of iron-laden mitochondria around the nucleus.

TYPES OF SIDEROBLASTIC ANAEMIAS

Based on etiology, sideroblastic anaemias are classified into hereditary and acquired types. The acquired type is further divided into primary and secondary forms:

I. HEREDITARY SIDEROBLASTIC ANAEMIA This is a rare X-linked disorder associated with defective enzyme activity of *aminolevulinic acid (ALA) synthetase* required for haem synthesis. The affected males have moderate to marked anaemia while the females are carriers of the disorder and do not develop anaemia. The condition manifests in childhood or in early adult life.

II. ACQUIRED SIDEROBLASTIC ANAEMIA The acquired sideroblastic anaemias are classified into primary and secondary types.

A. Primary acquired sideroblastic anaemia Primary, idiopathic, or refractory acquired sideroblastic anaemia occurs spontaneously in middle-aged and older individuals of both sexes. The disorder has its pathogenesis in disturbed growth and maturation of erythroid precursors at the level of haematopoietic stem cell, possibly due to reduced activity of the enzyme, ALA synthetase. The anaemia is of moderate to severe degree and appears insidiously. The bone marrow cells commonly show chromosomal abnormalities, neutropenia and thrombocytopenia with associated bleeding diathesis. The spleen and liver may be either normal or mildly enlarged, while the lymph nodes are not enlarged. Unlike other types of sideroblastic anaemia, this type is regarded as a myelodysplastic disorder in the FAB (French-American-British) classification and thus, can be a preleukaemic disorder (page 343). About 10% of individuals with refractory acquired sideroblastic anaemia develop acute myelogenous leukaemia.

B. Secondary acquired sideroblastic anaemia Acquired sideroblastic anaemia may develop secondary to a variety of drugs, chemicals, toxins, haematological and various other diseases.

1. *Drugs, chemicals and toxins:* Isoniazid, an anti-tuberculous drug and a pyridoxine antagonist, is most commonly associated with development of sideroblastic anaemia by producing abnormalities in pyridoxine metabolism. Other drugs occasionally causing acquired sideroblastic anaemia are: cycloserine, chloramphenicol and alkylating agents (e.g. cyclophosphamide). Alcohol and lead also cause sideroblastic anaemia. All these agents cause reversible sideroblastic anaemia which usually resolves following removal of the offending agent.

2. *Haematological disorders:* These include myelofibrosis, polycythaemia vera, acute leukaemia, myeloma, lymphoma and haemolytic anaemia.

3. *Miscellaneous:* Occasionally, secondary sideroblastic anaemia may occur in association with a variety of inflammatory, neoplastic and autoimmune diseases such as carcinoma, myxoedema, rheumatoid arthritis and SLE.

LABORATORY FINDINGS

Sideroblastic anaemias usually show the following haematological features:

1. There is generally moderate to severe degree of *anaemia*.
2. The *blood picture* shows hypochromic anaemia which may be microcytic, or there may be some normocytic red cells as well (dimorphic).
3. *Absolute values* (MCV, MCH and MCHC) are reduced in hereditary type but MCV is often raised in acquired type.

4. *Bone marrow examination* shows erythroid hyperplasia with usually macronormoblastic erythropoiesis. Marrow iron stores are raised and pathognomonic ring sideroblasts are present.

5. *Serum ferritin* levels are raised.

6. *Serum iron* is usually raised with almost complete saturation of TIBC.

7. There is increased *iron deposition* in the tissue.

PRINCIPLES OF TREATMENT

The treatment of secondary sideroblastic anaemia is primarily focussed on removal of the offending agent. No definite treatment is available for hereditary and idiopathic types of sideroblastic anaemias. However, pyridoxine is administered routinely to all cases of sideroblastic anaemia (200 mg per day for 2-3 months). Blood transfusions and other supportive therapy are indicated in all patients.

Differential diagnosis of various types of hypochromic anaemias by laboratory tests is summarised in [Table 10.5](#).

ANAEMIA OF CHRONIC DISORDERS

One of the commonly encountered anaemia is in patients of a variety of chronic systemic diseases in which anaemia develops secondary to a disease process but there is no actual invasion of the bone marrow. A list of such chronic systemic diseases is given in [Table 10.6](#). In general, anaemia in chronic disorders is usually normocytic normochromic but can have mild degree of microcytosis and hypochromia unrelated to iron deficiency. The severity of anaemia is usually directly related to the primary disease process. The anaemia is corrected only if the primary disease is alleviated.

PATHOGENESIS

A number of factors may contribute to the development of anaemia in chronic systemic disorders, and in many conditions, the anaemia is complicated by other causes such as iron, B₁₂ and folate deficiency, hypersplenism, renal failure with consequent reduced erythropoietic activity, endocrine abnormalities etc. However, in general, 2 factors appear to play significant role in the pathogenesis of anaemia in chronic disorders. These are: *defective red cell production and reduced red cell lifespan*.

1. Defective red cell production Though there is abundance of storage iron in these conditions but the amount of iron available to developing erythroid cells in the marrow is subnormal. The mononuclear phagocyte system is hyperplastic which traps all the available free iron due to the activity of iron

Table 10.5 Laboratory diagnosis of hypochromic anaemias.

| TEST | IRON DEFICIENCY | CHRONIC DISORDERS | THALASSAEMIA MINOR | SIDEROBLASTIC ANAEMIA |
|------------------------|-----------------|-----------------------|--------------------|---|
| 1. MCV, MCH, MCHC | Reduced | Low normal-to-reduced | Very low | Very low (except MCV raised in acquired type) |
| 2. Serum iron | Reduced | Reduced | Normal | Raised |
| 3. TIBC | Raised | Low-to-normal | Normal | Normal |
| 4. Serum ferritin | Reduced | Raised | Normal | Raised (complete saturation) |
| 5. Marrow-iron stores | Absent | Present | High | High |
| 6. Iron in normoblasts | Absent | Absent | Present | Ring sideroblasts |
| 7. Hb electrophoresis | Normal | Normal | Abnormal | Normal |

Table 10.6 Anaemias secondary to chronic systemic disorders.

1. ANAEMIA IN CHRONIC INFECTIONS/INFLAMMATION
 - a. *Infections* e.g. tuberculosis, lung abscess, pneumonia, osteomyelitis, subacute bacterial endocarditis, pyelonephritis.
 - b. *Non-infectious inflammations* e.g. rheumatoid arthritis, SLE, vasculitis, dermatomyositis, scleroderma, sarcoidosis, Crohn's disease.
 - c. *Disseminated malignancies* e.g. Hodgkin's disease, disseminated carcinomas and sarcomas.
2. ANAEMIA OF RENAL DISEASE e.g. uraemia, renal failure
3. ANAEMIA OF HYPOMETABOLIC STATE e.g. endocrinopathies (myxoedema, Addison's disease, hyperthyroidism, hypopituitarism, Addison's disease), protein malnutrition, scurvy and pregnancy, liver disease.

binding protein, lactoferrin. A defect in the transfer of iron from macrophages to the developing erythroid cells in the marrow leads to reduced availability of iron for haem synthesis despite adequate iron stores, elevating serum ferritin levels. The defect lies in suppression of erythropoietin by inflammatory cytokines at some stage in erythropoiesis, and hepcidin which is the key iron regulatory hormone. These inflammatory cytokines include TNF and IFN- β released in bacterial infections and tumours, and IL-1 and IFN- γ released in patients of rheumatoid arthritis and autoimmune vasculitis (Fig. 10.17).

2. Reduced red cell lifespan Decreased survival of circulating red cells in chronic renal disease is attributed to hyperplastic mononuclear phagocyte system.

LABORATORY FINDINGS

The characteristic features of anaemia in these patients uncomplicated by other deficiencies are as under:

- i) Haemoglobin** Anaemia is generally mild to moderate. A haemoglobin value of less than 8 g/dl suggests the presence of additional contributory factors.
- ii) Blood picture** The type of anaemia in these cases is generally normocytic normochromic but may have slight microcytosis and hypochromia.
- iii) Absolute values** Red cell indices indicate that in spite of normocytic normochromic anaemia, MCHC is slightly low.
- iv) Reticulocyte count** The reticulocyte count is generally low.
- v) Red cell survival** Measurement of erythrocyte survival generally reveals mild to moderate shortening of their lifespan.
- vi) Bone marrow** Examination of the marrow generally reveals normal erythroid maturation. However, the red cell precursors have reduced stainable iron than normal, while macrophages in the marrow usually contain increased amount of iron. Cases of chronic infection often have myeloid hyperplasia and increase in plasma cells.
- vii) Serum iron and TIBC** Serum iron is characteristically reduced in this group of anaemias while TIBC is low-to-normal (in contrast to iron deficiency where there is reduction in serum iron but high TIBC, see Table 10.5).
- viii) Serum ferritin** Serum ferritin levels are increased in these patients and is the most distinguishing feature

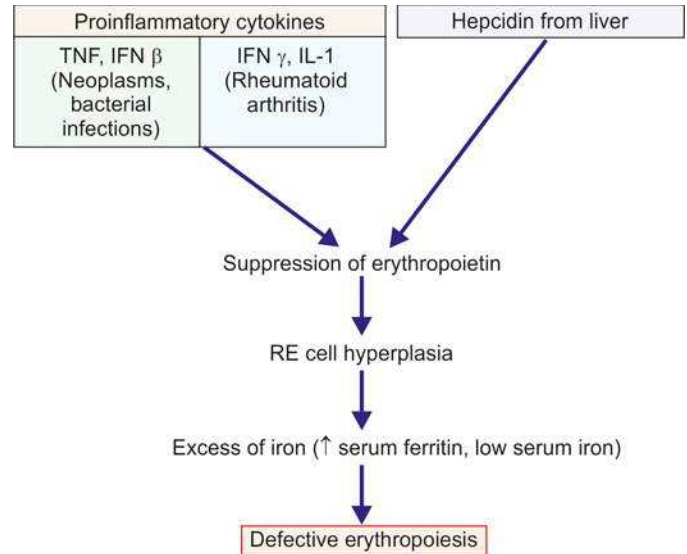

Figure 10.17 Pathogenesis of anaemia of chronic disorders through suppression of erythropoiesis by cytokines.

between true iron-deficiency anaemia and iron-deficient erythropoiesis in anaemia of chronic diseases.

ix) Other plasma proteins In addition, certain other plasma proteins called '*phase reactants*' are raised in patients with chronic inflammation, probably under the stimulus of interleukin-1 released by activated macrophages. These proteins include γ -globulin, C3, haptoglobin, α_1 -antitrypsin and fibrinogen. Elevation of these proteins is responsible for raised ESR commonly present in these patients.

GIST BOX 10.4 Hypochromic Anaemias

- ☐ Hypochromic anaemias are classified into 2 groups: due to iron deficiency and from causes other than iron deficiency (i.e. sideroblastic anaemia, thalassaemia and anaemia of chronic disorders).
- ☐ The commonest nutritional deficiency throughout the world is iron deficiency but its prevalence is higher in the developing countries.
- ☐ The development of iron deficiency may be due to increased blood loss, increased requirement, inadequate dietary intake or decreased intestinal absorption. Accordingly, the causes depend upon age and sex.
- ☐ Clinical consequences of iron deficiency manifest as anaemia itself and epithelial tissue changes.
- ☐ Laboratory diagnosis of iron deficiency is made by CBC and blood picture showing microcytosis and hypochromia, reduced red cell indices, serum iron and ferritin and bone marrow examination showing micronormoblastic picture with depleted iron stores.
- ☐ Sideroblastic anaemia is classified into hereditary and acquired. Marrow iron stores are raised and pathognomonic ring sideroblasts are present. Serum ferritin and serum iron are usually raised.
- ☐ Anaemia of chronic disorders is due to chronic systemic diseases, such as inflammatory or infectious and chronic renal diseases. *Serum ferritin is increased* and is the most distinguishing feature from true iron-deficiency anaemia.

MEGALOBlastic ANAEMIAS—VITAMIN B₁₂ AND FOLATE DEFICIENCY

Megaloblastic anaemias are associated with macrocytic blood picture and megaloblastic marrow erythropoiesis. This group is due to deficiency of vitamin B₁₂ and/or folate and includes megaloblastic picture from the following two types of etiologies:

1. Nutritional deficiency of vitamin B₁₂ or folate, or combined deficiency, most common in developing countries.
2. Deficiency of intrinsic factor, causing impaired absorption of vitamin B₁₂ called pernicious anaemia, is rare in India but more prevalent in individuals of European descent.

MEGALOBlastic ANAEMIA

The megaloblastic anaemias are disorders caused by impaired DNA synthesis and are characterised by a distinctive abnormality in the haematopoietic precursors in the bone marrow in which the *maturation of the nucleus is delayed relative to that of the cytoplasm*. Since cell division is slow but cytoplasmic development progresses normally, the nucleated red cell precursors tend to be larger which Ehrlich in 1880 termed *megaloblasts*. Megaloblasts are both morphologically and functionally abnormal with the result that the mature red cells formed from them and released into the peripheral blood are also abnormal in shape and size, the most prominent abnormality being *macrocytosis*.

The underlying defect for the asynchronous maturation of the nucleus is defective DNA synthesis due to deficiency of vitamin B₁₂ (cobalamin) and/or folic acid (folate). Less common causes are interference with DNA synthesis by congenital or acquired abnormalities of vitamin B₁₂ or folic acid metabolism. Before considering the megaloblastic anaemia, an outline of vitamin B₁₂ and folic acid metabolism is given for a better understanding of the subject.

The salient nutritional aspects and metabolic functions of vitamin B₁₂ and folic acid are summarised in [Table 10.7](#).

VITAMIN B₁₂ METABOLISM

BIOCHEMISTRY Vitamin B₁₂ or cobalamin is a complex organometallic compound having a cobalt atom situated within a corrin ring, similar to the structure of porphyrin from which haem is formed. In humans, there are 2 metabolically active forms of cobalamin—methyl-cobalamin and adenosyl-

Table 10.7 Salient features of vitamin B₁₂ and folate metabolism.

| FEATURE | VITAMIN B ₁₂ | FOLATE |
|-----------------------------------|-----------------------------|--------------------------------|
| 1. <i>Main foods</i> | Animal proteins only | Green vegetables, meats |
| 2. <i>Cooking</i> | Little effect | Easily destroyed |
| 3. <i>Daily requirements</i> | 2-4 µg | 100-200 µg |
| 4. <i>Daily intake</i> | 5-30 µg | 100-500 µg |
| 5. <i>Site of absorption</i> | Ileum | Duodenum and jejunum |
| 6. <i>Mechanism of absorption</i> | Intrinsic factor | Conversion to methyl-THF |
| 7. <i>Body stores</i> | 2-3 mg (enough for 2-4 yrs) | 10-12 mg (enough for 4 months) |

cobalamin, which act as coenzymes. The therapeutic vitamin B₁₂ preparation is called cyanocobalamin.

SOURCES The only dietary sources of vitamin B₁₂ are foods of animal protein origin such as kidney, liver, heart, muscle meats, fish, eggs, cheese and milk. In contrast to folate, fruits and vegetables contain practically no vitamin B₁₂ unless contaminated with bacteria. Cooking has little effect on its activity. Vitamin B₁₂ is synthesised in the human large bowel by microorganisms but is not absorbed from this site and, thus, the humans are entirely dependent upon dietary sources. The average daily requirement for vitamin B₁₂ is 2-4 µg.

ABSORPTION After ingestion, vitamin B₁₂ in food is released and forms a stable complex with gastric R-binder. R-binder is a form of glycoprotein found in various secretions (e.g. saliva, milk, gastric juice, bile), phagocytes and plasma. On entering the duodenum, the vitamin B₁₂-R-binder complex is digested releasing vitamin B₁₂ which then binds to intrinsic factor (IF). The IF is a glycoprotein of molecular weight 50,000 produced by the parietal cells of the stomach and its secretion roughly parallels that of hydrochloric acid. The vitamin B₁₂-IF complex, on reaching the distal ileum, binds to the specific receptors on the mucosal brush border, thereby enabling the vitamin to be absorbed. The IF, therefore, acts as cell-directed carrier protein similar to transferrin. The receptor-bound vitamin B₁₂-IF complex is taken into the ileal mucosal cells where after several hours the IF is destroyed, vitamin B₁₂ released and is transferred to another transport protein, transcobalamin (TC) II. The vitamin B₁₂-TC II complex is finally secreted into the portal circulation from where it is taken by the liver, bone marrow and other cells. There are 2 major vitamin B₁₂ binding proteins—TC I and TC II, and a minor protein TC III. TC I is not essential for vitamin B₁₂ transport but functions primarily as a storage protein while TC III is similar to TC II and binds a small amount of vitamin B₁₂ (see [Fig. 10.12,B](#)).

TISSUE STORES Normally, the liver is the principal storage site of vitamin B₁₂ and stores about 2 mg of the vitamin, while other tissues like the kidney, heart and brain together store about 2 mg. The body stores of vitamin B₁₂ are adequate for 2-4 years. Major source of loss is via bile and shedding of intestinal epithelial cells. A major part of the excreted vitamin B₁₂ is reabsorbed in the ileum by the IF resulting in enterohepatic circulation.

FUNCTIONS Vitamin B₁₂ plays an important role in general cell metabolism, particularly essential for normal haematopoiesis and for maintenance of integrity of the nervous system. Vitamin B₁₂ acts as a co-enzyme for 2 main biochemical reactions in the body:

◆ *Firstly, as methyl cobalamin (methyl B₁₂)* in the methylation of homocysteine to methionine by methyl tetrahydrofolate (THF). The homocysteine-methionine reaction is closely linked to folate metabolism ([Fig. 10.18](#)):

When this reaction is impaired, folate metabolism is deranged and results in defective DNA synthesis responsible for megaloblastic maturation.

◆ *Secondly, as adenosyl cobalamin (adenosyl B₁₂)* in propionate metabolism for the conversion of methyl malonyl co-enzyme A to succinyl co-enzyme A:

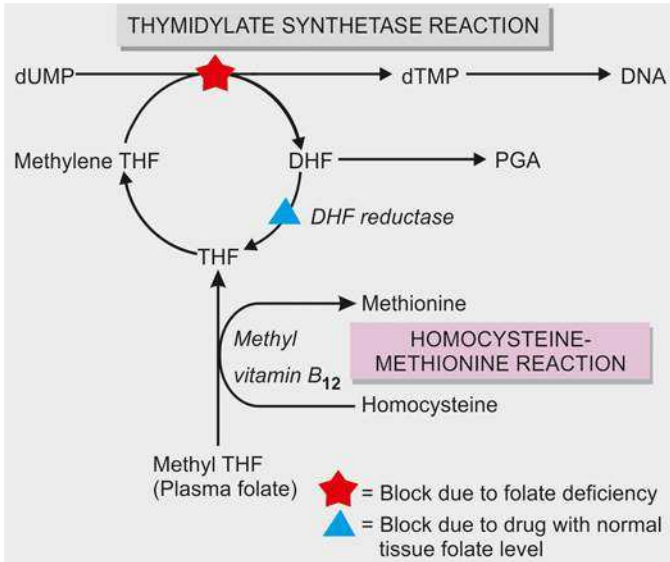

Figure 10.18 Biochemical basis of megaloblastic anaemia (THF = tetrahydrofolate; DHF = dihydrofolate; PGA = pteroyl glutamic acid; dUMP = deoxy uridylylate monophosphate; dTMP = deoxy thymidylylate monophosphate).

Lack of adenosyl B₁₂ leads to large increase in the level of methyl malonyl CoA and its precursor, propionyl CoA. This results in synthesis of certain fatty acids which are incorporated into the neuronal lipids. This biochemical abnormality may contribute to the neurologic complications of vitamin B₁₂ deficiency.

FOLATE METABOLISM

BIOCHEMISTRY Folate or folic acid, a yellow compound, is a member of water-soluble B complex vitamins with the chemical name of *pteroyl glutamic acid (PGA)*. Folic acid does not exist as such in nature but exists as folates in polyglutamate form (conjugated folates). For its metabolic action as co-enzyme, polyglutamates must be reduced to dihydro- and tetrahydrofolate forms.

SOURCES Folate exists in different plants, bacteria and animal tissues. Its main dietary sources are fresh green leafy vegetables, fruits, liver, kidney, and to a lesser extent, muscle meats, cereals and milk. Folate is labile and is largely destroyed by cooking and canning. Some amount of folate synthesised by bacteria in the human large bowel is not available to the body because its absorption takes place in the small intestine. Thus, humans are mainly dependent upon diet for its supply. The average daily requirement is 100-200 µg.

ABSORPTION AND TRANSPORT Folate is normally absorbed from the duodenum and upper jejunum and to a lesser extent, from the lower jejunum and ileum. However, absorption depends upon the form of folate in the diet. Polyglutamate form in the foodstuffs is first cleaved by the enzyme, folate conjugase, in the mucosal cells to mono- and diglutamates which are readily assimilated. Synthetic folic acid preparations in polyglutamate form are also absorbed as rapidly as mono- and diglutamate form because of the absence of natural inhibitors. Mono- and diglutamates undergo further reduction in the mucosal cells to form tetrahydrofolate (THF), a monoglutamate. THF circulates in the plasma as methylated compound, methyl THF,

bound to a protein. Once methyl THF is transported into the cell by a carrier protein, it is reconverted to polyglutamate (see **Fig. 10.12,C**).

TISSUE STORES The liver and red cells are the main storage sites of folate, largely as methyl THF polyglutamate form. The total body stores of folate are about 10-12 mg enough for about 4 months. Normally, folate is lost from the sweat, saliva, urine and faeces.

FUNCTIONS Folate plays an essential role in cellular metabolism. It acts as a co-enzyme for 2 important biochemical reactions involving transfer of 1-carbon units (viz. methyl and formyl groups) to various other compounds. These reactions are as under:

- ◆ **Thymidylate synthetase reaction** Formation of deoxy thymidylate monophosphate (dTMP) from its precursor form, deoxy uridylylate monophosphate (dUMP).
- ◆ **Methylation of homocysteine to methionine** This reaction is linked to vitamin B₁₂ metabolism (**Fig. 10.18**).

These biochemical reactions are considered in detail below together with biochemical basis of the megaloblastic anaemia.

BIOCHEMICAL BASIS OF MEGALOBlastic ANAEMIA

The basic biochemical abnormality common to both vitamin B₁₂ and folate deficiency is a block in the pathway of DNA synthesis and that there is an inter-relationship between vitamin B₁₂ and folate metabolism in the methylation reaction of homocysteine to methionine (**Fig. 10.18**).

As stated above, folate as co-enzyme methylene THF, is required for transfer of 1-carbon moieties (e.g. methyl and formyl) to form building blocks in DNA synthesis. These 1-carbon moieties are derived from serine or formimino-glutamic acid (FIGLU). Two of the important folate-dependent (1-carbon transfer) reactions for formation of building blocks in DNA synthesis are as under:

1. Thymidylate synthetase reaction This reaction involves synthesis of deoxy thymidylate monophosphate (dTMP) from deoxy uridylylate monophosphate (dUMP). The methyl group of dUMP → dTMP reaction is supplied by the co-enzyme, methylene-THF. After the transfer of 1-carbon from methylene-THF, dihydrofolate (DHF) is produced which must be reduced to active THF by the enzyme DHF-reductase before it can participate in further 1-carbon transfer reaction. Drugs like methotrexate (anti-cancer) and pyrimethamine (antimalarial) are inhibitory to the enzyme, DHF-reductase, thereby inhibiting the DNA synthesis.

2. Homocysteine-methionine reaction Homocysteine is converted into methionine by transfer of a methyl group from methylene-THF. After transfer of 1-carbon from methylene-THF, THF is produced. This reaction requires the presence of vitamin B₁₂ (methyl-B₁₂).

Deficiency of folate from any cause results in reduced supply of the coenzyme, methylene-THF, and thus interferes with the synthesis of DNA. Deficiency of vitamin B₁₂ traps folate as its transport form, methyl-THF, thereby resulting in reduced formation of the active form, methylene-THF, needed for DNA synthesis. This is referred to as *methyl-folate trap hypothesis*. An alternative hypothesis of inter-relationship of B₁₂ and folate is the *formate-saturation hypothesis*. According to this hypothesis, the active substrate is formyl-THF. Vitamin

B₁₂ deficiency results in reduced supply of formate to THF causing reduced generation of the active compound, formyl THF.

ETIOLOGY AND CLASSIFICATION OF MEGALOBlastic ANAEMIA

The etiology of megaloblastic anaemia varies in different parts of the world. As outlined in **Table 10.8**, megaloblastic anaemia is classified into 3 broad groups: vitamin B₁₂ deficiency, folate deficiency, and deficiency from other causes.

1. VITAMIN B₁₂ DEFICIENCY In Western countries, deficiency of vitamin B₁₂ is more commonly due to pernicious (Addisonian) anaemia. True vegetarians like traditional Indian Hindus and breast-fed infants have dietary lack of vitamin B₁₂. Gastrectomy by lack of intrinsic factor, and small intestinal lesions involving distal ileum where absorption of vitamin B₁₂ occurs, may cause deficiency of the vitamin. Deficiency of vitamin B₁₂ takes at least 2 years to develop when the body stores are totally depleted.

2. FOLATE DEFICIENCY Folate deficiency is more often due to poor dietary intake. Other causes include malabsorption, excess folate utilisation such as in pregnancy and in various disease states, chronic alcoholism, and excess urinary folate loss. Folate deficiency arises more rapidly than vitamin B₁₂ deficiency since the body's stores of folate are relatively low which can last for up to 4 months only.

Patients with tropical sprue are often deficient in both vitamin B₁₂ and folate. Combined deficiency of vitamin B₁₂ and folate may occur from severe deficiency of vitamin B₁₂ because of the biochemical interrelationship with folate metabolism.

3. OTHER CAUSES In addition to deficiency of vitamin B₁₂ and folate, megaloblastic anaemias may occasionally be

induced by other factors unrelated to vitamin deficiency. These include many drugs which interfere with DNA synthesis, acquired defects of haematopoietic stem cells, and rarely, congenital enzyme deficiencies.

CLINICAL FEATURES

Deficiency of vitamin B₁₂ and folate may cause following clinical manifestations which may be present singly or in combination and in varying severity:

1. Anaemia Macrocytic megaloblastic anaemia is the cardinal feature of deficiency of vitamin B₁₂ and/or folate. The onset of anaemia is usually insidious and gradually progressive.

2. Glossitis Typically, the patient has a smooth, beefy, red tongue.

3. Neurologic manifestations Vitamin B₁₂ deficiency, particularly in patients of pernicious anaemia, is associated with significant neurological manifestations in the form of subacute combined, degeneration of the spinal cord and peripheral neuropathy (Chapter 28), while folate deficiency may occasionally develop neuropathy only. The underlying pathologic process consists of demyelination of the peripheral nerves, the spinal cord and the cerebrum. Signs and symptoms include numbness, paraesthesia, weakness, ataxia, poor finger coordination and diminished reflexes.

4. Others In addition to the cardinal features mentioned above, patients may have various other symptoms. These include: mild jaundice, angular stomatitis, purpura, melanin pigmentation, symptoms of malabsorption, weight loss and anorexia.

LABORATORY FINDINGS

The investigations of a suspected case of megaloblastic anaemia are aimed at 2 aspects:

A. General laboratory investigations of anaemia which include blood picture, red cell indices, bone marrow findings, and biochemical tests.

B. Special tests to establish the cause of megaloblastic anaemia as to know whether it is due to deficiency of vitamin B₁₂ or folate.

Based on these principles, the following scheme of investigations is followed:

A. General Laboratory Findings

1. BLOOD PICTURE AND RED CELL INDICES Estimation of haemoglobin, examination of a blood film and evaluation of absolute values are essential preliminary investigations (**Fig. 10.19**):

i) Haemoglobin Haemoglobin estimation reveals values below the normal range. The fall in haemoglobin concentration may be of a variable degree.

ii) Red cells Red blood cell morphology in a blood film shows the characteristic macrocytosis. However, *macrocytosis* can also be seen in several other disorders such as: haemolysis, liver disease, chronic alcoholism, hypothyroidism, aplastic anaemia, myeloproliferative disorders and reticulocytosis. In addition, the blood smear demonstrates marked anisocytosis, poikilocytosis and presence of macro-ovalocytes. Basophilic stippling and occasional normoblast may also be seen (**Fig. 10.20, A**).

Table 10.8 Etiologic classification of megaloblastic anaemia.

| |
|---|
| I. VITAMIN B ₁₂ DEFICIENCY |
| A. <i>Inadequate dietary intake</i> e.g. strict vegetarians, breast-fed infants. |
| B. <i>Malabsorption</i> |
| 1. <i>Gastric causes</i> : pernicious anaemia, gastrectomy, congenital lack of intrinsic factor. |
| 2. <i>Intestinal causes</i> : tropical sprue, ileal resection, Crohn's disease, intestinal blind loop syndrome, fish-tapeworm infestation. |
| II. FOLATE DEFICIENCY |
| A. <i>Inadequate dietary intake</i> e.g. in alcoholics, teenagers, infants, old age, poverty. |
| B. <i>Malabsorption</i> e.g. in tropical sprue, coeliac disease, partial gastrectomy, jejunal resection, Crohn's disease. |
| C. <i>Excess demand</i> |
| 1. <i>Physiological</i> : pregnancy, lactation, infancy. |
| 2. <i>Pathological</i> : malignancy, increased haematopoiesis, chronic exfoliative skin disorders, tuberculosis, rheumatoid arthritis. |
| D. <i>Excess urinary folate loss</i> e.g. in active liver disease, congestive heart failure. |
| III. OTHER CAUSES |
| A. <i>Impaired metabolism</i> e.g. inhibitors of dihydrofolate (DHF) reductase such as methotrexate and pyrimethamine; alcohol, congenital enzyme deficiencies. |
| B. <i>Unknown etiology</i> e.g. in Di Guglielmo's syndrome, congenital dyserythropoietic anaemia, refractory megaloblastic anaemia. |

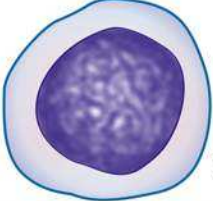

| LABORATORY FINDINGS | | NORMAL | MEGALOBLASTIC ANAEMIA |
|---------------------|-----------------------|---|---|
| BLOOD | RED CELL MORPHOLOGY |  Normal red cell |  Macrocytic red cell |
| | RED CELL INDICES | MCV, MCH, MCHC all normal | MCV ↑, MCH ↑, MCHC Normal or ↓ |
| BONE MARROW | MARROW ERYTHROPOIESIS |  Normoblastic |  Megaloblastic |
| | MARROW IRON STORES |  Normal |  Increased |

Figure 10.19 General laboratory findings in megaloblastic anaemia.

iii) Reticulocyte count The reticulocyte count is generally low to normal in untreated cases.

iv) Absolute values The red cell indices reveal an elevated MCV (above 120 fl) proportionate to the severity of macrocytosis, elevated MCH (above 50 pg) and normal or reduced MCHC.

v) Leucocytes The total white blood cell count may be reduced. Presence of characteristic hypersegmented neutrophils (having more than 5 nuclear lobes) in the blood film should raise the suspicion of megaloblastic anaemia. An occasional myelocyte may also be seen.

vi) Platelets Platelet count may be moderately reduced in severely anaemic patients. Bizarre forms of platelets may be seen.

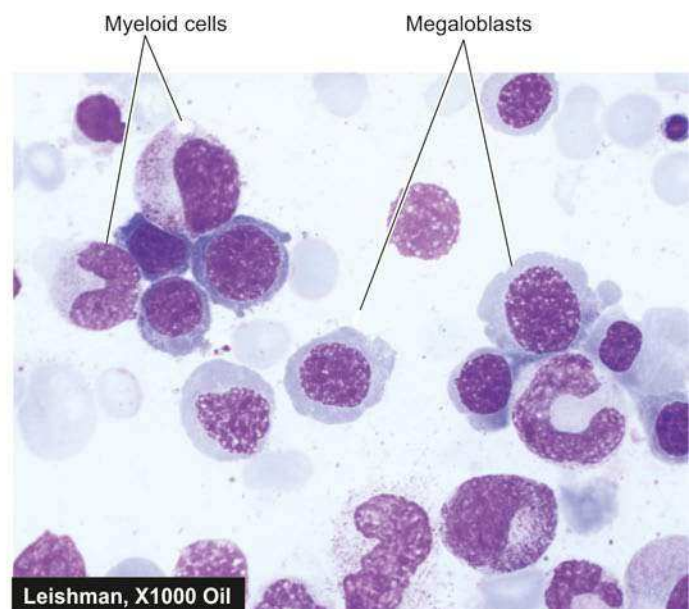

2. BONE MARROW FINDINGS The bonemarrow examination is very helpful in the diagnosis of megaloblastic anaemia. Significant findings of marrow examination are as under (**Fig. 10.20, B**):

i) Marrow cellularity The marrow is hypercellular with a decreased myeloid-erythroid ratio.

ii) Erythropoiesis There is erythroid hyperplasia due to characteristic megaloblastic erythropoiesis. *Megaloblasts* are abnormal, large, nucleated erythroid precursors, having nuclear-cytoplasmic asynchrony i.e. the nuclei are less mature than the development of cytoplasm. The nuclei are large, having fine, sieve-like and open chromatin that stains lightly, while the haemoglobinisation of the cytoplasm proceeds normally or at a faster rate i.e. *nuclear*

A, PERIPHERAL BLOOD SMEAR

B, BONE MARROW ASPIRATE SMEAR

Figure 10.20 Megaloblastic anaemia. A, PBF showing prominent macrocytosis of red cells and hypersegmented neutrophils. B, Examination of bone marrow aspirate showing megaloblastic erythropoiesis.

Table 10.9 Contrasting features of megaloblast and erythroblast.

| FEATURE | ERYTHROBLAST | MEGALOBLAST |
|---------------------------|--------------------------------|----------------------------------|
| 1. Cell size | Normal | Larger than corresponding stage |
| 2. Nuclear size | Normal | Larger than corresponding stage |
| 3. Nuclear chromatin | Normal for corresponding stage | Lighter, open even in late stage |
| 4. Nuclear maturation | Normal for corresponding stage | Lags behind in late stage |
| 5. Mitosis | Normal | Frequent, abnormal |
| 6. Cytoplasmic maturation | Normal for corresponding stage | Unaffected |
| 7. Colour of cytoplasm | Normal for corresponding stage | Normal for corresponding stage |

maturation lags behind that of cytoplasm (compared from iron deficiency anaemia in which cytoplasmic maturation lags behind, page 276). Megaloblasts with abnormal mitoses may be seen. Features distinguishing megaloblast from erythroblast are summed up in Table 10.9. Ineffective erythropoiesis such as presence of degenerated erythroid precursors may be present.

iii) Other cells Granulocyte precursors are also affected to some extent. Giant forms of metamyelocytes and band cells may be present in the marrow. Megakaryocytes are usually present in normal number but may occasionally be decreased and show abnormal morphology such as hypersegmented nuclei and agranular cytoplasm.

iv) Marrow iron Prussian blue staining for iron in the marrow shows an increase in the number and size of iron granules in the erythroid precursors. Ring sideroblasts are, however, rare. Iron in the reticulum cells is increased.

v) Chromosomes Marrow cells may show variety of random chromosomal abnormalities such as chromosome breaks, centromere spreading etc.

3. BIOCHEMICAL FINDINGS In addition to the general blood and marrow investigations and specific tests to determine the cause of deficiency (described below), the following biochemical abnormalities are observed in cases of megaloblastic anaemia:

- i) There is rise in *serum unconjugated bilirubin and LDH* as a result of ineffective erythropoiesis causing marrow cell breakdown.
- ii) The *serum iron and ferritin* may be normal or elevated.

B. Special Tests for Cause of Specific Deficiency

In evaluating a patient of megaloblastic anaemia, it is important to determine the specific vitamin deficiency by assay of vitamin B₁₂ and folate. In sophisticated clinical laboratories, currently automated multiparametric, random access analysers are employed based on separation techniques by chemiluminescence and enzyme-linked fluorescence detection systems which have largely replaced the traditional microbiologic assays for vitamin B₁₂ and folate. Traditional tests are briefly described below.

TESTS FOR VITAMIN B₁₂ DEFICIENCY The normal range of vitamin B₁₂ in serum is 280-1000 pg/ml. Values less than 100 pg/ml indicate clinically deficient stage. Traditional tests employed to establish vitamin B₁₂ deficiency are serum vitamin B₁₂ assay, Schilling (24-hour urinary excretion) test and serum enzyme levels.

1. **SERUM VITAMIN B₁₂ ASSAY** Assay of vitamin B₁₂ in blood can be done by 2 methods—microbiological assay and radioassay.

i) Microbiological assay In this test, the serum sample to be assayed is added to a medium containing all other essential growth factors required for a vitamin B₁₂-dependent microorganism. The medium along with microorganism is incubated and the amount of vitamin B₁₂ is determined turbidimetrically which is then compared with the growth produced by a known amount of vitamin B₁₂. Several organisms have been used for this test such as *Euglena gracilis*, *Lactobacillus leichmannii*, *Escherichia coli* and *Ochromonas malhamensis*. *E. gracilis* is, however, considered more sensitive and accurate. The addition of antibiotics to the test interferes with the growth and yields false low result.

ii) Radioassay Assays of serum B₁₂ by radioisotope dilution (RID) and radioimmunoassay (RIA) have been developed. These tests are more sensitive and have the advantage over microbiologic assays in that they are simpler and more rapid, and the results are unaffected by antibiotics and other drugs which may affect the living organisms.

2. **SCHILLING TEST (24-HOUR URINARY EXCRETION TEST)** Schilling test is done to detect vitamin B₁₂ deficiency as well as to distinguish and detect lack of IF and malabsorption syndrome. The results of test also depend upon good renal function and proper urinary collection. Radioisotope used for labeling B₁₂ is either ⁵⁸Co or ⁵⁷Co. The test is performed in 3 stages as under:

Stage I: Without IF The patient after an overnight fasting is administered oral dose of 1 mg of radioactively labelled vitamin B₁₂ ('hot' B₁₂) in 200 µl of water. At the same time, 1 mg of unlabelled vitamin B₁₂ ('cold' B₁₂) is given by intramuscular route; this 'cold' B₁₂ will saturate the serum as well as the tissue binding sites. The patient is kept fasting for a further period of 2 hours, following which urinary excretion of B₁₂ is estimated:

- ◆ In normal individuals, 24-hour urinary excretion is >10% of the oral dose of 'hot' B₁₂.
- ◆ Patients with IF deficiency excrete lower quantity of 'hot' B₁₂ which is further confirmed by repeating the test as in stage II given below.

Stage II: With IF If the 24-hour urinary excretion of 'hot' B₁₂ is low, the test is repeated using the same procedure as in stage I but in addition high oral dose of IF is administered along with 'hot' B₁₂.

◆ If the 24-hour urinary excretion of 'hot' B₁₂ is now normal, the low value in first stage of the test was due to IF deficiency (i.e. pernicious anaemia).

◆ Patients with pernicious anaemia have abnormal test even after treatment with vitamin B₁₂ due to IF deficiency. However, abnormal 24-hour urinary excretion of 'hot' B₁₂ is further investigated in stage III for a cause in intestinal malabsorption of 'hot' B₁₂.

Stage III: Test for malabsorption of vitamin B₁₂ Some patients absorb vitamin B₁₂ in water as was stipulated in the original Schilling test. Modified Schilling test employs the use of protein-bound vitamin B₁₂. In conditions causing malabsorption, the test is repeated after a course of treatment with antibiotics or anti-inflammatory drugs.

3. SERUM ENZYME LEVELS Besides Schilling test, another way of distinguishing whether megaloblastic anaemia is due to cobalamine or folate is by serum determination of methylmalonic acid and homocysteine by sophisticated enzymatic assays. Both are elevated in cobalamine deficiency, while in folate deficiency there is only elevation of homocysteine and not of methylmalonic acid.

TESTS FOR FOLATE DEFICIENCY The normal range of serum folate is 6-18 ng/ml. Values of 4 ng/ml or less are generally considered to be diagnostic of folate deficiency. Measurement of *formiminoglutamic acid (FIGLU) urinary excretion* after histidine load was used formerly for assessing folate status but it is less specific and less sensitive than the serum assays. Currently, there are 3 tests used to detect folate deficiency—urinary excretion of FIGLU, serum and red cell folate assay.

1. URINARY EXCRETION OF FIGLU Folic acid is required for conversion of formiminoglutamic acid (FIGLU) to glutamic acid in the catabolism of histidine. Thus, on oral administration of histidine, urinary excretion of FIGLU is increased if folate deficiency is present.

2. SERUM FOLATE ASSAY The folate in serum can be estimated by 2 methods—microbiological assay and radioassay.

i) Microbiological assay This test is based on the principle that the serum folate acid activity is mainly due to the presence of a folic acid co-enzyme, 5-methyl THF, and that this compound is required for growth of the microorganism, *Lactobacillus casei*. The growth of *L. casei* is inhibited by addition of antibiotics.

ii) Radioassay The principle and method of radioassay by radioisotope dilution (RID) test are similar to that for serum B₁₂ assay. The test employs labelled pteroylglutamic acid or methyl-THF. Commercial kits are available which permit simultaneous assay of both vitamin B₁₂ and folate.

3. RED CELL FOLATE ASSAY Red cells contain 20-50 times more folate than the serum; thus red cell folate assay is more reliable indicator of tissue stores of folate than serum folate assay. Microbiological radioassay and protein-binding assay methods can be used for estimation of red cell folate. Red cell folate values are decreased in patients with megaloblastic anaemia as well as in patients with pernicious anaemia.

PRINCIPLES OF TREATMENT

Most cases of megaloblastic anaemia need therapy with appropriate vitamin. This includes: hydroxycobalamin as intramuscular injection 1000 µg for 3 weeks and oral folic acid 5 mg tablets daily for 4 months. Severely-anaemic patients in whom a definite deficiency of either vitamin cannot be established with certainty are treated with both vitamins concurrently. Blood transfusion should be avoided since it may cause circulatory overload. Packed cells may, however, be infused slowly.

Treatment of megaloblastic anaemia is quite gratifying. The marrow begins to revert back to normal morphology within a few hours of initiating treatment and becomes normoblastic within 48 hours of start of treatment. Reticulocytosis appears within 4-5 days after therapy is started and peaks at day 7. Haemoglobin should rise by 2-3 g/dl each fortnight. The peripheral neuropathy may show some improvement but subacute combined degeneration of the spinal cord is irreversible.

PERNICIOUS ANAEMIA

Pernicious anaemia (PA) was first described by Addison in 1855 as a chronic disorder of middle-aged and elderly individual of either sex in which intrinsic factor (IF) secretion ceases owing to atrophy of the gastric mucosa. The condition is, therefore, also termed Addisonian megaloblastic anaemia. The average age at presentation is 60 years but rarely it can be seen in children under 10 years of age (juvenile pernicious anaemia). PA is seen most frequently in individuals of northern European descent and African Americans and is uncommon in South Europeans and Orientals.

PATHOGENESIS

There is evidence to suggest that the atrophy of gastric mucosa in PA resulting in absence or low level of IF is caused by an autoimmune reaction against gastric parietal cells. The evidences in support of immunological abnormalities in pernicious anaemia are as under:

1. The incidence of PA is high in patients with *other autoimmune diseases* such as Graves' disease, myxoedema, thyroiditis, vitiligo, diabetes and idiopathic adrenocortical insufficiency.
2. Patients with PA have abnormal *circulating autoantibodies* such as anti-parietal cell antibody (90% cases) and anti-intrinsic factor antibody (50% cases).
3. *Relatives* of patients with PA have an increased incidence of the disease or increased presence of autoantibodies.
4. *Corticosteroids* have been reported to be beneficial in curing the disease both pathologically and clinically.
5. PA is more common in patients with *agammaglobulinaemia* supporting the role of cellular immune system in destruction of parietal cells.
6. Certain *HLA types* have been reported to be associated with PA.

MORPHOLOGIC FEATURES The most characteristic pathologic finding in PA is gastric atrophy affecting the acid- and pepsin-secreting portion of the stomach and sparing the antrum (page 532). Gastric epithelium may show cellular atypia. About 2-3% cases of PA develop carcinoma of the stomach. Other pathologic changes are secondary

to vitamin B₁₂ deficiency and include megaloblastoid alterations in the gastric and intestinal epithelium and neurologic abnormalities such as peripheral neuropathy and spinal cord damage.

CLINICAL FEATURES

The disease has insidious onset and progresses slowly. The clinical manifestations are mainly due to vitamin B₁₂ deficiency. These include: anaemia, glossitis, neurological abnormalities (neuropathy, subacute combined degeneration of the spinal cord, retrobulbar neuritis), gastrointestinal manifestations (diarrhoea, anorexia, weight loss, dyspepsia), hepatosplenomegaly, congestive heart failure and haemorrhagic manifestations. Other autoimmune diseases such as autoimmune thyroiditis may be associated.

PRINCIPLES OF TREATMENT

Patients of PA are treated with vitamin B₁₂ in the following way:

1. Parenteral vitamin B₁₂ replacement therapy.
2. Symptomatic and supportive therapy such as physiotherapy for neurologic deficits and occasionally blood transfusion.
3. Follow-up for early detection of cancer of the stomach.

Most of the abnormalities due to vitamin B₁₂ deficiency can be corrected except the irreversible damage to the spinal cord. Corticosteroid therapy can improve the gastric lesion with a return of acid secretion but the higher incidence of gastric polyps and cancer of the stomach in these patients can only be detected by frequent follow-up.

GIST BOX 10.5

Megaloblastic and Pernicious Anaemias: Vitamin B₁₂ and Folate Deficiency

- ▣ Megaloblastic anaemias are associated with macrocytic blood picture and megaloblastic marrow erythropoiesis. This group is due to deficiency of vitamin B₁₂ and/or folate.
- ▣ The only dietary sources of vitamin B₁₂ are foods of animal protein origin while folate exists in different plants, bacteria and animal tissues.

- ▣ The basic biochemical abnormality in both vitamin B₁₂ and folate deficiency is a block in the pathway of DNA synthesis.
- ▣ Clinical features of megaloblastic anaemia are anaemia, glossitis, and neurological manifestations.
- ▣ Laboratory diagnosis is made by macrocytic blood picture, raised MCV and MCH, and megaloblastic erythropoiesis in the bone marrow with raised iron stores.
- ▣ Specific deficiency of vitamin B₁₂ and folate can be made by serum assay and Schilling test.
- ▣ Pernicious anaemia is megaloblastic erythropoiesis from impaired absorption of vitamin B₁₂ which is due to deficiency of intrinsic factor from atrophic gastritis.

HAEMOLYTIC ANAEMIAS AND ANAEMIA DUE TO BLOOD LOSS

DEFINITION AND CLASSIFICATION

Haemolytic anaemias are defined as anaemias resulting from an increase in the rate of red cell destruction. Normally, effete red cells undergo lysis at the end of their lifespan of 120 ± 30 days within the cells of reticuloendothelial (RE) system in the spleen and elsewhere (extravascular haemolysis), and haemoglobin is not liberated into the plasma in appreciable amounts. The red cell lifespan is shortened in haemolytic anaemia i.e. there is accelerated haemolysis. However, shortening of red cell lifespan does not necessarily result in anaemia. In fact, compensatory bone marrow hyperplasia may cause 6 to 8-fold increase in red cell production without causing anaemia to the patient, so-called *compensated haemolytic disease*.

The premature destruction of red cells in haemolytic anaemia may occur at either of the following 2 sites:

- ◆ **Firstly**, the red cells undergo lysis in the circulation and release their contents into plasma (*intravascular haemolysis*). In these cases the plasma haemoglobin rises substantially and part of it may be excreted in the urine (*haemoglobinuria*).
- ◆ **Secondly**, the red cells are taken up by cells of the RE system where they are destroyed and digested (*extravascular*

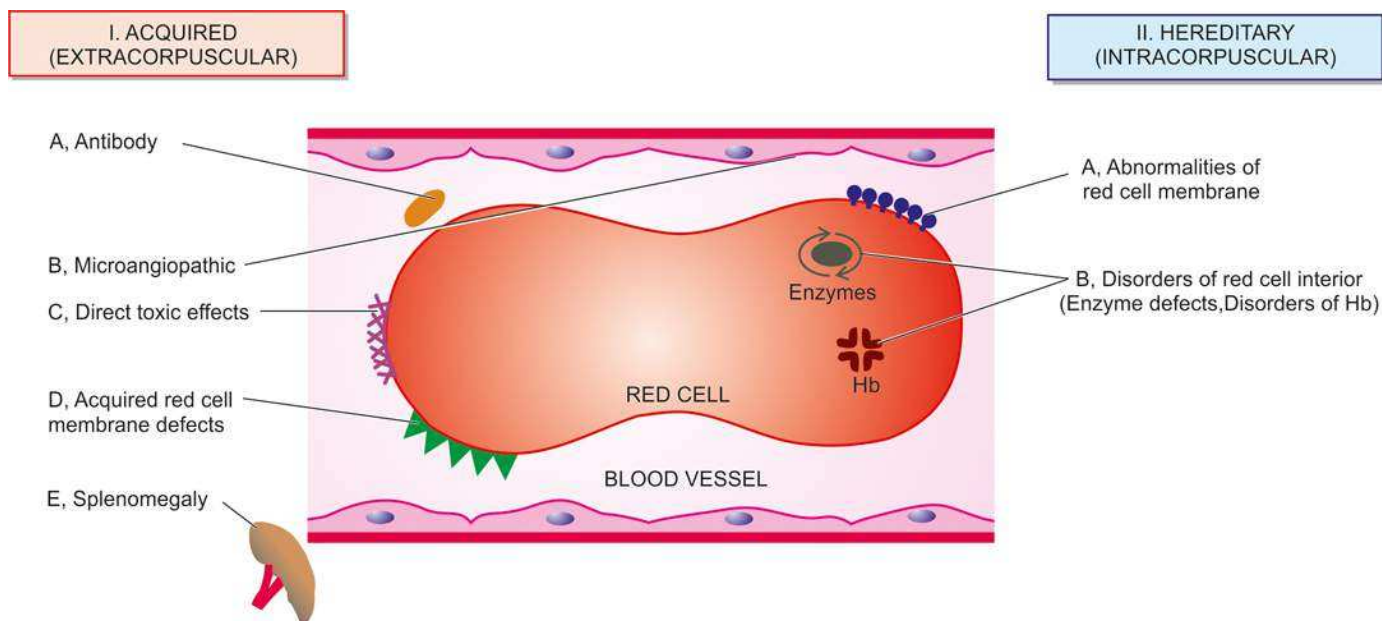

Figure 10.21 Diagrammatic representation of classification of haemolytic anaemias based on principal mechanisms of haemolysis.

haemolysis). In extravascular haemolysis, plasma haemoglobin level is, therefore, barely raised.

Extravascular haemolysis is more common than the former. One or more factors may be involved in the pathogenesis of various haemolytic anaemias.

Clinically, haemolytic anaemias may be acute or chronic, mild to severe, hereditary or acquired. Haemolytic anaemias are broadly classified into 2 main categories:

- I. *Acquired haemolytic anaemias* caused by a variety of extrinsic environmental factors (*i.e. extracorporeal*).
- II. *Hereditary haemolytic anaemias* are usually the result of intrinsic red cell defects (*i.e. intracorporeal*).

A simplified classification based on these mechanisms is given in **Table 10.10** and diagrammatically represented in **Fig. 10.21**.

GENERAL ASPECTS

A number of clinical and laboratory features are shared by various types of haemolytic anaemias. These are briefly described below:

GENERAL CLINICAL FEATURES

Some of the general clinical features common to most congenital and acquired haemolytic anaemias are as under:

1. Presence of pallor of mucous membranes.
2. Positive family history with life-long anaemia in patients with congenital haemolytic anaemia.
3. Mild fluctuating jaundice due to unconjugated hyperbilirubinaemia.
4. Urine turns dark on standing due to excess of urobilinogen in urine.

| 2. Hereditary elliptocytosis (hereditary ovalocytosis) |
| 3. Hereditary stomatocytosis |
| B. <i>Disorders of red cell interior</i> |
| 1. <i>Red cell enzyme defects (Enzymopathies)</i> |
| i) Defects in the hexose monophosphate shunt: G6PD deficiency |
| ii) Defects in the Embden-Meyerhof (or glycolytic) pathway: pyruvate kinase deficiency |
| 2. <i>Disorders of haemoglobin (Haemoglobinopathies)</i> |
| i) Structurally abnormal haemoglobins: sickle syndromes, other haemoglobinopathies |
| ii) Reduced globin chain synthesis: thalassaemias |

5. Splenomegaly is found in most chronic haemolytic anaemias, both congenital and acquired.
6. Pigment gallstones are found in some cases.

LABORATORY EVALUATION OF HAEMOLYSIS

Pathways by which haemoglobin derived from effete red cells is metabolised is already discussed on page 272. The investigations of a patient suspected to have haemolytic anaemia should provide answers to 3 vital questions:

1. Is there evidence of haemolysis?
2. What is the type of haemolytic mechanism?
3. What is the precise diagnosis?

The laboratory findings are conveniently divided into the following 4 groups:

I. Tests of Increased Red Cell Breakdown

1. *Serum bilirubin*—unconjugated (indirect) bilirubin is raised.
2. *Urine urobilinogen* is raised but there is no bilirubinuria.
3. *Faecal stercobilinogen* is raised.
4. *Serum haptoglobin* (α -globulin binding protein) is reduced or absent.
5. *Plasma lactic dehydrogenase* is raised.
6. *Evidences of intravascular haemolysis* in the form of haemoglobinaemia, haemoglobinuria, methaemoglobinaemia and haemosiderinuria.

II. Tests of Increased Red Cell Production

1. *Reticulocyte count* reveals reticulocytosis which is generally early and is hence most useful initial test of marrow erythroid hyperplasia.
2. *Routine blood film* shows macrocytosis, polychromasia and presence of normoblasts.
3. *Bone marrow* shows erythroid hyperplasia with usually raised iron stores.
4. *X-ray of bones* shows evidence of expansion of marrow space, especially in tubular bones and skull.

III. Tests of Damage to Red Cells

1. *Routine blood film* shows a variety of abnormal morphological appearances of red cells described on page 269 and illustrated in **Fig. 10.10** already. A summary of contributory features of morphology of RBCs in arriving at the diagnosis of haemolytic anaemia and its cause is given in **Table 10.11**.
2. *Osmotic fragility* is increased or decreased.
3. *Autohaemolysis test* with or without addition of glucose.
4. *Coombs' antiglobulin test*.
5. *Electrophoresis* for abnormal haemoglobins.
6. *Estimation of HbA₂*.
7. *Estimation of HbF*.
8. *Tests for sickling*.
9. *Screening test for G6PD deficiency* and other enzymes (e.g. Heinz bodies test).

IV. Tests for Shortened Red Cell Lifespan

A shortened red cell survival is best tested by ⁵¹Cr labelling method. Normal RBC lifespan of 120 days is shortened to 20-40 days in moderate haemolysis and to 5-20 days in severe haemolysis.

Table 10.11 Red cell morphologic features in various types of haemolytic anaemias.

| FEATURE | ETIOLOGY | TYPE OF HAEMOLYTIC ANAEMIA |
|-------------------------------------|---|--|
| 1. <i>Spherocytes</i> | Loss of spectrin from membrane | Hereditary spherocytosis AIHA |
| 2. <i>Target cells (Leptocytes)</i> | Increased ratio of surface area: volume | Thalassaemias Liver disease HbS disease HbC disease |
| 3. <i>Schistocytes</i> | Traumatic damage to red cell membrane | Microangiopathy |
| 4. <i>Sickle cells</i> | Polymerisation of HbS | Sickle syndromes |
| 5. <i>Acanthocytes (Spur cells)</i> | Abnormality in membrane lipids | Severe liver disease |
| 6. <i>Heinz bodies</i> | Precipitated Hb | Unstable Hb |

Contrasting features of intravascular and extravascular haemolysis are given in **Table 10.12**.

After these general comments on clinical and laboratory features of haemolysis, we now turn to discuss various types of haemolytic anaemias given in **Table 10.10**.

I. ACQUIRED HAEMOLYTIC ANAEMIAS

Acquired haemolytic anaemias are caused by a variety of extrinsic factors, namely: antibody (immunohaemolytic anaemia), mechanical factors (microangiopathic haemolytic anaemia), direct toxic effect (in malaria, clostridial infection etc), splenomegaly, and certain acquired membrane abnormalities (paroxysmal nocturnal haemoglobinuria). These are discussed below:

A. IMMUNOHAEMOLYTIC ANAEMIAS

Immunohaemolytic anaemias are a group of anaemias occurring due to antibody production by the body against its own red cells. Immune haemolysis in these cases may be induced by one of the following three types of antibodies:

1. *Autoimmune haemolytic anaemia (AIHA)* characterised by formation of autoantibodies against patient's own red cells.

Depending upon the reactivity of autoantibody, AIHA is further divided into 2 types:

- 'Warm' antibody AIHA in which the autoantibodies are reactive at body temperature (37°C).
- 'Cold' antibody AIHA in which the autoantibodies react better with patient's own red cells at 4°C.

2. *Drug-induced immunohaemolytic anaemia*.

3. *Isoimmune haemolytic anaemia* in which the antibodies are acquired by blood transfusions, pregnancies and haemolytic disease of the newborn.

An important diagnostic tool in all cases of immunohaemolytic anaemias is Coombs' antiglobulin test for detection of incomplete Rh-antibodies in saline directly (direct Coombs') or after addition of albumin (indirect Coombs').

Autoimmune Haemolytic Anaemia (AIHA)

'WARM' ANTIBODY AIHA

PATHOGENESIS Warm antibodies reactive at body temperature and coating the red cells are generally IgG class antibodies and occasionally they are IgA. Little is known about the origin of these acquired red blood cell antibodies in AIHA but the mechanism of destruction of red cells coated with IgG is better understood. Human red cells coated with IgG antibodies are bound to the surface of RE cells, especially splenic macrophages. A part of the coated cell membrane is lost resulting in spherical transformation of the red cells (acquired spherocytosis). Red cells coated with IgG along with C3 on the surface further promote this red cell-leucocyte interaction, accounting for more severe haemolysis. The spleen is particularly efficient in trapping red cells coated with IgG antibodies. It is, thus, the major site of red cell destruction in warm antibody AIHA.

CLINICAL FEATURES Warm antibody AIHA may occur at any age and in either sex. The disease may occur without any apparent cause (idiopathic) but about a quarter of patients develop this disorder as a complication of an underlying disease affecting the immune system such as SLE, chronic lymphocytic leukaemia, lymphomas and certain drugs such as methyl DOPA, penicillin etc (**Table 10.13**).

The disease tends to have remissions and relapses. The usual clinical features are as follows:

- Chronic anaemia of varying severity with remissions and relapses.
- Splenomegaly.
- Occasionally hyperbilirubinaemia.

Table 10.12 Contrasting features of extravascular and intravascular haemolysis.

| FEATURE | EXTRAVASCULAR HAEMOLYSIS | INTRAVASCULAR HAEMOLYSIS |
|--|---|--------------------------|
| 1. <i>Frequency</i> | More common | Less common |
| 2. <i>Location</i> | RE system organs (spleen, bone marrow, liver) | In peripheral blood |
| 3. <i>Iron stores</i> | Increased | Decreased |
| 4. <i>Serum ferritin</i> | Normal to high | Low |
| 5. <i>Plasma haemoglobin</i> | Absent | Present |
| 6. <i>Methaemoglobin</i> | Absent | Present |
| 7. <i>Haemoglobinuria</i> | Absent | Present |
| 8. <i>Haemosiderinuria</i> | Absent | Present |
| 9. <i>Unconjugated hyperbilirubinaemia</i> | Markedly elevated | Mildly elevated |
| 10. <i>Serum LDH</i> | Mildly elevated | Markedly elevated |

Table 10.13 Conditions predisposing to autoimmune haemolytic anaemia (AIHA).

- A. WARM ANTIBODY AIHA
1. Idiopathic (primary)
 2. Lymphomas-leukaemias e.g. non-Hodgkin's lymphoma, CLL, Hodgkin's disease.
 3. Collagen vascular diseases e.g SLE
 4. Drugs e.g. methyl dopa, penicillin, quinidine group
 5. Post-viral
- B. COLD ANTIBODY AIHA
1. Cold agglutinin disease
 - a) Acute: *Mycoplasma* infection, infectious mononucleosis
 - b) Chronic: Idiopathic, lymphomas
 2. PCH (*Mycoplasma* infection, viral flu, measles, mumps, syphilis)

LABORATORY FINDINGS The haematological and biochemical findings in such cases are as under:

1. Mild to moderate chronic anaemia.
2. Reticulocytosis.
3. Prominent spherocytosis in the peripheral blood film.
4. Positive direct Coombs' (antiglobulin) test for presence of warm antibodies on the red cell, best detected at 37°C.
5. A positive indirect Coombs' (antiglobulin) test at 37°C may indicate presence of large quantities of warm antibodies in the serum.
6. Unconjugated (indirect) hyperbilirubinaemia.
7. Co-existent immune thrombocytopenia along with occasional venous thrombosis may be present (termed Evans' syndrome).
8. In more severe cases, haemoglobinaemia and haemoglobinuria may be present.

Treatment of these cases consists of removal of the cause whenever present, corticosteroid therapy, and in severe cases blood transfusions. Splenectomy is the second line of therapy in this disorder.

'COLD' ANTIBODY AIHA

PATHOGENESIS Antibodies which are reactive in the cold (4°C) may induce haemolysis under 2 conditions: cold agglutinin disease and paroxysmal cold haemoglobinuria.

1. Cold agglutinin disease In cold agglutinin disease, the antibodies are IgM type which bind to the red cells best at 4°C. These cold antibodies are usually directed against the *I* antigen on the red cell surface. Agglutination of red blood cells by IgM cold agglutinins is most profound at very low temperature but upon warming to 37°C or above, disagglutination occurs quickly. Haemolytic effect is mediated through fixation of C3 to the red blood cell surface and not by agglutination alone. Most cold agglutinins affect juvenile red blood cells.

The etiology of cold antibody remains unknown. It is seen in the course of certain infections (e.g. *Mycoplasma* pneumonia, infectious mononucleosis) and in lymphomas.

2. Paroxysmal cold haemoglobinuria (PCH) In PCH, cold antibody is an IgG antibody (Donath-Landsteiner antibody) which is directed against *P* blood group antigen and brings about complement-mediated haemolysis. Attacks of PCH are precipitated by exposure to cold.

PCH is uncommon and may be seen in association with tertiary syphilis or as a complication of certain infections such as *Mycoplasma*, pneumonia, flu, measles and mumps.

CLINICAL FEATURES The clinical manifestations are due to haemolysis and not due to agglutination. These include the following:

1. Chronic anaemia which is worsened by exposure to cold.
2. Raynaud's phenomenon.
3. Cyanosis affecting the cold exposed regions such as tips of nose, ears, fingers and toes.
4. Haemoglobinaemia and haemoglobinuria occur on exposure to cold.

LABORATORY FINDINGS The haematologic and biochemical findings are somewhat similar to those found in warm antibody AIHA except the thermal amplitude. These findings are as follows:

1. Chronic anaemia.
2. Low reticulocyte count since *young red cells are affected more*.
3. Spherocytosis is less marked.
4. Positive direct Coombs' test for detection of C3 on the red cell surface but IgM responsible for C3 coating on red cells is not found.
5. The cold antibody titre is very high at 4°C and very low at 37°C (Donath-Landsteiner test). IgM class cold antibody has specificity for *I* antigen, while the rare IgG class antibody of PCH has *P* blood group antigen specificity.

Treatment consists of keeping the patient warm and treating the underlying cause.

Drug-induced Immuno-haemolytic Anaemia

Drugs may cause immuno-haemolytic anaemia by 3 different mechanisms:

1. α-METHYL DOPA TYPE ANTIBODIES A small proportion of patients receiving α-methyl dopa develop immuno-haemolytic anaemia which is identical in every respect to warm antibody AIHA described above.

2. PENICILLIN-INDUCED IMMUNOHAEMOLYSIS Patients receiving large doses of penicillin or penicillin-type antibiotics develop antibodies against the red blood cell-drug complex which induces haemolysis.

3. INNOCENT BYSTANDER IMMUNOHAEMOLYSIS Drugs such as quinidine form a complex with plasma proteins to which an antibody forms. This drug-plasma protein-antibody complex may induce lysis of bystanding red blood cells or platelets.

In each type of drug-induced immuno-haemolytic anaemia, discontinuation of the drug results in gradual disappearance of haemolysis.

Isoimmune Haemolytic Anaemia

Isoimmune haemolytic anaemias are caused by acquiring isoantibodies or alloantibodies by blood transfusions, pregnancies and in haemolytic disease of the newborn. These antibodies produced by one individual are directed against red blood cells of the other. These conditions are considered on page 319.

B. MICROANGIOPATHIC HAEMOLYTIC ANAEMIA

Microangiopathic haemolytic anaemia is caused by abnormalities in the microvasculature. It is generally due

to mechanical trauma to the red cells in circulation and is characterised by red cell fragmentation (schistocytosis). There are 3 different ways by which microangiopathic haemolytic anaemia results:

1. EXTERNAL IMPACT Direct external trauma to red blood cells when they pass through microcirculation, especially over the bony prominences, may cause haemolysis during various activities e.g. in prolonged marchers, joggers, karate players etc. These patients develop haemoglobinuria, haemoglobinuria (march haemoglobinuria), and sometimes myoglobinuria as a result of damage to muscles.

2. CARDIAC HAEMOLYSIS A small proportion of patients who receive prosthetic cardiac valves or artificial grafts develop haemolysis. This has been attributed to direct mechanical trauma to the red cells or shear stress from turbulent blood flow.

3. FIBRIN DEPOSIT IN MICROVASCULATURE Deposition of fibrin in the microvasculature exposes the red cells to physical obstruction and eventual fragmentation of red cells and trapping of the platelets. Fibrin deposits in the small vessels may occur in the following conditions:

- i) *Abnormalities of the vessel wall* e.g. in hypertension, eclampsia, disseminated cancers, transplant rejection, haemangioma etc.
- ii) *Thrombotic thrombocytopenic purpura.*
- iii) *Haemolytic-uraemic syndrome.*
- iv) *Disseminated intravascular coagulation (DIC).*
- v) *Vasculitis in collagen diseases.*

All these conditions are described in relevant sections separately.

C. HAEMOLYTIC ANAEMIA FROM DIRECT TOXIC EFFECTS

Haemolysis may result from direct toxic effects of certain agents. These include the following examples:

1. *Malaria* by direct parasitisation of red cells (black-water fever) (**Fig. 10.22**).
2. *Bartonellosis* by direct infection of red cells by the microorganisms.
3. *Septicaemia* with *Clostridium welchii* by damaging the red cells.
4. *Other microorganisms* such as pneumococci, staphylococci and *Escherichia coli*.
5. *Copper* by direct haemolytic effect on red cells in Wilson's disease and patients on haemodialysis.
6. *Lead poisoning* shows basophilic stippling of red blood cells.
7. *Snake and spider bites* cause haemolysis by their venoms.
8. *Extensive burns.*

D. PAROXYSMAL NOCTURNAL HAEMOGLOBINURIA (PNH)

PNH is a rare acquired disorder of red cell membrane in which there is chronic intravascular haemolysis due to undue sensitivity of red blood cells to complement due to defective synthesis of a red cell membrane protein. The defect affects all the cells of myeloid progenitor lineage (RBCs, WBCs, platelets) suggesting a deficient haematopoiesis. The disorder generally presents in adult life.

PATHOGENESIS PNH is considered as an acquired clonal disease of the cell membrane while normal clone

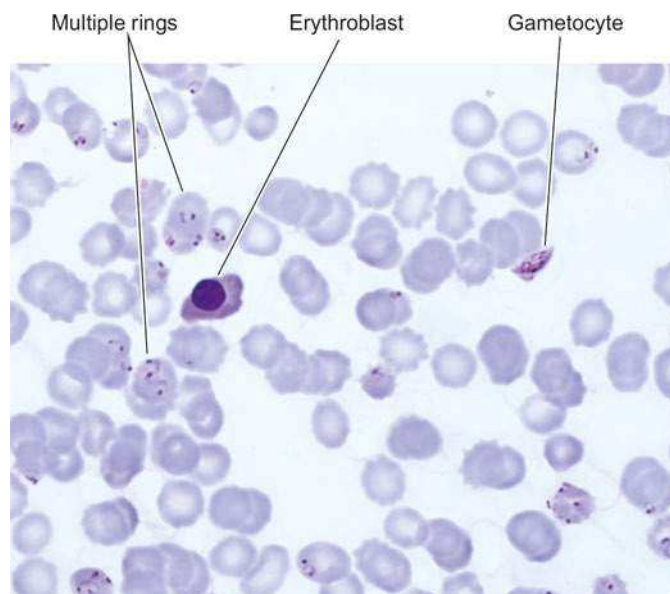

Figure 10.22 Malarial parasite, *Plasmodium falciparum*, in the peripheral blood showing numerous ring stages and a crescent of gametocyte. The background shows a normoblast.

also continues to proliferate. The defect is a mutation in the stem cells affecting myeloid progenitor cells that is normally required for the biosynthesis of glycosyl phosphatidyl inositol (GPI) essential for anchoring of the cell; the mutant form of the gene is an X-linked gene called PIG-A (phosphatidyl inositol glycan). Thus, as a result of mutation, there is partial or complete deficiency of anchor protein. Out of about 20 such proteins described so far, the lack of two of the proteins—*decay accelerating factor (DAF, CD55)* and a *membrane inhibitor of reactive lysis (MIRL, CD59)*, makes the RBCs unduly sensitive to the lytic effect of complement.

Since PNH is a stem cell disorder, it may be accompanied with other stem cell disorders such as aplastic anaemia and myelodysplastic syndrome.

CLINICAL AND LABORATORY FINDINGS Clinical and laboratory findings are as under:

- i) Haemolytic anaemia.
- ii) Pancytopenia (mild granulocytopenia and thrombocytopenia frequent).
- iii) Intermittent clinical haemoglobinuria; acute haemolytic episodes occur at night identified by passage of brown urine in the morning.
- iv) Haemosiderinuria very common.
- v) Venous thrombosis as a common complication.

The presence of inordinate sensitivity of red blood cells, leucocytes and platelets to complement in PNH can be demonstrated *in vitro* by *Ham's test* using red cell lysis at acidic pH or by sucrose haemolysis test.

About 20% cases of PNH may develop myeloproliferative or myelodysplastic disorder and some even develop acute myeloid leukaemia.

E. HAEMOLYTIC ANAEMIA IN SPLENOMEGALY

Haemolytic anaemia is common in splenic enlargement from any cause (page 367). Normally, the spleen acts as a filter and traps the damaged red blood cells, destroys them and

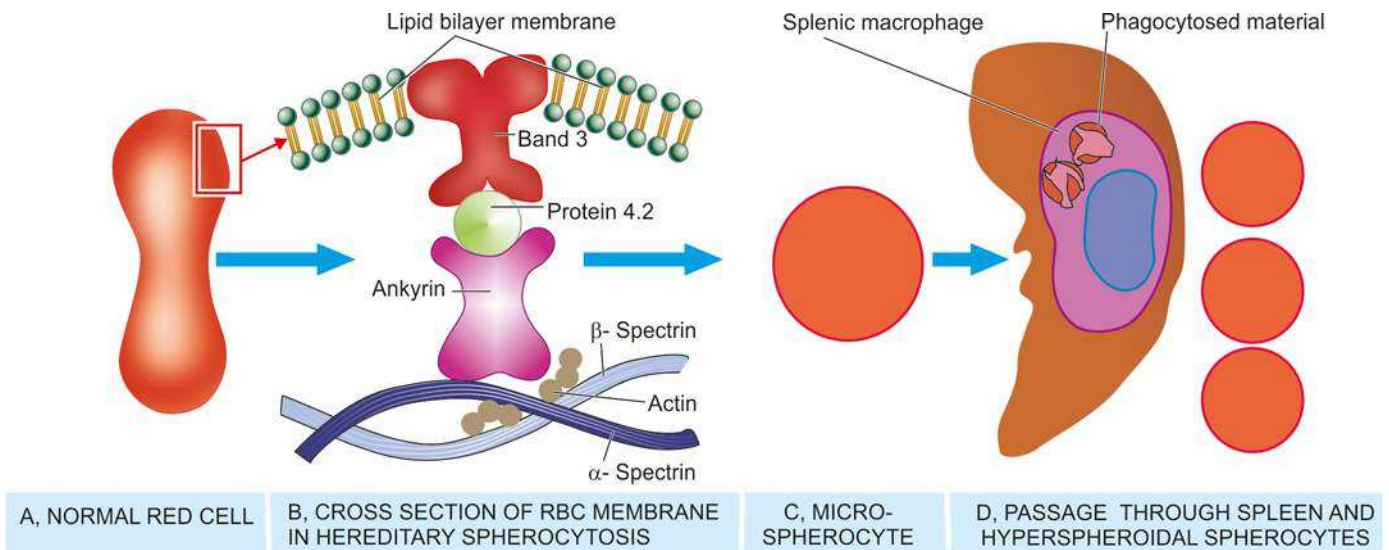

Figure 10.23 Diagrammatic representation of pathogenesis of hereditary spherocytosis. A, Normal red cell with biconcave surface and normal size. B, Red cell membrane as seen in cross section in hereditary spherocytosis. Mutations in membrane proteins— α -spectrin, β -spectrin and ankyrin, result in defect in anchoring of lipid bilayer of the membrane to the underlying cytoskeleton. C, This results in spherical contour and small size so as to contain the given volume of haemoglobin in the deformed red cell. D, During passage through the spleen, these rigid spherical cells lose their cell membrane further. This produces a circulating subpopulation of hyperspheroidal spherocytes while splenic macrophages in large numbers phagocytose defective red cells causing splenomegaly.

the splenic macrophages phagocytose the damaged red cells. A normal spleen poses no risk to normal red blood cells. But splenomegaly exaggerates the damaging effect to which the red cells are exposed. Besides haemolytic anaemia, splenomegaly is usually associated with pancytopenia. Splenectomy or reduction in size of spleen by appropriate therapy relieves the anaemia as well as improves the leucocyte and platelet counts.

II. HEREDITARY HAEMOLYTIC ANAEMIAS

Hereditary haemolytic anaemias are usually the result of intracorporeal defects. Accordingly, they are broadly classified into 2 groups:

- A. Hereditary abnormalities of red cell membrane.
- B. Hereditary disorders of the interior of the red cells.

A. HEREDITARY ABNORMALITIES OF RED CELL MEMBRANE

The abnormalities of red cell membrane are readily identified on blood film examination. There are 3 important types of inherited red cell membrane defects: hereditary spherocytosis, hereditary elliptocytosis (hereditary ovalocytosis) and hereditary stomatocytosis.

Hereditary Spherocytosis

Hereditary spherocytosis is a common type of hereditary haemolytic anaemia of autosomal dominant inheritance in which the red cell membrane is abnormal.

PATHOGENESIS The molecular abnormality in hereditary spherocytosis is a defect in proteins which anchor the lipid bilayer to the underlying cytoskeleton. These protein abnormalities are as under and are schematically illustrated in **Fig. 10.23**:

1. **Spectrin deficiency** Almost all cases have deficiency in the structural protein of the red cell membrane, spectrin.

Spectrin deficiency correlates with the severity of anaemia. Mutation in spectrin by recessive inheritance called α -spectrin causes more severe form of anaemia, while mutation by dominant inheritance forming β -spectrin results in mild form of the disease.

2. **Ankyrin abnormality** About half the cases of hereditary spherocytosis have defect in ankyrin, protein that binds protein 3 and spectrin. Homozygous state with recessive inheritance pattern has severe anaemia while heterozygotes with more common dominant inheritance pattern have milder anaemia.

Inherited mutation in spectrin or ankyrin causes defect in anchoring of lipid bilayer cell membrane. Red cells with such unstable membrane but with normal volume, when released in circulation, lose their membrane further, till they can accommodate the given volume. This results in formation of spheroidal contour and smaller size of red blood cells, termed *microspherocytes*. These deformed red cells are not flexible, unlike normal biconcave red cells. These rigid cells are unable to pass through the spleen, and in the process they lose their surface membrane further. This produces a subpopulation of *hyperspheroidal red cells* in the peripheral blood which are subsequently destroyed in the spleen.

CLINICAL FEATURES The disorder may be clinically apparent at any age from infancy to old age and has equal sex incidence. The family history may be present. The major clinical features are as under:

1. *Anaemia* is usually mild to moderate.
2. *Splenomegaly* is a constant feature.
3. *Jaundice* occurs due to increased concentration of unconjugated (indirect) bilirubin in the plasma (also termed congenital haemolytic jaundice).
4. *Pigment gallstones* are frequent due to increased bile pigment production. Splenectomy offers the only reliable mode of treatment.

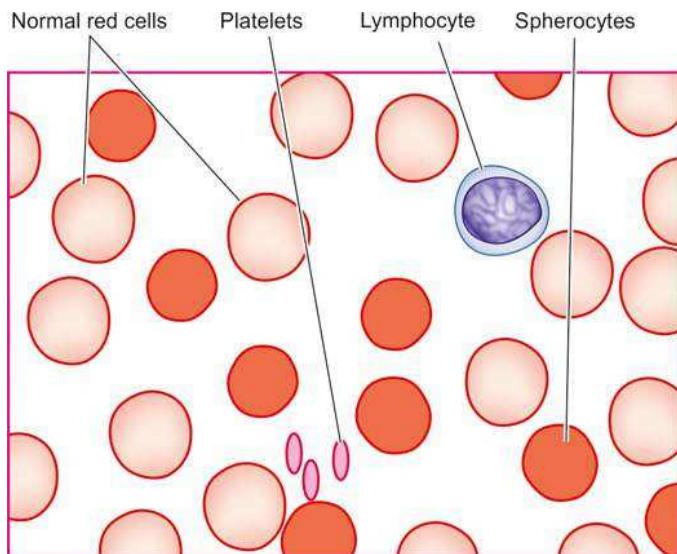

Figure 10.24 Peripheral blood film findings in hereditary spherocytosis.

LABORATORY FINDINGS The usual haematological and biochemical findings are as under:

1. *Anaemia* of mild to moderate degree.
2. *Reticulocytosis*, usually 5-20%.
3. Blood film shows the characteristic abnormality of erythrocytes in the form of microspherocytes (**Fig. 10.24**).
4. MCV is usually normal or slightly decreased but *MCHC* is increased.
5. Osmotic fragility test is helpful in testing the spheroidal nature of red cells which lyse more readily in solutions of low salt concentration i.e. *osmotic fragility is increased* (**Fig. 10.25**).
6. *Autohaemolysis test* is similar to osmotic fragility test after incubation and shows increased spontaneous autohaemolysis (10-15% red cells) as compared to normal red cells (less than 4%). Autohaemolysis is correctable by addition of glucose.
7. *Direct Coombs' (antiglobulin) test* is negative so as to distinguish this condition from acquired spherocytosis of AIHA in which case it is positive.

Spherocytes may also be seen in blood film in acquired immune haemolytic anaemia and following red cell transfusion.

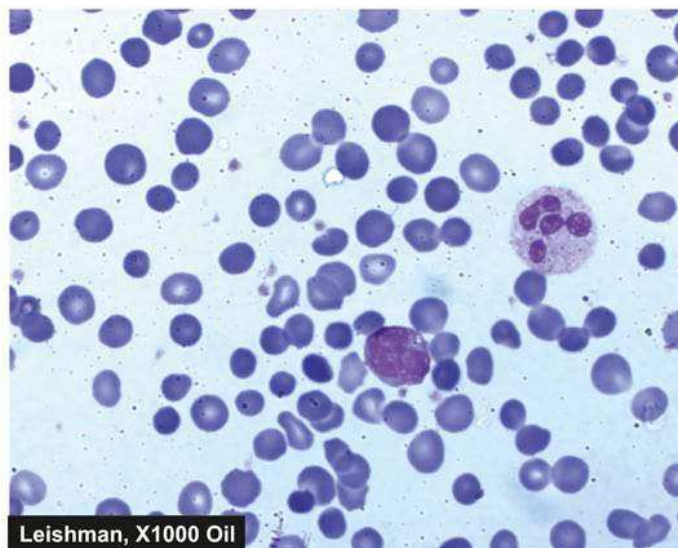

Hereditary Elliptocytosis (Hereditary Ovalocytosis)

Hereditary elliptocytosis or hereditary ovalocytosis is another autosomal dominant disorder involving red cell membrane protein *spectrin*. Some patients have an inherited defect in erythrocyte membrane protein 4.1 that interconnects spectrin with actin in the cytoskeleton. The disorder is similar in all respects to hereditary spherocytosis except that the blood film shows oval or elliptical red cells and is clinically a milder disorder than hereditary spherocytosis.

Acquired causes of elliptocytosis include iron deficiency and myeloproliferative disorders.

Hereditary Stomatocytosis

Stomatocytes are cup-shaped RBCs having one surface concave and the other side as convex. This causes a central slit-like or mouth-like appearance of red cells. The underlying defect is in membrane protein, *stomat*, having autosomal

dominant pattern of inheritance. The stomatocytes are swollen red cells (overhydrated red cells) due to increased permeability to sodium and potassium. The affected patients have mild anaemia and splenomegaly.

B. HEREDITARY DISORDERS OF RED CELL INTERIOR

Inherited disorders involving the interior of the red blood cells are classified into 2 groups:

1. Red cell enzyme defects (Enzymopathies) These cause defective red cell metabolism involving 2 pathways (**Fig. 10.26**):

- i) *Defects in the hexose monophosphate shunt*: Common example is glucose-6-phosphate dehydrogenase (G6PD) deficiency.
- ii) *Defects in the Embden-Meyerhof (glycolytic) pathway*: Example is pyruvate kinase (PK) deficiency.

2. Disorders of haemoglobin (haemoglobinopathies)

These are divided into 2 subgroups:

- i) *Structurally abnormal haemoglobin*: Examples are sickle syndromes and other haemoglobinopathies.
- ii) *Reduced globin chain synthesis*: Common examples are various types of thalassaemias.

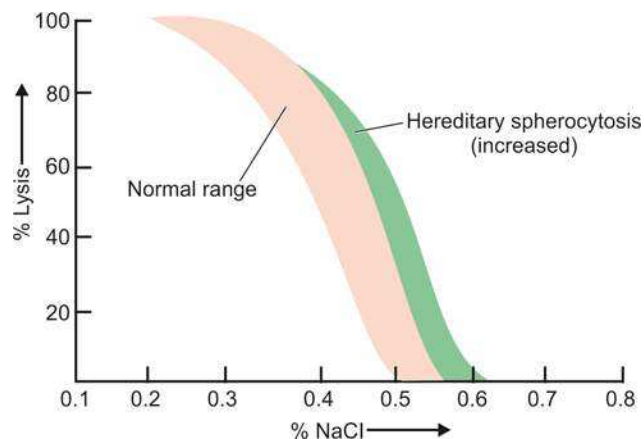

Figure 10.25 Osmotic fragility test in hereditary spherocytosis showing increased fragility.

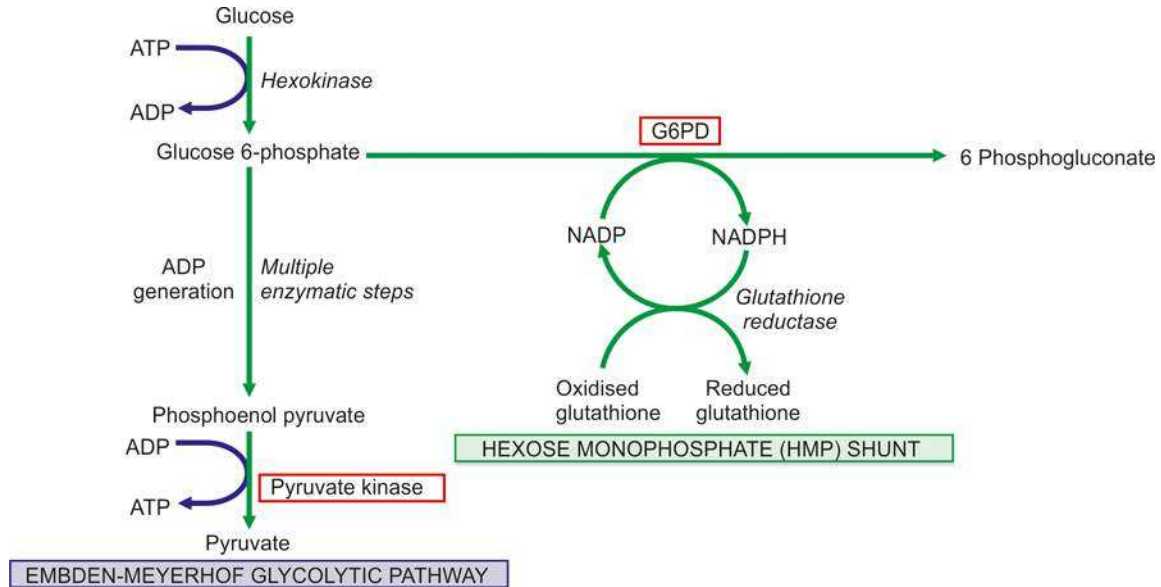

Figure 10.26 Abbreviated pathways of anaerobic glycolysis (Embden-Meyerhof) and hexose monophosphate (HMP) shunt in the metabolism of erythrocyte. The two red cell enzyme defects, glucose-6 phosphate dehydrogenase (G6PD) and pyruvate kinase, are shown in bold.

These disorders are discussed below.

Red Cell Enzyme Defects (Enzymopathies)

G6PD DEFICIENCY

Among the defects in hexose monophosphate shunt, the most common is G6PD deficiency. It affects millions of people throughout the world. G6PD gene is located on the X chromosome and its deficiency is, therefore, a sex (X)-linked trait affecting males, while the females are carriers and are asymptomatic. Several variants of G6PD have been described. The normal G6PD variant is designated as type B but blacks have normally A+ (positive) type G6PD variant. The most common and significant clinical variant is A-(negative) type found in black males. Like the HbS gene, the A-type G6PD variant confers protection against malaria. Individuals with A-type G6PD variant have shortened red cell lifespan but without anaemia. However, these individuals develop haemolytic episodes on exposure to oxidant stress such as viral and bacterial infections, certain drugs (antimalarials, sulfonamides, nitrofurantoin, aspirin, vitamin K), metabolic acidosis and on ingestion of fava beans (favism).

PATHOGENESIS Normally, red blood cells are well protected against oxidant stress because of adequate generation of reduced glutathione via the hexose monophosphate shunt. Individuals with inherited deficiency of G6PD, an enzyme required for hexose monophosphate shunt for glucose metabolism, fail to develop adequate levels of reduced glutathione in their red cells. This results in oxidation and precipitation of haemoglobin within the red cells forming Heinz bodies. Besides G6PD deficiency, deficiency of various other enzymes involved in the hexose monophosphate shunt may also infrequently cause clinical problems.

CLINICAL FEATURES The clinical manifestations are as under:

1. Acute haemolytic anaemia This develops in males, being X-linked disorder, within hours of exposure to oxidant stress such as drugs like primaquin, infection, favism and metabolic acidosis. The haemolysis is, however, self-limiting even if the

exposure to the oxidant is continued since it *affects the older red cells only*. Haemoglobin level may return to normal when the older population of red cells has been destroyed and only younger cells remain. Some patients may have only darkening of the urine from haemoglobinuria but more severely affected ones develop constitutional symptoms including jaundice.

2. Chronic haemolytic anaemia Cases having severe enzyme deficiency have chronic persistent haemolysis throughout life.

3. Neonatal jaundice Infants born with G6PD deficiency may continue to have unconjugated hyperbilirubinaemia and may even develop kernicterus.

LABORATORY FINDINGS These are as under:

1. During the period of acute haemolysis, there is rapid fall in haematocrit by 25-30%, features of intravascular haemolysis such as rise in plasma haemoglobin, haemoglobinuria, rise in unconjugated bilirubin and fall in plasma haptoglobin. Formation of Heinz bodies is visualised by means of supravital stains such as crystal violet, also called *Heinz body haemolytic anaemia*. However, Heinz bodies are not seen after the first one or two days since they are removed by the spleen, leading to formation of 'bite cells' and fragmented red cells.

2. Between the crises, the affected patient generally has no anaemia. The red cell survival is, however, shortened.

The diagnosis of G6PD enzyme deficiency is made by one of the screening tests (e.g. methaemoglobin reduction test or MRT, fluorescent screening test, ascorbate cyanide screening test), or by direct enzyme assay on red cells.

Treatment is directed towards the prevention of haemolytic episodes such as stoppage of offending drug. Blood transfusions are rarely indicated.

PK DEFICIENCY

Pyruvate kinase (PK) deficiency is the only significant enzymopathy of the Embden-Meyerhof glycolytic pathway. The disorder is inherited as an autosomal recessive

pattern. Heterozygote state is entirely asymptomatic, while the homozygous individual presents during early childhood with anaemia, jaundice and splenomegaly.

LABORATORY FINDINGS These are as under:

1. Normocytic and normochromic anaemia.
2. Reticulocytosis.
3. Blood film shows bizarre red cells.
4. Osmotic fragility is usually normal but after incubation it is increased.
5. Autohaemolysis is increased, but unlike hereditary spherocytosis, is not corrected by addition of glucose.
6. Direct specific enzyme assay on red cells is the only method of establishing the diagnosis.

Haemoglobinopathies

Haemoglobin in RBCs may be abnormally synthesised due to inherited defects. These disorders may be of two types:

- ◆ **Qualitative disorders** in which there is structural abnormality in synthesis of haemoglobin e.g. sickle cell syndrome, other haemoglobinopathies.
- ◆ **Quantitative disorders** in which there quantitatively decreased globin chain synthesis of haemoglobin e.g. thalassaemias.

Both these groups of disorders may occur as *homozygous* state in which both genes coding for that character are abnormal, or *heterozygous* when one gene is abnormal and the other gene is normal. However, there are examples of combined disorders too in which there are two different mutations in loci of two corresponding genes (i.e. double heterozygous) e.g. HbS gene from one parent and β -thal gene from the other parent resulting in $\beta^S\beta^{\text{thal}}$. These disorders may vary in presentation from asymptomatic laboratory abnormalities to intrauterine death.

There are geographic variations in the distribution of various haemoglobinopathies world over as shown in Fig. 10.27. Major examples of these disorders are described below.

STRUCTURALLY ABNORMAL HAEMOGLOBINS

SICKLE SYNDROMES

The most important and widely prevalent type of haemoglobinopathy is due to the presence of sickle haemoglobin (HbS) in the red blood cells. The red cells with HbS develop 'sickling' when they are exposed to low oxygen tension. Sickle syndromes have the highest frequency in black race and in Central Africa where *falciparum* malaria is endemic. Patients with HbS are relatively protected against *falciparum* malaria. Sickle syndromes occur in 3 different forms:

1. As *heterozygous state* for HbS: sickle cell trait (AS).
2. As *homozygous state* for HbS: sickle cell anaemia (SS).
3. As *double heterozygous states* e.g. sickle β -thalassaemia, sickle-C disease (SC), sickle-D disease (SD).

Heterozygous State: Sickle Cell Trait

Sickle cell trait (AS) is a benign heterozygous state of HbS in which only one abnormal gene is inherited. Patients with AS develop no significant clinical problems except when they become severely hypoxic and may develop sickle cell crises.

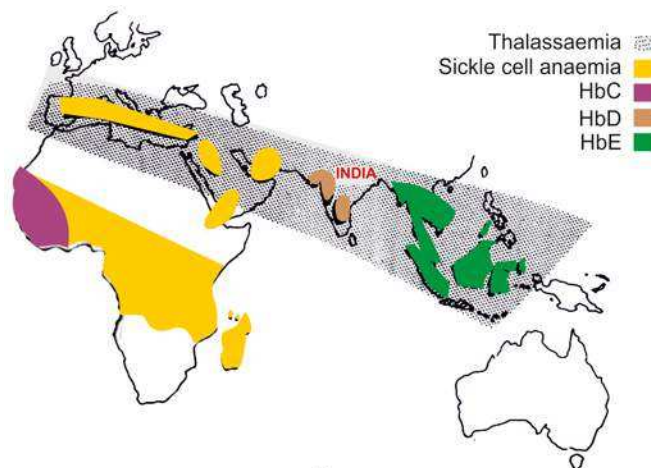

Figure 10.27 The geographic distribution of major haemoglobinopathies and thalassaemias. Thalassaemia and HbD are the haemoglobin disorders common in India.

LABORATORY FINDINGS These patients have no anaemia and have normal appearance of red cells. But in hypoxic crisis, sickle cell crises develop. The diagnosis is made by 2 tests:

1. **Demonstration of sickling** done under condition of reduced oxygen tension by an oxygen consuming reagent, sodium metabisulfite.
2. **Haemoglobin electrophoresis** reveals 35-40% of the total haemoglobin as HbS.

Homozygous State: Sickle Cell Anaemia

Sickle cell anaemia (SS) is a homozygous state of HbS in the red cells in which an abnormal gene is inherited from each parent. SS is a severe disorder associated with protean clinical manifestations and decreased life expectancy.

PATHOGENESIS Following abnormalities are observed (Fig. 10.28):

1. Basic molecular lesion In HbS, basic genetic defect is the *single point mutation* in one amino acid out of 146 in haemoglobin molecule—there is *substitution of valine for glutamic acid* at 6-residue position of the β -globin, producing Hb $\alpha_2\beta_2^S$.

2. Mechanism of sickling During deoxygenation, the red cells containing HbS change from biconcave disc shape to an elongated crescent-shaped or sickle-shaped cell. This process termed *sickling* occurs both within the intact red cells and *in vitro* in free solution. The mechanism responsible for sickling upon deoxygenation of HbS-containing red cells is the polymerisation of deoxygenated HbS which aggregates to form elongated rod-like polymers. These elongated fibres align and distort the red cell into classic sickle shape.

3. Reversible-irreversible sickling The oxygen-dependent sickling process is usually reversible. However, damage to red cell membrane leads to formation of irreversibly sickled red cells even after they are exposed to normal oxygen tension.

4. Factors determining rate of sickling: Following factors determine the rate at which the polymerisation of HbS and consequent sickling take place:

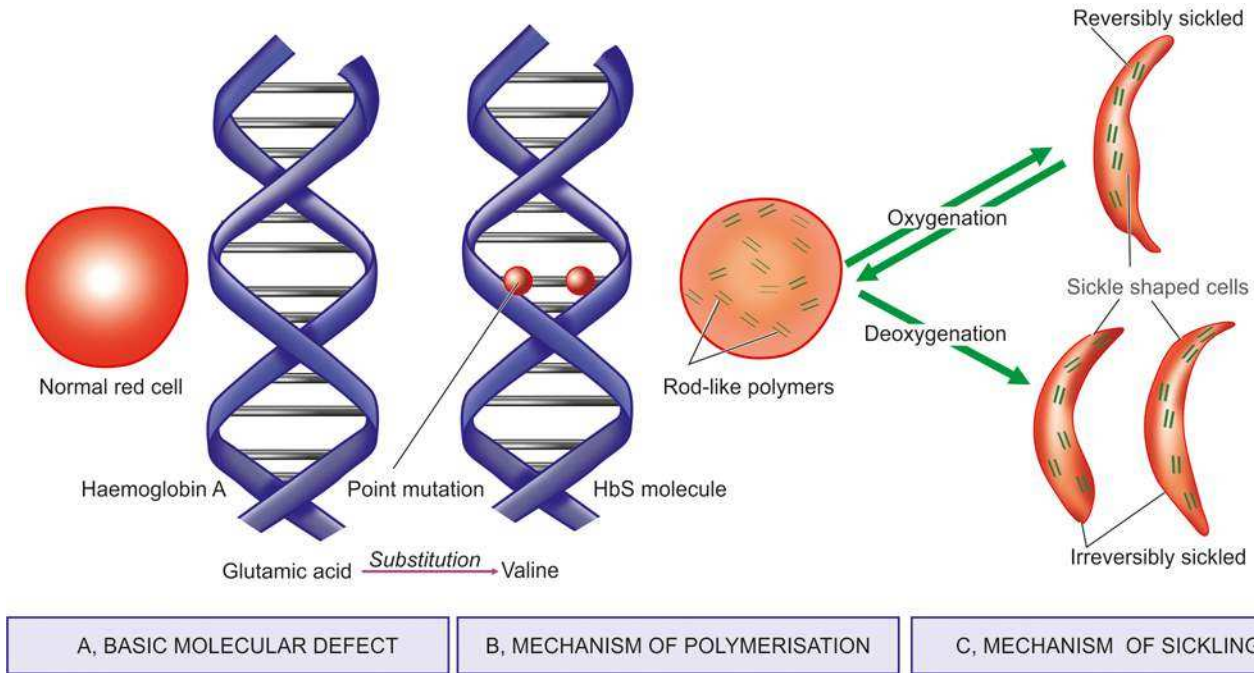

Figure 10.28 Pathogenesis of sickle cell anaemia. A, Basic molecular defect. B, Mechanism of polymerisation and consequent sickling of red cells containing HbS. C, Mechanism of sickling on oxygenation-deoxygenation.

- i) *Presence of non-HbS haemoglobins*: The red cells in patients of SS have predominance of HbS and a small part consists of non-HbS haemoglobins, chiefly HbF (2-20% of the total haemoglobin). HbF-containing red cells are protected from sickling while HbA-containing red cells participate readily in co-polymerisation with HbS.
- ii) *Intracellular concentration of HbS*.
- iii) *Total haemoglobin concentration*.
- iv) *Extent of deoxygenation*.
- v) *Acidosis and dehydration*.
- vi) *Increased concentration of 2, 3-BPG in the red cells*.

CLINICAL FEATURES The clinical manifestations of homozygous sickle cell disease are widespread. The symptoms begin to appear after 6th month of life when most of the HbF is replaced by HbS. Infection and folic acid deficiency result in more severe clinical manifestations. These features are as under (**Fig. 10.29**):

1. Anaemia There is usually severe chronic haemolytic anaemia (primarily extravascular) with onset of aplastic crisis in between. The symptoms of anaemia are generally mild since HbS gives up oxygen more readily than HbA to the tissues.

2. Vaso-occlusive phenomena Patients of SS develop recurrent vaso-occlusive episodes throughout their lives due to obstruction to capillary blood flow by sickled red cells upon deoxygenation or dehydration. Vaso-obstruction affecting different organs and tissues results in infarcts which may be of 2 types:

- i) *Microinfarcts* affecting particularly the abdomen, chest, back and joints and are the cause of recurrent painful crises in SS.
- ii) *Macroinfarcts* involving most commonly the spleen (splenic sequestration, autosplenectomy), bone marrow (pains), bones (aseptic necrosis, osteomyelitis), lungs (pulmonary infections),

kidneys (renal cortical necrosis), CNS (stroke), retina (damage) and skin (ulcers), and result in anatomic and functional damage to these organs.

3. Constitutional symptoms In addition to the features of anaemia and infarction, patients with SS have impaired growth and development and increased susceptibility to infection due to markedly impaired splenic function.

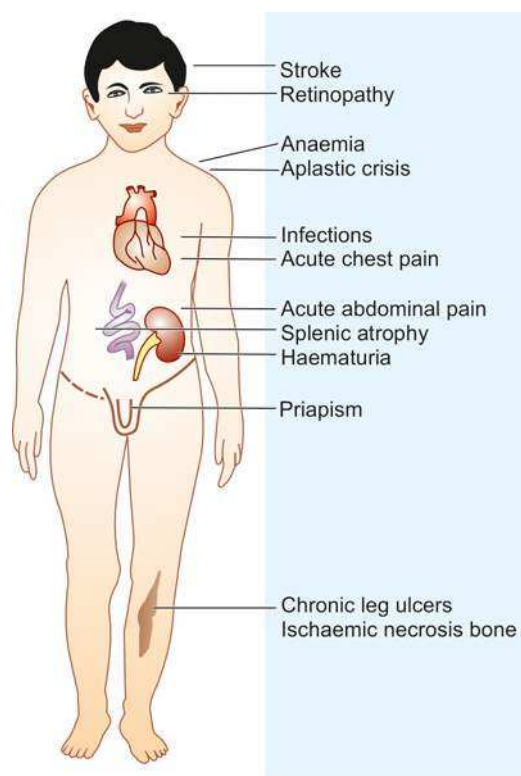

Figure 10.29 Major clinical manifestations of sickle cell disease.

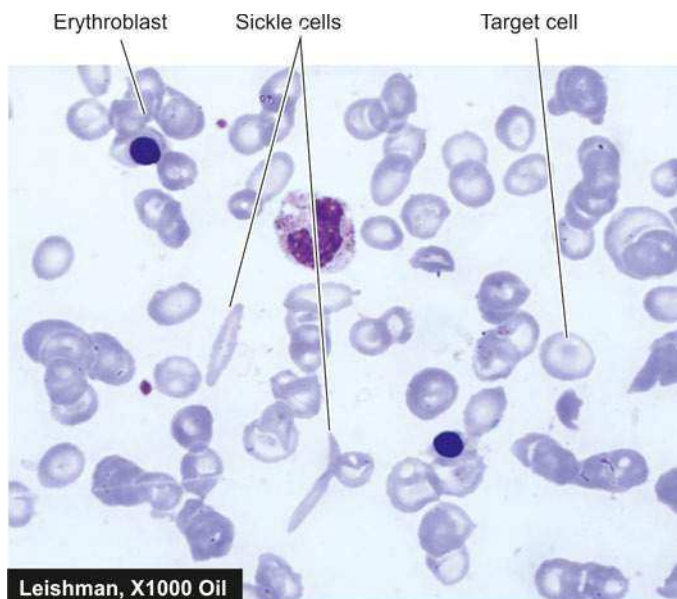

Figure 10.30 Sickle cell anaemia. PBF shows crescent shaped elongated red blood cells, a few target cells and a few erythroblasts.

LABORATORY FINDINGS The diagnosis of SS is considered high in blacks with haemolytic anaemia. The laboratory findings in these cases are as under (**Fig. 10.30**):

1. Moderate to severe anaemia (haemoglobin concentration 6-9 g/dl).
2. The blood film shows sickle cells and target cells and features of splenic atrophy such as presence of Howell-Jolly bodies.
3. A positive sickling test with a reducing substance such as sodium metabisulfite.
4. Haemoglobin electrophoresis shows no normal HbA but shows predominance of HbS and 2-20% HbF.

Double Heterozygous States

Double heterozygous conditions involving combination of HbS with other haemoglobinopathies may occur. Most common among these are sickle- β -thalassaemia ($\beta^S\beta^{\text{thal}}$), sickle C disease (SC), and sickle D disease (SD). All these disorders behave like mild form of sickle cell disease. Their diagnosis is made by haemoglobin electrophoresis and separating the different haemoglobins.

OTHER STRUCTURAL HAEMOGLOBINOPATHIES

Besides sickle haemoglobin, about 400 structurally different abnormal human haemoglobins have been discovered in different parts of the world. Some of them are associated with clinical manifestations, while others are of no consequence. A few important and common variants are briefly described below:

HbC Haemoglobinopathy

HbC haemoglobinopathy is prevalent in West Africa and in American blacks. The molecular lesion in HbC is substitution of lysine for glutamic acid at β -6 globin chain position. The disorder of HbC may occur as benign homozygous HbC disease, or as asymptomatic heterozygous HbC trait, or as double heterozygous combinations such as sickle-HbC disease and HbC- β thalassaemia.

HbD Haemoglobinopathy

HbD occurs in North-West India, Pakistan and Iran. About 3% of Sikhs living in Punjab are affected with HbD haemoglobinopathy (called *HbD Punjab*, also known as *Hb-Los Angeles*). HbD Punjab arises from the substitution of glutamine for glutamic acid at β -121 globin chain position.

HbE Haemoglobinopathy

HbE is predominantly found in South-East Asia, India, Burma and Sri Lanka. HbE arises from the substitution of lysine for glutamic acid at β -26 globin chain position. Like other abnormal haemoglobins, HbE haemoglobinopathy may also occur as asymptomatic heterozygous HbE trait, compensated haemolytic homozygous HbE disease, or as double heterozygous states in combination with other haemoglobinopathies such as HbE- β thalassaemia and HbE- α thalassaemia.

Haemoglobin O-Arab Disease

Hb O-Arab disease was first identified in an Arab family but has now been detected in American blacks too. The homozygous form of the disease appears as mild haemolytic anaemia with splenomegaly.

Unstable-Hb Haemoglobinopathy

The unstable haemoglobins are those haemoglobin variants which undergo denaturation and precipitation within the red cells as Heinz bodies. These give rise to what is known as *congenital non-spherocytic haemolytic anaemia* or *congenital Heinz body haemolytic anaemia*. These disorders have either autosomal dominant inheritance or develop from spontaneous mutations. The unstable haemoglobins arise from either a single amino acid substitution in the globin chain or due to deletion of one or more amino acids within the β -globin chain so that the firm bonding of the haem group within the molecule is disturbed leading to formation of methaemoglobin and precipitation of globin chains as Heinz bodies.

Over 100 unstable haemoglobins have been described. They are named according to the city where they are encountered. For instance: Hb-Koln, Hb-Hammersmith, Hb-Zurich, Hb-Sydney, and so on. The diagnosis of unstable Hb disease is made by test for Heinz bodies and by haemoglobin electrophoresis.

REDUCED GLOBIN CHAIN SYNTHESIS: THALASSAEMIAS

DEFINITION

The thalassaemias are a diverse group of hereditary disorders in which there is reduced synthesis of one or more of the globin polypeptide chains. Thus, thalassaemias, unlike haemoglobinopathies which are qualitative disorders of haemoglobin, are *quantitative abnormalities of polypeptide globin chain synthesis*. Thalassaemias were first described in people of Mediterranean countries (North Africa, Southern Europe) from where it derives its name 'Mediterranean anaemia.' The word '*thalassa*' in Greek means 'the sea' since the condition was found commonly in regions surrounding the Mediterranean sea. The condition also occurs in the Middle East, Indian subcontinent, South-East Asia and, in general in blacks (*see Fig. 10.27*). In India, thalassaemia is seen through country and an estimated 35 million have β -thalassaemia major. Its incidence is particularly high in some races such as Punjabis who migrated from Pakistan after partition, Bengalis, Gujratis and Parsis.

Table 10.14 Classification of thalassaemias.

| TYPE | HB | HB-ELECTROPHORESIS | GENOTYPE | CLINICAL SYNDROME |
|--|-------------|-------------------------------------|---|---|
| α-THALASSAEMIAS | | | | |
| 1. <i>Hydrops foetalis</i> | 3-10 gm/dl | Hb Barts (g_4) (100%) | Deletion of four α -genes | Fatal <i>in utero</i> or in early infancy |
| 2. <i>Hb-H disease</i> | 2-12 gm/dl | HbF (10%), HbH (2-4%) | Deletion of three α -genes | Haemolytic anaemia |
| 3. <i>α-Thalassaemia trait</i> | 10-14 gm/dl | Almost normal | Deletion of two α -genes | Microcytic hypochromic blood picture but no anaemia |
| β-THALASSAEMIAS | | | | |
| 1. <i>β-Thalassaemia major</i> | < 5 gm/dl | HbA (0-50%), HbF(50-98%) | $\beta^{\text{thal}}/\beta^{\text{thal}}$ | Severe congenital haemolytic anaemia, requires blood transfusions |
| 2. <i>β-Thalassaemia intermedia</i> | 5-10 gm/dl | Variable | Multiple mechanisms | Severe anaemia, but regular blood transfusions not required |
| 3. <i>β-Thalassaemia minor</i> | 10-12 gm/dl | HbA ₂ (4-9%), HbF (1-5%) | $\beta^{\text{A}}/\beta^{\text{thal}}$ | Usually asymptomatic |

GENETICS AND CLASSIFICATION

Thalassaemias are genetically transmitted disorders. Normally, an individual inherits two β -globin genes located one each on two chromosomes 11, and two α -globin genes one each on two chromosomes 16, from each parent i.e. normal adult haemoglobin (HbA) is $\alpha_2\beta_2$. Depending upon whether the genetic defect or deletion lies in transmission of α - or β -globin chain genes, thalassaemias are classified into α - and β -thalassaemias. Thus, patients with α -thalassaemia have structurally normal α -globin chains but their production is impaired. Similarly, in β -thalassaemia, β -globin chains are structurally normal but their production is decreased. Each of the two main types of thalassaemias may occur as heterozygous (called *α - and β -thalassaemia minor or trait*), or as homozygous state (termed *α - and β -thalassaemia major*). The former is generally asymptomatic, while the latter is a severe congenital haemolytic anaemia.

A classification of various types of thalassaemias along with the clinical syndromes produced and salient laboratory findings are given in **Table 10.14**.

PATHOPHYSIOLOGY OF ANAEMIA IN THALASSAEMIA

A constant feature of all forms of thalassaemia is the presence of anaemia which occurs from following mechanisms:

α -Thalassaemia In α -thalassaemia major, the obvious cause of anaemia is the inability to synthesise adult haemoglobin, while in α -thalassaemia trait there is reduced production of normal adult haemoglobin.

β -Thalassaemia In β -thalassaemia major, the most important cause of anaemia is premature red cell destruction brought about by erythrocyte membrane damage caused by the precipitated α -globin chains. Other contributory factors are: shortened red cell lifespan, ineffective erythropoiesis, and haemodilution due to increased plasma volume. A deficiency of β -globin chains in β -thalassaemia leads to large excess of α -chains within the developing red cells. Part of these excessive α -chains are removed by pairing with γ -globin chains as HbF, while the remainder unaccompanied α -chains precipitate rapidly within the red cell as *Heinz bodies* (**Fig. 10.31**).

*In a normal adult, distribution of haemoglobin is as under: HbA ($\alpha_2\beta_2$) = 95-98%, HbA₂ ($\alpha_2\delta_2$) (a minor variant of HbA) = 1.5-3.5%, HbF ($\alpha_2\gamma_2$) = less than 1%. But the level of HbF in children under 6 months is slightly higher.

The precipitated α -chains cause red cell membrane damage. During their passage through the splenic sinusoids, these red cells are further damaged and develop pitting due to removal of the precipitated aggregates. Thus, such red cells are irreparably damaged and are phagocytosed by the RE cells of the spleen and the liver causing anaemia, hepatosplenomegaly, and excess of tissue iron stores. Patients with β -thalassaemia minor, on the other hand, have very mild ineffective erythropoiesis, haemolysis and shortening of red cell lifespan.

α -THALASSAEMIA

MOLECULAR PATHOGENESIS α -thalassaemias are disorders in which there is defective synthesis of α -globin chains resulting in depressed production of haemoglobins that contain α -chains i.e. HbA, HbA₂ and HbF. The α -thalassaemias are most commonly due to deletion of one or more of the

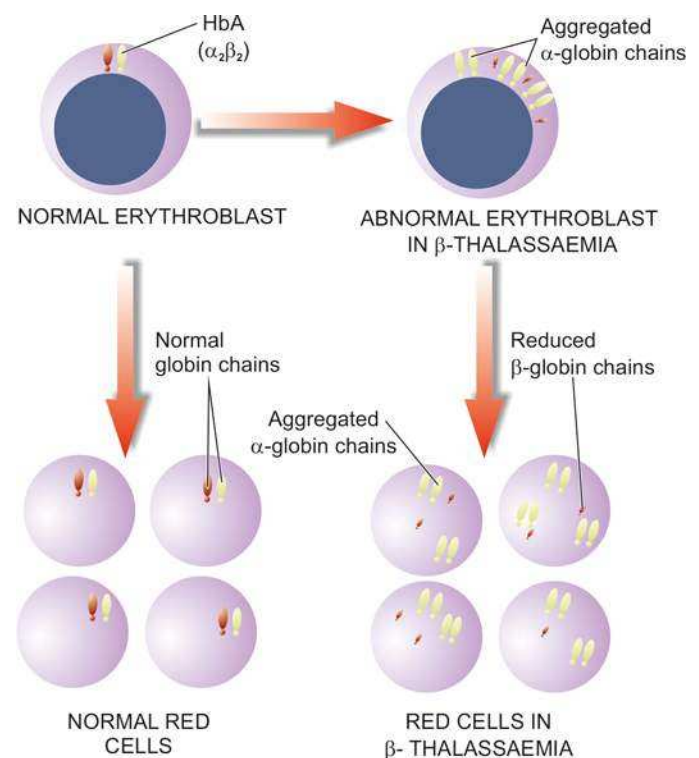

Figure 10.31 Pathogenesis of β -thalassaemia major.

α -chain genes located on short arm of chromosome 16. Since there is a pair of α -chain genes, the clinical manifestations of α -thalassaemia depend upon the number of genes deleted. Accordingly, α -thalassaemias are classified into 4 types:

1. Four α -gene deletion: Hb Bart's hydrops foetalis.
2. Three α -gene deletion: HbH disease.
3. Two α -gene deletion: α -thalassaemia trait.
4. One α -gene deletion: α -thalassaemia trait (carrier).

Hb Bart's Hydrops Foetalis

When there is deletion of all the four α -chain genes (homozygous state) it results in total suppression of α -globin chain synthesis causing the most severe form of α -thalassaemia called Hb Bart's hydrops foetalis. Hb Bart's is a gamma globin chain tetramer (γ_4) which has high oxygen affinity leading to severe tissue hypoxia.

CLINICAL FEATURES Hb Bart's hydrops foetalis is incompatible with life due to severe tissue hypoxia. The condition is either fatal *in utero* or the infant dies shortly after birth. If born alive, the features similar to severe Rh haemolytic disease are present (page 319).

LABORATORY FINDINGS Infants with Hb Bart's hydrops foetalis born alive may have the following laboratory findings:

1. Severe anaemia (haemoglobin below 6 g/dl).
2. Blood film show marked anisopoikilocytosis, hypochromia, microcytosis, polychromasia, basophilic stippling, numerous normoblasts and target cells.
3. Reticulocyte count is high.
4. Serum bilirubin level is elevated.
5. Haemoglobin electrophoresis shows 80-90% Hb-Bart's and a small amount of Hb-H and Hb-Portland but no HbA, HbA₂ or HbF.

HbH Disease

Deletion of three α -chain genes produces HbH which is a β -globin chain tetramer (β_4) and markedly impaired α -chain synthesis. HbH is precipitated as Heinz bodies within the affected red cells. An elongated α -chain variant of HbH disease is termed *Hb Constant Spring*.

CLINICAL FEATURES HbH disease is generally present as a well-compensated haemolytic anaemia. The features are intermediate between that of β -thalassaemia minor and major. The severity of anaemia fluctuates and may fall to very low levels during pregnancy or infections. Majority of patients have splenomegaly and may develop cholelithiasis.

LABORATORY FINDINGS These are as follows:

1. Moderate anaemia (haemoglobin 8-9 g/dl).
2. Blood film shows severe microcytosis, hypochromia, basophilic stippling, target cells and normoblasts.
3. Mild reticulocytosis.
4. HbH inclusions as Heinz bodies can be demonstrated in mature red cells with brilliant cresyl blue stain.
5. Haemoglobin electrophoresis shows 2-4% HbH and the remainder consists of HbA, HbA₂ and HbF.

α -Thalassaemia Trait

α -thalassaemia trait may occur by the following molecular pathogenesis:

♦ By deletion of two of the four α -chain genes in homozygous form called *homozygous α -thalassaemia*, or in double heterozygous form termed *heterozygous α -thalassaemia*.

♦ By deletion of a single α -chain gene causing heterozygous α -thalassaemia trait called *heterozygous α -thalassaemia*.

CLINICAL FEATURES α -thalassaemia trait due to two α -chain gene deletion is asymptomatic. It is suspected in a patient of refractory microcytic hypochromic anaemia in whom iron deficiency and β -thalassaemia minor have been excluded and the patient belongs to the high-risk ethnic group. One gene deletion α -thalassaemia trait is a silent carrier state.

LABORATORY FINDINGS The patients of α -thalassaemia trait may have the following haematological findings:

1. Haemoglobin level normal or mildly reduced.
2. Blood film shows microcytic and hypochromic red cell morphology but no evidence of haemolysis or anaemia.
3. MCV, MCH and MCHC may be slightly reduced.
4. Haemoglobin electrophoresis reveals small amount of Hb-Bart's in neonatal period (1-2% in α -thalassaemia 2 and 5-6% in α -thalassaemia 1) which gradually disappears by adult life. HbA₂ is either normal or slightly decreased (contrary to the elevated HbA₂ levels in β -thalassaemia trait).

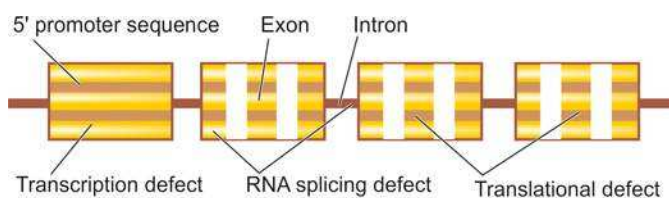

β -THALASSAEMIAS

MOLECULAR PATHOGENESIS β -thalassaemias are caused by decreased rate of β -chain synthesis resulting in reduced formation of HbA in the red cells. The molecular pathogenesis of the β -thalassaemias is more complex than that of α -thalassaemias. In contrast to α -thalassaemia, gene deletion rarely ever causes β -thalassaemia and is only seen in an entity called *hereditary persistence of foetal haemoglobin (HPFH)*. Instead, most of β -thalassaemias arise from different types of mutations of β -globin gene resulting from single base changes. The symbol β^0 is used to indicate the complete absence of β -globin chain synthesis while β^+ denotes partial synthesis of the β -globin chains. More than 100 such mutations have been described affecting the preferred sites in the coding sequences e.g. in promoter region, termination region, splice junctions, exons, introns. Some of the important ones having effects on β -globin chain synthesis are as under (Fig. 10.32):

i) *Transcription defect*: Mutation affecting transcriptional promoter sequence causing reduced synthesis of β -globin chain. Hence the result is partially preserved synthesis i.e. β^+ *thalassaemia*.

ii) *Translation defect*: Mutation in the coding sequence causing stop codon (chain termination) interrupting β -globin messenger RNA. This would result in no synthesis of β -globin chain i.e. β^0 *thalassaemia*.

iii) *mRNA splicing defect*: Mutation leads to defective mRNA processing forming abnormal mRNA that is degraded in the

β -globin gene mutation on chromosome 11

Figure 10.32 Schematic representation of sites of β -globin gene mutation in chromosome 11 giving rise to β -thalassaemia.

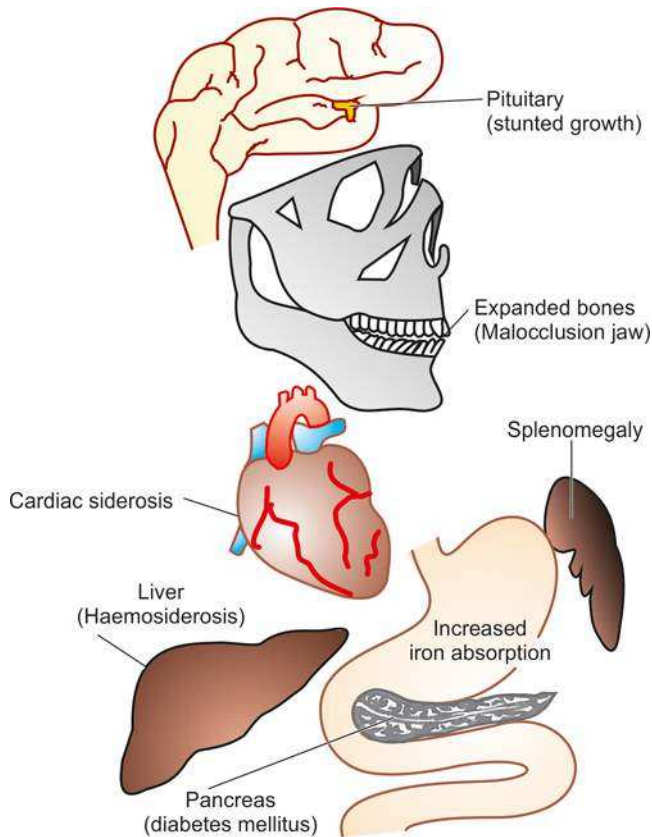

Figure 10.33 Major clinical features of β -thalassaemia major.

nucleus. Depending upon whether part of splice site remains intact or is totally degraded, it may result in β^+ *thalassaemia* or β^0 *thalassaemia*.

Depending upon the extent of reduction in β -chain synthesis, there are 3 types of β -thalassaemia:

1. Homozygous form: β -Thalassaemia major It is the most severe form of congenital haemolytic anaemia. It is further of 2 types (**Fig. 10.33**):

i) β^0 *thalassaemia major* characterised by complete absence of β -chain synthesis.

ii) β^+ *thalassaemia major* having incomplete suppression of β -chain synthesis.

2. β -Thalassaemia intermedia It is β -thalassaemia of intermediate degree of severity that does not require regular blood transfusions. These cases are genetically heterozygous (β^0/β or β^+/β).

3. Heterozygous form: β -thalassaemia minor (trait) It is a mild asymptomatic condition in which there is moderate suppression of β -chain synthesis.

Besides β -thalassaemia minor, a few uncommon globin chain combinations resulting in β -thalassaemia trait are as under:

i) $\delta\beta$ -*thalassaemia minor* in which there is total absence of both β and δ chain synthesis and is characterised by elevated HbF level but unlike β -thalassaemia minor there is normal or reduced HbA₂ level.

ii) *Hb Lepore syndrome* characterised by non-homologous fusion of β - and δ -genes forming an abnormal haemoglobin called Hb Lepore (named after a family called Lepore). There is total absence of normal β -chain synthesis.

An individual may inherit one β -chain gene from each parent and produce heterozygous, homozygous, or double heterozygous states. Statistically, 25% of offsprings born to two heterozygotes (i.e. β -thalassaemia trait) will have the homozygous state i.e. β -thalassaemia major.

β -Thalassaemia Major

β -thalassaemia major, also termed Mediterranean or Cooley's anaemia is the most common form of congenital haemolytic anaemia. β -thalassaemia major is a homozygous state with either complete absence of β -chain synthesis (β^0 *thalassaemia major*) or only small amounts of β -chains are formed (β^+ *thalassaemia major*). These result in excessive formation of alternate haemoglobins, HbF ($\alpha_2\gamma_2$) and HbA₂ ($\alpha_2\delta_2$).

CLINICAL FEATURES Clinical manifestations appear insidiously and are as under (**Fig. 10.34**):

1. Anaemia starts appearing within the first 4-6 months of life when the switch over from γ -chain to β -chain production occurs.
2. Marked hepatosplenomegaly occurs due to excessive red cell destruction, extramedullary haematopoiesis and iron overload.

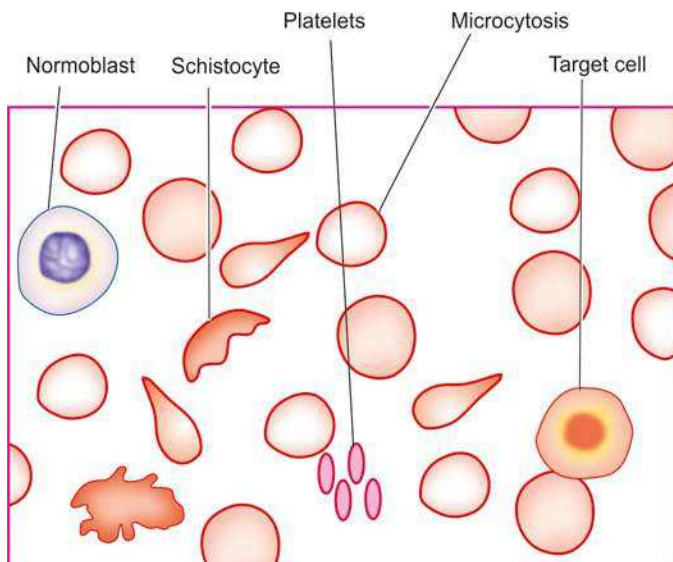

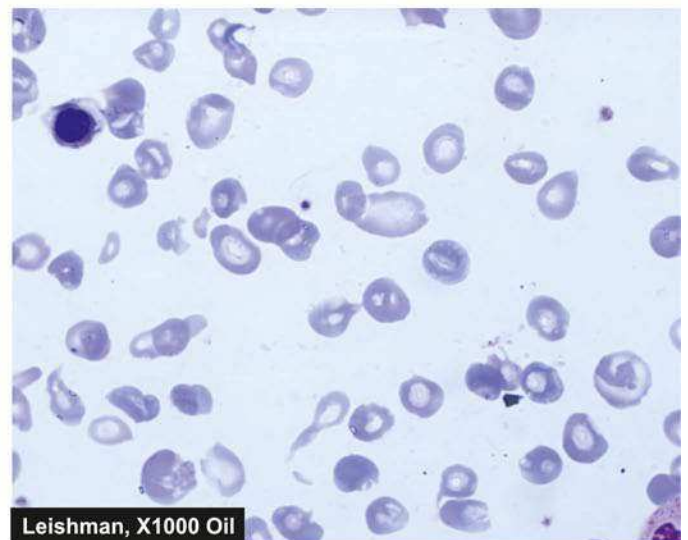

Figure 10.34 Peripheral blood film findings in β -thalassaemia major.

- Expansion of bones occurs due to marked erythroid hyperplasia leading to thalassaemic facies and malocclusion of the jaw.
- Iron overload due to repeated blood transfusions causes damage to the endocrine organs resulting in slow rate of growth and development, delayed puberty, diabetes mellitus and damage to the liver and heart.

LABORATORY FINDINGS The haematological investigations reveal the following findings:

- Anaemia*, usually severe.
- Blood film* shows severe microcytic hypochromic red cell morphology, marked anisopoikilocytosis, basophilic stippling, presence of many target cells, tear drop cells and normoblasts (Fig. 10.35).
- Serum bilirubin* (unconjugated) is generally raised.
- Reticulocytosis* is generally present.
- MCV, MCH and MCHC* are significantly reduced.
- WBC count* is often raised with some shift to left of the neutrophil series, with presence of some myelocytes and metamyelocytes.
- Platelet count* is usually normal but may be reduced in patients with massive splenomegaly.
- Osmotic fragility characteristically reveals increased resistance to saline haemolysis i.e. *decreased osmotic fragility* (Fig. 10.36).
- Haemoglobin electrophoresis* shows presence of increased amounts of HbF, increased amount of HbA₂, and almost complete absence or presence of variable amounts of HbA. The increased level of HbA₂ has not been found in any other haemoglobin abnormality except β -thalassaemia. The increased synthesis of HbA₂ is probably due to increased activity at both δ -chain loci.
- Bone marrow aspirate examination* shows normoblastic erythroid hyperplasia with predominance of intermediate and late normoblasts which are generally smaller in size than normal. Iron staining demonstrates siderotic granules in the cytoplasm of normoblasts, increased reticuloendothelial iron but ring sideroblasts are only occasionally seen.

PRINCIPLES OF TREATMENT Treatment of β -thalassaemia major is largely supportive.

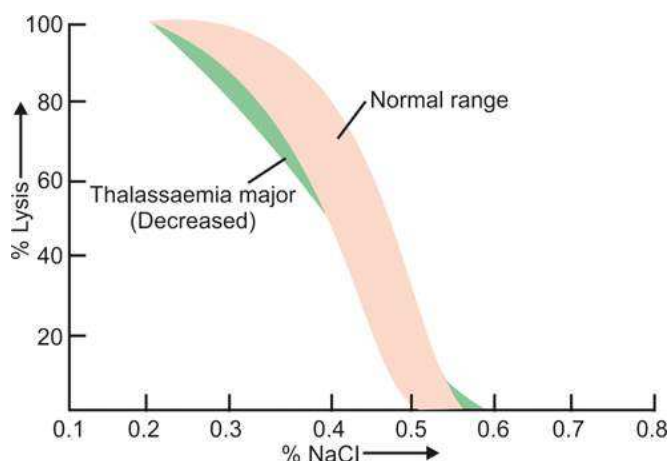

Figure 10.35 Osmotic fragility testing β -thalassaemia major showing decreased fragility.

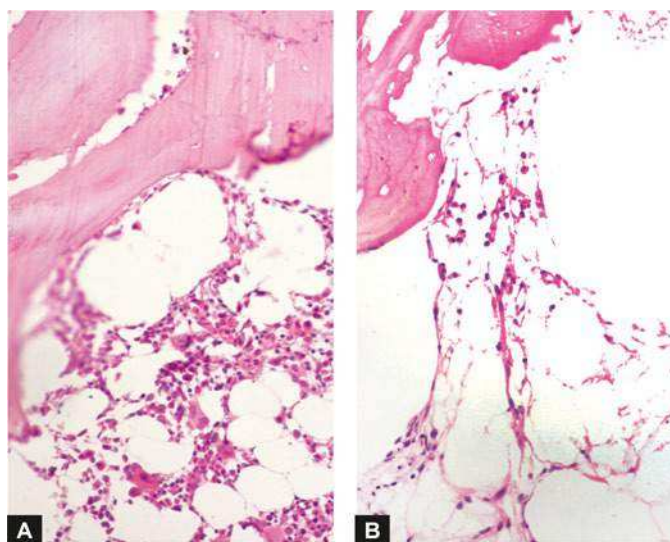

Figure 10.36 Bone marrow trephine biopsy in aplastic anaemia contrasted against normal cellular marrow. A, normal marrow biopsy shows about 50% fatty spaces and about 50% is haematopoietic marrow which contains a heterogeneous mixture of myeloid, erythroid and lymphoid cells. B, In aplastic anaemia, the biopsy shows suppression of myeloid and erythroid cells and replacement of haematopoietic elements by fat. There are scanty foci of cellular components composed chiefly of lymphoid cells.

- Anaemia is generally severe and patients require regular blood transfusions (4-6 weekly) to maintain haemoglobin above 8 g/dl.
- In order to maintain increased demand of hyperplastic marrow, folic acid supplement is given.
- Splenectomy is beneficial in children over 6 years of age since splenic sequestration contributes to shortened red cell lifespan.
- Prevention and treatment of iron overload is done by chelation therapy (desferrioxamine). Oral chelation with kelfer or deferiprone is also available now.
- Bone marrow transplantation from HLA-matched donor that provides stem cells which can form normal haemoglobin is being done in many centres with fair success rate, especially when done at an early stage before end-organ damage has supervened.
- Some workers have found success with cord blood transfusion.
- Gene therapy of thalassaemia involving genetic manipulation in haematopoietic stem cells may become an option for future.

Since these patients require multiple blood transfusions, they are at increased risk of developing AIDS. In general, patients with β -thalassaemia major have short life expectancy. The biggest problem is iron overload and consequent myocardial siderosis leading to cardiac arrhythmias, congestive heart failure, and ultimately death.

β -Thalassaemia Minor

The β -thalassaemia minor or β -thalassaemia trait, a heterozygous state, is a common entity characterised by moderate reduction in β -chain synthesis.

CLINICAL FEATURES Clinically, the condition is usually asymptomatic and the diagnosis is generally made when the

patient is being investigated for mild chronic anaemia. The spleen may be palpable.

LABORATORY FINDINGS These are as under:

1. *Mild anaemia*; mean haemoglobin level is about 15% lower than in normal person for the age and sex.
2. *Blood film* shows mild anisopoikilocytosis, microcytosis and hypochromia, occasional target cells and basophilic stippling.
3. *Serum bilirubin* may be normal or slightly raised.
4. *Mild reticulocytosis* is often present.
5. *MCV, MCH and MCHC* may be slightly reduced.
6. Osmotic fragility test shows increased resistance to haemolysis i.e. *decreased osmotic fragility*.
7. *Haemoglobin electrophoresis* is confirmatory for the diagnosis and shows about two-fold increase in HbA₂ and a slight elevation in HbF (2-3%).

PRINCIPLES OF TREATMENT Patients with β -thalassaemia minor do not require any treatment. But they should be explained about the genetic implications of the disorder, particularly to those of child-bearing age. If the two subjects of β -thalassaemia trait marry, there is a 25% chance of developing thalassaemia major in offsprings. Patients with β -thalassaemia minor have normal life expectancy but those who are treated under the mistaken diagnosis of iron deficiency may develop siderosis and its complications.

PREVENTION OF THALASSAEMIA Finally, since thalassaemia is an inheritable disease, its prevention is possible by making an antenatal diagnosis. This is done by chorionic villous biopsy or cells obtained by amniocentesis and foetal DNA studied by PCR amplification technique for presence of genetic mutations of thalassaemias.

ANAEMIA OF BLOOD LOSS

Depending upon the rate of blood loss due to haemorrhage, the effects of post-haemorrhagic anaemia appear.

ACUTE BLOOD LOSS When the loss of blood occurs suddenly, the following events take place:

- i) Immediate threat to life due to hypovolaemia which may result in shock and death.
- ii) If the patient survives, shifting of interstitial fluid to intravascular compartment with consequent haemodilution with low haematocrit.
- iii) Hypoxia stimulates production of erythropoietin resulting in increased marrow erythropoiesis.

LABORATORY FINDINGS

- i) Normocytic and normochromic anaemia
- ii) Low haematocrit
- iii) Increased reticulocyte count in peripheral blood (10-15% after one week) reflecting accelerated marrow erythropoiesis.

CHRONIC BLOOD LOSS When the loss of blood is slow and insidious, the effects of anaemia will become apparent only when the rate of loss is more than rate of production and the iron stores are depleted. This results in iron deficiency anaemia as discussed already (page 274).

GIST BOX 10.6

Haemolytic Anaemias and Anaemia Due to Blood Loss

- ☐ Haemolytic anaemias (HA) result from an increased rate of red cell destruction and premature destruction of red cells either at intravascular or extravascular locations, the latter is more common.
- ☐ HA are divided into hereditary and acquired, the former are more common.
- ☐ Immune HA are due to antibody production in the body against own red cells. These may be autoimmune (warm and cold antibody), drug-induced or isoimmune.
- ☐ Microangiopathic HA are caused due to abnormalities in the microvasculature.
- ☐ PNH is a chronic acquired HA due to defect in the stem cells and hence affects all cells in myeloid progenitor lineage.
- ☐ Hereditary defects in the red cell membrane are spherocytosis (spectrin deficiency or ankyrin defect), elliptocytosis (spectrin or protein 4.1 defect) and stomatocytosis.
- ☐ Inherited defects in red cell enzymes are deficiency of G6PD and pyruvate kinase.
- ☐ Haemoglobinopathies may be qualitative (structural e.g. sickle cell syndrome) or quantitative (reduced globin synthesis e.g. thalassaemia) disorders of haemoglobin.
- ☐ Sickle cell syndrome is widely prevalent and is due to genetic defect of a single point mutation. Red cells have sickle haemoglobin which undergo sickling when they are exposed to low oxygen tension. There is vasoocclusive phenomenon.
- ☐ Thalassaemias are hereditary defects of reduced synthesis of either α -(α -thalassaemia) or β -(β -thalassaemia) globin chains which are structurally normal.
- ☐ β -thalassaemia is more common and may occur as a trait (heterozygous) or major (homozygous) form of disease.
- ☐ β -thalassaemia major has high foetal haemoglobin, anaemia, hepatosplenomegaly and iron overload.
- ☐ β -thalassaemia trait cases have mild persistent anaemia and high HbA₂.

APLASTIC ANAEMIA AND OTHER PRIMARY BONE MARROW DISORDERS

'*Bone marrow failure*' is the term used for primary disorders of the bone marrow which result in impaired formation of the erythropoietic precursors and consequent anaemia. It includes the following disorders:

1. *Aplastic anaemia*, most importantly.
2. *Other primary bone marrow disorders* e.g. myelophthisic anaemia, pure red cell aplasia, and myelodysplastic syndromes.

These disorders are examples of hypoproliferative anaemias in which anaemia is not the only finding but the major problem is pancytopenia i.e. anaemia, leucopenia and thrombocytopenia. While myelodysplastic syndromes are discussed in Chapter 12 (page 343), other conditions are considered below.

APLASTIC ANAEMIA

Aplastic anaemia is defined as pancytopenia (i.e. simultaneous presence of anaemia, leucopenia and thrombocytopenia) resulting from aplasia of the bone marrow. The underlying

Table 10.15 Causes of aplastic anaemia.

| |
|--|
| A. PRIMARY APLASTIC ANAEMIA |
| 1. <i>Fanconi's anaemia (congenital)</i> |
| 2. <i>Immunologically-mediated (acquired)</i> |
| B. SECONDARY APLASTIC ANAEMIA |
| 1. <i>Drugs</i> |
| i) Dose-related aplasia e.g. with antimetabolites (methotrexate), mitotic inhibitors (daunorubicin), alkylating agents (busulfan), nitroso urea, anthracyclines. |
| ii) Idiosyncratic aplasia e.g. with chloramphenicol, sulfa drugs, oxyphenbutazone, phenylbutazone, chlorpromazine, gold salts. |
| 2. <i>Toxic chemicals</i> e.g. benzene derivatives, insecticides, arsenicals. |
| 3. <i>Infections</i> e.g. infectious hepatitis, EB virus infection, AIDS, other viral illnesses. |
| 4. <i>Miscellaneous</i> e.g. association with SLE and therapeutic X-rays |

defect in all cases appears to be sufficient reduction in the number of haematopoietic pluripotent stem cells which results in decreased or total absence of these cells for division and differentiation.

ETIOLOGY AND CLASSIFICATION

More than half the cases of aplastic anaemia are idiopathic. Cases with known etiology are classified into 2 main types: primary and secondary (**Table 10.15**):

A. PRIMARY APLASTIC ANAEMIA Primary aplastic anaemia includes 2 entities: a congenital form called Fanconi's anaemia and an immunologically-mediated acquired form.

1. Fanconi's anaemia This has an autosomal recessive inheritance and is often associated with other congenital anomalies such as skeletal and renal abnormalities, and sometimes mental retardation.

2. Immune causes In many cases, suppression of haematopoietic stem cells by immunologic mechanisms may cause aplastic anaemia. The observations in support of autoimmune mechanisms are the clinical response to immunosuppressive therapy and *in vitro* marrow culture experiments.

B. SECONDARY APLASTIC ANAEMIA Secondary causes are more common than primary and include a variety of industrial, physical, chemical, iatrogenic and infectious causes:

1. Drugs A number of drugs are cytotoxic to the marrow and cause aplastic anaemia. The association of a drug with aplastic anaemia may be either predictably dose-related or an idiosyncratic reaction.

i) *Dose-related aplasia* of the bone marrow occurs with antimetabolites (e.g. methotrexate), mitotic inhibitors (e.g. daunorubicin), alkylating agents (e.g. busulfan), nitroso urea and anthracyclines. In such cases, withdrawal of the drug usually allows recovery of the marrow elements.

ii) *Idiosyncratic aplasia* is depression of the bone marrow due to qualitatively abnormal reaction of an individual to a drug when first administered. The most serious and most common example of idiosyncratic aplasia is associated with chloramphenicol. Other such common drugs are sulfa drugs, oxyphenbutazone, phenylbutazone, chlorpromazine, gold salts etc.

2. Toxic chemicals These include examples of industrial, domestic and accidental use of substances such as benzene derivatives, insecticides, arsenicals etc.

3. Infections Aplastic anaemia may occur following viral hepatitis, Epstein-Barr virus infection, AIDS and other viral illnesses.

4. Miscellaneous Lastly, aplastic anaemia has been reported in association with certain other illnesses such as SLE, and with therapeutic X-rays.

CLINICAL FEATURES

The onset of aplastic anaemia may occur at any age and is usually insidious. The clinical manifestations include the following:

1. Anaemia and its symptoms like mild progressive weakness and fatigue.
2. Haemorrhage from various sites due to thrombocytopenia such as from the skin, nose, gums, vagina, bowel, and occasionally in the CNS and retina.
3. Infections of the mouth and throat are commonly present.
4. The lymph nodes, liver and spleen are generally not enlarged.

LABORATORY FINDINGS

The diagnosis of aplastic anaemia is made by a thorough laboratory evaluation and excluding other causes of pancytopenia (**Table 10.16**). The following haematological features are found:

1. Anaemia Haemoglobin levels are moderately reduced. The blood picture generally shows normocytic normochromic anaemia but sometimes macrocytosis may be present. The reticulocyte count is reduced or zero.

2. Leucopenia The absolute granulocyte count is particularly low (below 1500/ μ l) with relative lymphocytosis. The neutrophils are morphologically normal but their alkaline phosphatase score is high.

3. Thrombocytopenia Platelet count is always reduced.

4. Bone marrow examination A bone marrow aspirate may yield a 'dry tap'. A trephine biopsy is generally essential for making the diagnosis which reveals patchy cellular areas in a hypocellular or aplastic marrow due to replacement by fat. There is usually a severe depression of myeloid cells, megakaryocytes and erythroid cells so that the marrow chiefly consists of lymphocytes and plasma cells (**Fig. 10.36**). Haematopoietic stem cells bearing CD34 marker are markedly reduced or absent.

| 2. Non-haematologic metastatic malignancies |
| 3. Storage diseases |
| 4. Osteopetrosis |
| 5. Myelofibrosis |

PRINCIPLES OF TREATMENT

The patients of mild aplasia may show spontaneous recovery, while the management of severe aplastic anaemia is a most challenging task. In general, younger patients show better response to proper treatment. The broad outlines of the treatment are as under:

A. General management It consists of the following:

1. Identification and elimination of the possible cause.
2. Supportive care consisting of blood transfusions, platelet concentrates, and treatment and prevention of infections.

B. Specific treatment The specific treatment has been attempted with varying success and includes the following:

1. *Marrow stimulating agents* such as androgen may be administered orally.
2. *Immunosuppressive therapy* with agents such as anti-thymocyte globulin and anti-lymphocyte serum has been tried with 40-50% success rate. Very high doses of glucocorticoids or cyclosporine may yield similar responses. But splenectomy does not have any role in the management of aplastic anaemia.
3. *Bone marrow transplantation* is considered in severe cases under the age of 40 years where the HLA and mixed culture-matched donor is available. (*Other indications* for bone marrow transplantation are: acute leukaemias—AML in first remission and ALL in second remission, thalassaemia major and combined immunodeficiency disease). Complications of bone marrow transplantation such as severe infections, graft rejection and graft-versus-host disease (GVHD) may occur (Chapter 3).

Severe aplastic anaemia is a serious disorder terminating in death within 6-12 months in 50-80% of cases. Death is usually due to bleeding and/or infection.

MYELOPHTHISIC ANAEMIA

Development of severe anaemia may result from infiltration of the marrow termed as myelophthisic anaemia. The causes for marrow infiltrations include the following (**Table 10.16**):

1. Haematologic malignancies (e.g. leukaemia, lymphoma, myeloma).
2. Metastatic deposits from non-haematologic malignancies (e.g. cancer breast, stomach, prostate, lung, thyroid).
3. Advanced tuberculosis.
4. Primary lipid storage diseases (Gaucher's and Niemann-Pick's disease).
5. Osteopetrosis and myelofibrosis may rarely cause myelophthisis.

LABORATORY FINDINGS

The type of anaemia in myelophthisis is generally normocytic normochromic with some fragmented red cells, basophilic stippling and normoblasts in the peripheral blood. Thrombocytopenia is usually present but the leucocyte count is increased with slight shift-to-left of myeloid cells i.e. a picture of *leucoerythroblastic reaction* consisting of immature myeloid cells and normoblasts is seen in the peripheral blood.

Treatment consists of reversing the underlying pathologic process.

PURE RED CELL APLASIA

Pure red cell aplasia (PRCA) is a rare syndrome involving a selective failure in the production of erythroid elements in the bone marrow but with normal granulopoiesis and megakaryocytopoiesis. Patients have normocytic normochromic anaemia with normal granulocyte and platelet count. Reticulocytes are markedly decreased or are absent.

PRCA exists in the following forms:

1. Transient self-limited PRCA It is due to temporary marrow failure in aplastic crisis in haemolytic anaemias and in acute B19 parvovirus infection and in transient erythroblastopenia in normal children.

2. Acquired PRCA It is seen in middle-aged adults in association with some other diseases, most commonly thymoma; others are connective tissue diseases (SLE, rheumatoid arthritis), lymphoid malignancies (lymphoma, T-cell chronic lymphocytic leukaemia) and solid tumours.

3. Chronic B19 parvovirus infections PRCA may occur from chronic B19 parvovirus infection in children and is common and treatable. B19 parvovirus produces cytopathic effects on the marrow erythroid precursor cells and are characteristically seen as giant pronormoblasts.

4. Congenital PRCA (Blackfan-Diamond syndrome) It is a rare chronic disorder detected at birth or in early childhood. It occurs due to mutation in a ribosomal RNA processing gene termed as *RPS19*. The disorder is corrected by glucocorticoids and marrow transplantation.

GIST BOX 10.7

Aplastic Anaemia and Other Primary Bone Marrow Disorders

- Aplastic anaemia is pancytopenia due to aplasia of bone marrow. It may be primary (inherited) or secondary (acquired). Secondary causes are more common and may be due to drugs, toxic chemicals or viral infections.
- Other primary bone marrow failure disorders are myelophthisic anaemia (from marrow infiltration), pure red cell aplasia (selective failure of marrow erythropoiesis) and myelodysplastic syndromes.

CLINICAL CASE 4

A 25 years old female daily wager presented with progressive pallor, malaise and dyspnoea for 4 weeks. She gives history of two abortions in the last 6 months and heavy and irregular menstrual bleeding for the same duration.

On examination, she has no significant lymphadenopathy or organomegaly.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 907 (Appendix II)

✱ CLINICAL CASE 5

A 3 years old female child is brought by the mother to the paediatrician with persisting pallor, stunted growth and protuberant abdomen. The mother herself is also mildly anaemic which, according to her, has remained like this ever since she remembers and it did not improve with any medication.

The facial appearance of the child shows prominence of forehead and cheeks and slightly protruding upper teeth. On examination, the child has pallor ++ but no apparent jaundice or

cyanosis. On palpation of the abdomen, the spleen is enlarged by two fingers below the costal margin and the liver is just palpable. There is no lymphadenopathy. CVS and respiratory system are unremarkable.

1. **Discuss the clinical correlation with pathogenesis of the features.**
2. **What is the probable diagnosis?**
3. **How will you investigate and confirm the diagnosis?**

Answers on page 907 (Appendix II)

Disorders of Platelets, Bleeding Disorders and Basic Transfusion Medicine

DISORDERS OF PLATELETS

THROMBOPOIESIS

As outlined in previous chapter and illustrated in Fig. 10.3, the trilineage myeloid stem cells in the bone marrow differentiate into erythroid progenitor, granulocyte-monocyte progenitor, and megakaryocyte progenitor cells. Platelets are formed in the bone marrow by a process of fragmentation of the cytoplasm of megakaryocytes. Platelet production is under the control of thrombopoietin, the nature and origin of which are not yet established. The stages in platelet production are: megakaryoblast, promegakaryocyte, megakaryocyte, and discoid platelets (Fig. 11.1).

MEGAKARYOBLAST The earliest precursor of platelets in the bone marrow is megakaryoblast. It arises from haematopoietic stem cell by a process of differentiation.

PROMEGAKARYOCYTE A megakaryoblast undergoes endoreduplication of nuclear chromatin i.e. nuclear chromatin replicates repeatedly in multiples of two without division of the cell. Ultimately, a large cell containing up to 32 times the normal diploid content of nuclear DNA (polyploidy) is formed when further nuclear replication ceases and cytoplasm becomes granular.

MEGAKARYOCYTE A mature megakaryocyte is a large cell, 30-90 μm in diameter, and contains 4-16 nuclear lobes having coarsely clumped chromatin. The cytoplasm is abundant, light blue in colour and contains red-purple granules. Platelets are

formed from pseudopods of megakaryocyte cytoplasm which get detached into the blood stream. Each megakaryocyte may form up to 4000 platelets. The formation of platelets from the stem cell takes about 10 days.

PLATELETS Platelets are small (1-4 μm in diameter), discoid, non-nucleate structures containing red-purple granules. The normal platelet count ranges from 150,000-400,000/ μl and the lifespan of platelets is 7-10 days. About 70% of platelets are in circulation while remaining 30% lie sequestered in the spleen. Newly-formed platelets spend 24-36 hours in the spleen before being released into circulation but splenic stasis does not cause any injury to the platelets normally. Factors such as stress, epinephrine and exercise stimulate platelet production.

The main *functions* of platelets is in haemostasis which includes two closely linked processes:

1. Primary haemostasis This term is used for platelet plug formation at the site of injury. It is an immediate phenomenon appearing within seconds of injury and is responsible for cessation of bleeding from microvasculature. Primary haemostasis involves three steps: platelet adhesion, platelet granule release and platelet aggregation which are regulated by changes in membrane phospholipids, and calcium (Fig. 11.2). At molecular level, these important events are depicted diagrammatically in Fig. 11.3 and briefly outlined below:

i) *Platelet adhesion:* Platelets adhere to collagen in the subendothelium due to presence of receptor on platelet surface, glycoprotein (Gp) Ia-IIa which is an integrin. The adhesion to the vessel wall is further stabilised by von Willebrand factor, an adhesion glycoprotein. This is achieved by formation of a link

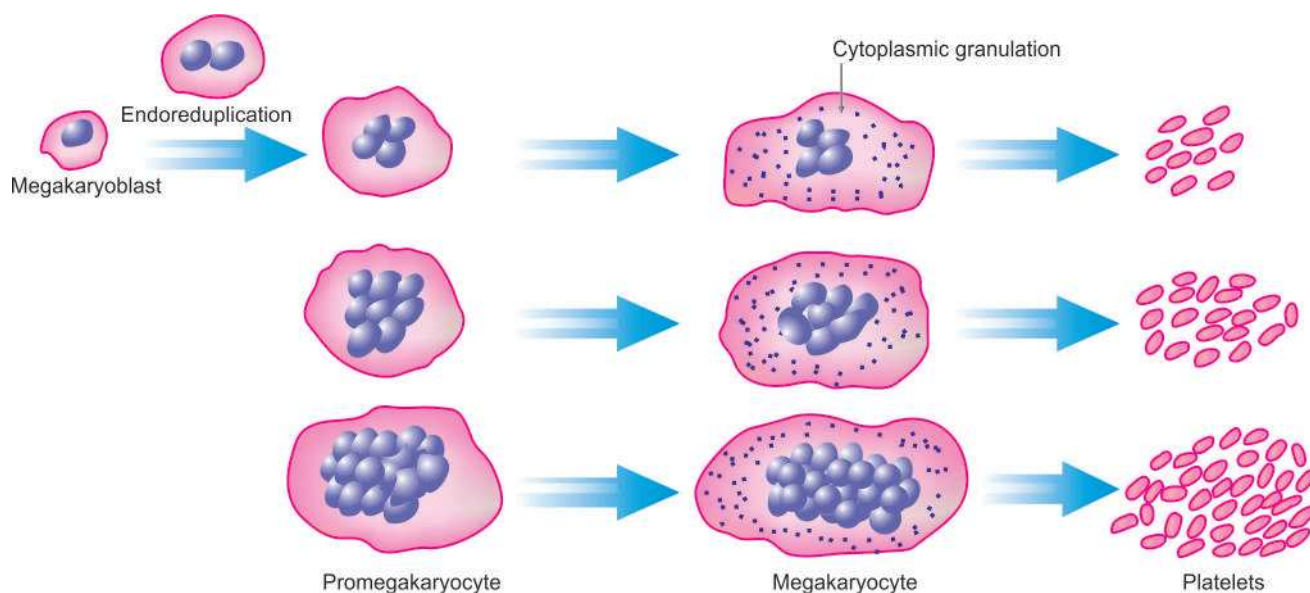

Figure 11.1 Thrombopoiesis.

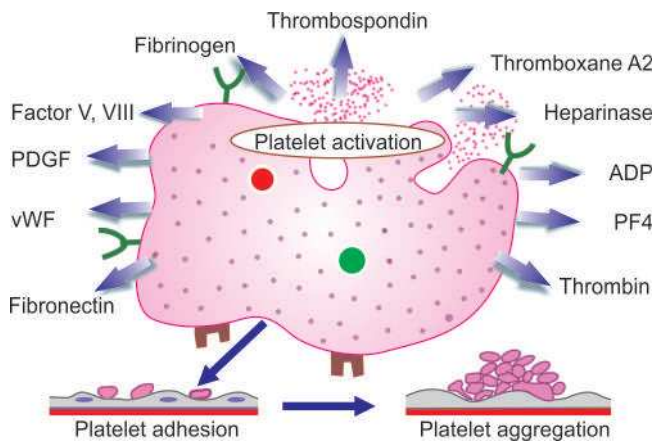

Figure 11.2 Main events in primary haemostasis—platelet adhesion, release (activation) and aggregation.

between von Willebrand factor and another platelet receptor, GpIb-IX complex.

ii) **Platelet release:** After adhesion, platelets become activated and release three types of granules from their cytoplasm: dense granules, α -granules and lysosomal vesicles. Important products released from these granules are: ADP, ATP, calcium, serotonin, platelet factor 4, factor V, factor VIII, thrombospondin, platelet-derived growth factor (PDGF), von Willebrand factor (vWF), fibronectin, fibrinogen, plasminogen activator inhibitor -1 (PAI-1) and thromboxane A2.

iii) **Platelet aggregation:** This process is mediated by fibrinogen which forms bridge between adjacent platelets via glycoprotein receptors on platelets, GpIIb-IIIa.

2. Secondary haemostasis This involves plasma coagulation system resulting in fibrin plug formation and takes several minutes for completion. This is discussed in detail in Chapter 4.

Following topics have been discussed in this chapter:

1. Investigation of haemostatic function
2. Bleeding disorders
3. Blood groups and blood transfusion

GIST BOX 11.1 Thrombopoiesis

- ▣ The stages in platelet production are megakaryoblast, promegakaryocyte, megakaryocyte, and discoid platelets.
- ▣ The major functions of platelets are haemostasis by platelet adhesion, release reaction, and aggregation.

INVESTIGATIONS OF HAEMOSTATIC FUNCTION

In general, the haemostatic mechanisms have 2 primary functions:

1. To promote *local haemostasis* at the site of injured blood vessel.
2. To ensure that the circulating blood remains in *fluid state* while in the vascular bed i.e. to prevent the occurrence of generalised thrombosis.

Formation of haemostatic plug is a complex mechanism and involves maintenance of a delicate balance among at least 5 components (Fig. 11.4). Accordingly, there are specific tests for assessing each of these components:

- A. **Blood vessel wall:** Tests for disordered vascular haemostasis
- B. **Platelets:** Tests for platelets and their functions

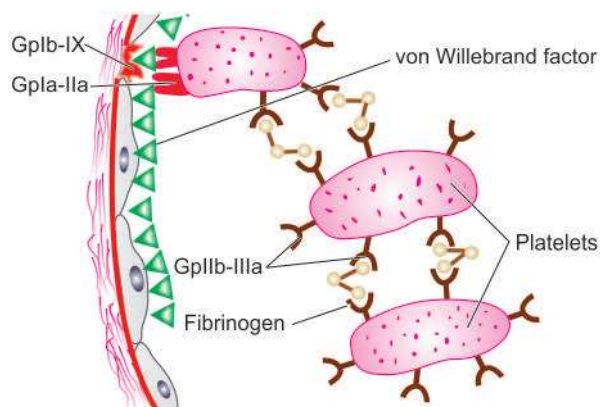

Figure 11.3 Molecular mechanisms in platelet adhesion and release reaction (Gp = glycoprotein).

C. **Plasma coagulation factors:** Tests for blood coagulation

D. **Fibrinolytic system:** Tests for fibrinolysis

E. **Inhibitors:** Tests for coagulation inhibitors

Anything that interferes with any of these components results in defective haemostasis with abnormal bleeding. In general, in order to establish a definite diagnosis in any case suspected to have abnormal haemostatic functions, the following scheme is followed:

1. Comprehensive *clinical evaluation*, including the patient's history, family history and details of the site, frequency and character of haemostatic defect.
2. Series of *screening tests* for assessing the abnormalities in various components involved in maintaining haemostatic balance.
3. *Specific tests* to pinpoint the cause.

A brief review of general principles of tests used to investigate haemostatic abnormalities is presented below and summarised in **Table 11.1**.

A. INVESTIGATION OF DISORDERED VASCULAR HAEMOSTASIS

Disorders of vascular haemostasis may be due to increased vascular permeability, reduced capillary strength and failure to contract after injury. Tests of defective vascular function are as under:

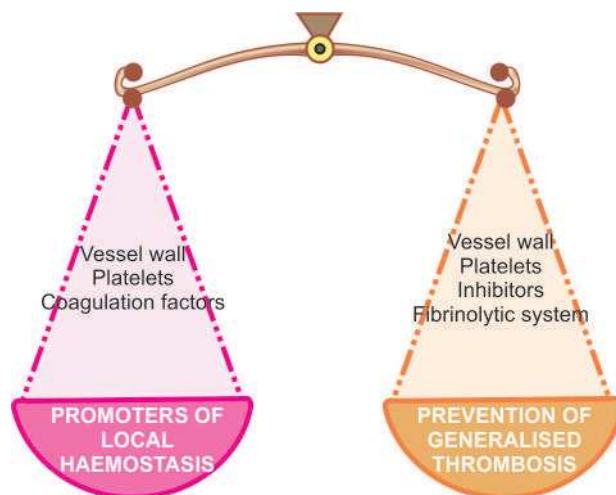

Figure 11.4 The haemostatic balance.

Table 11.1 Screening tests for haemostasis (coagulation tests).

| LABORATORY TEST | FACTOR/FUNCTION MEASURED | ASSOCIATED DISORDERS |
|---------------------------------------|--|--|
| 1. <i>Bleeding time</i> | Platelet function, vascular integrity | i) Qualitative disorders of platelets ii) von Willebrand's disease iii) Quantitative disorders of platelets iv) Acquired vascular disorders |
| 2. <i>Platelet count</i> | Quantification of platelets | i) Thrombocytopenia ii) Thrombocytosis |
| 3. <i>Prothrombin time</i> | Evaluation of extrinsic and common pathway (deficiency of factors I, II, V, VII, X) | i) Oral anticoagulant therapy ii) DIC iii) Liver disease |
| 4. <i>Partial thromboplastin time</i> | Evaluation of intrinsic and common pathway (deficiency of factors I, II, V, VIII, IX, X, XI, XII) | i) Parenteral heparin therapy ii) DIC iii) Liver disease |
| 5. <i>Thrombin time</i> | Evaluation of common pathway | i) Afibrinogenaemia ii) DIC iii) Parenteral heparin therapy |

1. BLEEDING TIME This simple test is based on the principle of formation of haemostatic plug following a standard incision on the volar surface of the forearm and the time the incision takes to stop bleeding is measured. The test is dependent upon capillary function as well as on platelet number and ability of platelets to adhere to form aggregates. Normal range is 3-8 minutes. A prolonged bleeding time may be due to following causes:

- i) Thrombocytopenia.
- ii) Disorders of platelet function.
- iii) von Willebrand's disease.
- iv) Vascular abnormalities (e.g. in Ehlers-Danlos syndrome).
- v) Severe deficiency of factor V and XI.

2. HESS CAPILLARY RESISTANCE TEST (TOURNIQUET TEST) This test is done by tying sphygmomanometer cuff to the upper arm and raising the pressure in it between diastolic and systolic for 5 minutes. After deflation, the number of petechiae appearing in the next 5 minutes in 3 cm² area over the cubital fossa are counted. Presence of more than 20 petechiae is considered a positive test. The test is positive in increased capillary fragility as well as in thrombocytopenia.

B. INVESTIGATION OF PLATELETS AND PLATELET FUNCTION

Haemostatic disorders are commonly due to abnormalities in platelet number, morphology or function.

1. SCREENING TESTS The screening tests carried out for assessing platelet-related causes are as under:

- i) Peripheral blood platelet count.
- ii) Skin bleeding time.
- iii) Examination of fresh blood film to see the morphologic abnormalities of platelets.

2. SPECIAL TESTS If these screening tests suggest a disorder of platelet function, the following platelet function tests may be carried out:

- i) *Platelet adhesion tests* such as retention in a glass bead column, and other sophisticated techniques.

- ii) *Aggregation tests* which are turbidometric techniques using ADP, collagen or ristocetin.

- iii) *Granular content* of the platelets and their release can be assessed by electron microscopy or by measuring the substances released.

- iv) *Platelet coagulant activity* is measured indirectly by prothrombin consumption index.

C. INVESTIGATION OF BLOOD COAGULATION

The normal blood coagulation system consists of cascade of activation of 13 coagulation factors. These form intrinsic, extrinsic and common pathways which culminate in formation of thrombin that acts on fibrinogen to produce fibrin. Fibrin clot so formed is strengthened by factor XIII which itself gets activated by thrombin. The process of fibrinolysis or clot dissolution and the role of platelets in activation of cascade and formation of haemostatic plug is illustrated in **Fig. 11.5**. Coagulation tests include screening and confirmatory special tests as under:

SCREENING TESTS Tests for blood coagulation system include a battery of screening tests. These are as under:

1. Whole blood coagulation time The estimation of whole blood coagulation time done by various capillary and tube methods is of limited value since it is an insensitive and nonspecific test. Normal range is 4-9 minutes at 37°C.

2. Activated partial thromboplastin time (APTT) or partial thromboplastin time with kaolin (PTTK) This test is used to measure the intrinsic system factors (VIII, IX, XI and XII) as well as factors common to both intrinsic and extrinsic systems (factors X, V, prothrombin and fibrinogen). The test consists of addition of 3 substances to the plasma—calcium, phospholipid and a surface activator such as kaolin. The normal range is 30-40 seconds. The common causes of a prolonged PTTK (or APTT) are as follows:

- i) Parenteral administration of heparin.
- ii) Disseminated intravascular coagulation.

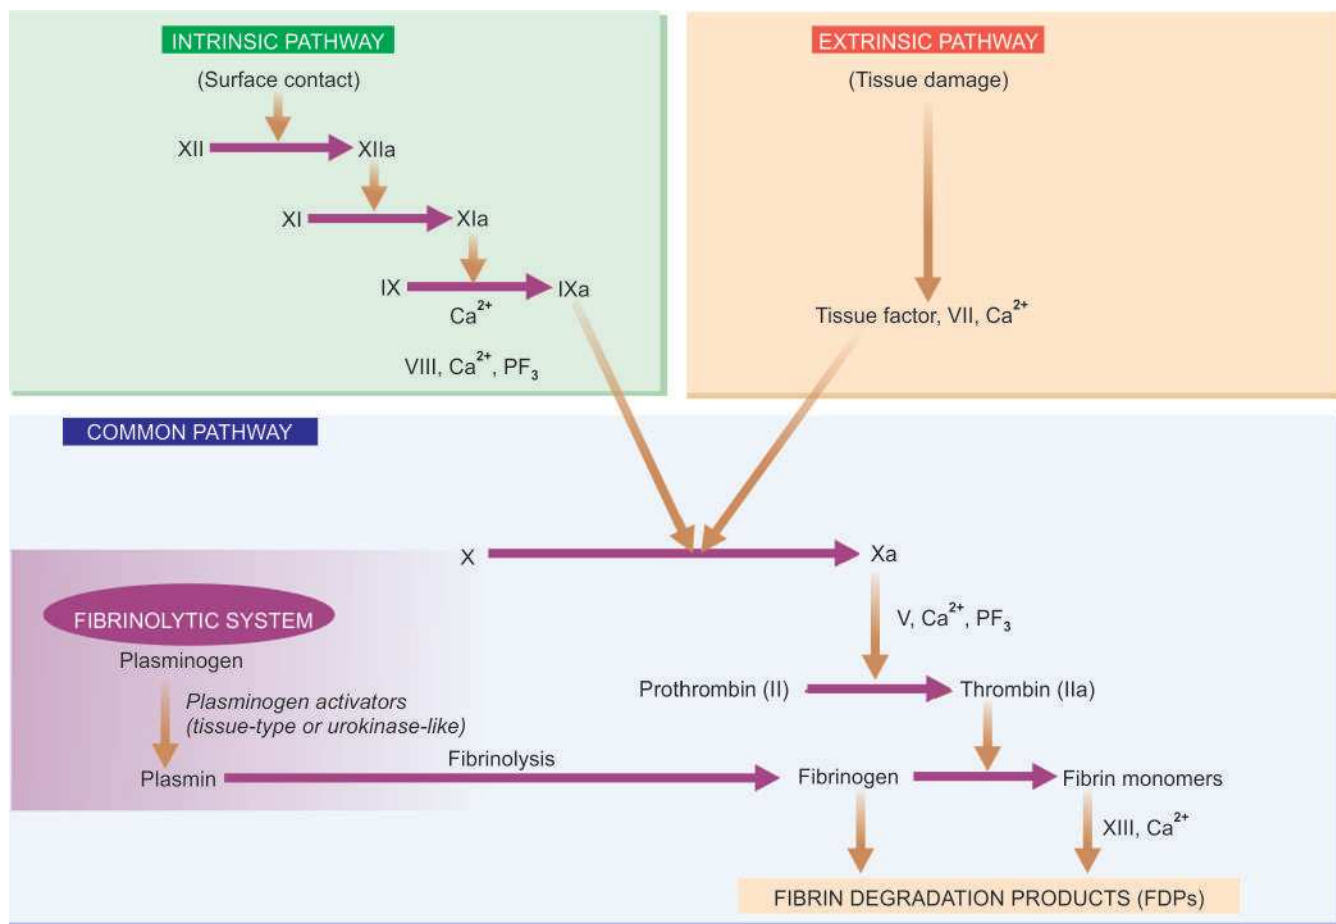

Figure 11.5 Pathways of blood coagulation, fibrinolytic system and participation of platelets in activation of the cascade and their role in haemostatic plug formation.

- iii) Liver disease.
- iv) Circulating anticoagulants.

3. One-stage prothrombin time (PT) PT measures the extrinsic system factor VII as well as factors in the common pathway. In this test, tissue thromboplastin (e.g. brain extract) and calcium are added to the test. The normal PT in this test is 10-14 seconds. The common causes of prolonged one-stage PT are as under:

- i) Administration of oral anticoagulant drugs.
- ii) Liver disease, especially obstructive liver disease.
- iii) Vitamin K deficiency.
- iv) Disseminated intravascular coagulation.

4. Measurement of fibrinogen The *screening tests* for fibrinogen deficiency are semiquantitative fibrinogen titre and thrombin time (TT). The normal value of thrombin time is under 20 seconds, while a fibrinogen titre in plasma dilution up to 32 is considered normal. Following are the common causes for higher values in both these tests:

- i) Hypofibrinogenaemia (e.g. in DIC).
- ii) Raised concentration of FDP.
- iii) Presence of heparin.

SPECIAL TESTS In the presence of an abnormality in screening tests, detailed investigations for the possible cause are carried out. These include the following:

1. Coagulation factor assays These bioassays are based on results of PTTK or PT tests and employ the use of substrate

plasma that contains all other coagulation factors except the one to be measured. The unknown level of the factor activity is compared with a standard control plasma with a known level of activity. Results are expressed as percentage of normal activity.

2. Quantitative assays The coagulation factors can be quantitatively assayed by immunological and other chemical methods.

D. INVESTIGATION OF FIBRINOLYTIC SYSTEM

Increased levels of circulating plasminogen activator are present in patients with hyperfibrinolysis. Following *screening tests* are done to assess these abnormalities in fibrinolytic system:

1. Estimation of fibrinogen.
2. Fibrin degradation products (FDP) in the serum.
3. Ethanol gelation test.
4. Euglobin or whole blood lysis time.

More *specific tests* include: functional assays, immunological assays by ELISA, and chromogenic assays of plasminogen activators, plasminogen, plasminogen activator inhibitor, and FDP.

E. INVESTIGATION OF COAGULATION INHIBITORS

There is an inbuilt system in the body by which coagulation remains confined as per need and does not become generalised. Important inhibitors are as under:

1. Antithrombin III This binds to thrombin and forms thrombin-antithrombin complex which does not permit coagulation.

2. Protein C and S Activated protein C acts as anticoagulant by cleaving and inactivating activated factor V and VIII. This reaction is further augmented by a cofactor, protein S. Deficiency of protein C and S, or failure of action of activated protein C on activated factor V due to mutation of the target site on factor V (Leiden factor) leads to hypercoagulability.

GIST BOX 11.2

Investigations of Haemostatic Function

- ▣ Haemostatic balance is maintained by 5 components: blood vessel wall, platelets, coagulation factors, fibrinolysis and inhibitors. There are screening tests and special or confirmatory tests for each of these.
- ▣ Tests for vessels wall are bleeding time and Hess capillary test.
- ▣ Platelets tests are counts, and tests for adhesion, aggregation and release.
- ▣ Screening tests for coagulation factors are coagulation test, activated partial thromboplastin time, prothrombin time and thrombin time. Special tests are assay of various coagulation factors.
- ▣ Tests for fibrinolysis are euglobin lysis test and measurement of FDPs.
- ▣ Tests for inhibitors are for antithrombin and protein C and S.

BLEEDING DISORDERS (HAEMORRHAGIC DIATHESIS)

Bleeding disorders or haemorrhagic diatheses are a group of disorders characterised by defective haemostasis with abnormal bleeding. The tendency to bleeding may be *spontaneous* in the form of small haemorrhages into the skin and mucous membranes (e.g. petechiae, purpura, ecchymoses), or there may be excessive external or internal bleeding *following trivial trauma* and surgical procedure (e.g. haematoma, haemarthrosis etc).

The causes of haemorrhagic diatheses may or may not be related to platelet abnormalities. These causes are broadly divided into the following groups:

- I. Haemorrhagic diathesis due to vascular abnormalities
- II. Haemorrhagic diathesis related to platelet abnormalities
- III. Disorders of coagulation factors
- IV. Haemorrhagic diathesis due to fibrinolytic defects
- V. Combination of all these as occurs in disseminated intravascular coagulation (DIC).

Besides, a brief comment of hypercoagulable state is also made.

HAEMORRHAGIC DIATHESSES DUE TO VASCULAR DISORDERS

Vascular bleeding disorders, also called non-thrombocytopenic purpuras or vascular purpuras, are normally mild and characterised by petechiae, purpuras or ecchymoses confined to the skin and mucous membranes. The pathogenesis of bleeding is poorly understood since majority of the standard screening tests of haemostasis including the bleeding time,

coagulation time, platelet count and platelet function, are usually normal. Vascular purpuras arise from damage to the capillary endothelium, abnormalities in the subendothelial matrix or extravascular connective tissue that supports the blood vessels, or from formation of abnormal blood vessels.

Vascular bleeding disorders may be *inherited* or *acquired*.

A. INHERITED VASCULAR BLEEDING DISORDERS

A few examples of hereditary vascular disorders are given below:

1. Hereditary haemorrhagic telangiectasia (Osler-Weber-Rendu disease) This is an uncommon inherited autosomal dominant disorder. The condition begins in childhood and is characterised by abnormally telangiectatic (dilated) capillaries due to vascular malformations in the skin and mucosal surfaces, especially on lips, tongue, nose and palms and soles. Clinically, patients present with bleeding from stomach, epistaxis or from other mucosal surfaces.

2. Inherited disorders of connective tissue matrix These include Marfan's syndrome, Ehlers-Danlos syndrome and pseudoxanthoma elasticum, all of which have inherited defect in the connective tissue matrix and, thus, have fragile skin vessels and easy bruising.

B. ACQUIRED VASCULAR BLEEDING DISORDERS

Several acquired conditions are associated with vascular purpuras. These are as under:

1. Henoch-Schönlein purpura The salient features of Henoch-Schönlein or anaphylactoid purpura are as under:

- i) It is a self-limited type of hypersensitivity vasculitis occurring in children and young adults.
- ii) The hypersensitivity vasculitis produces purpuric rash on the extensor surfaces of arms, legs and on the buttocks, as well as haematuria, colicky abdominal pain due to bleeding into the GIT, polyarthralgia and acute nephritis.
- iii) In spite of these haemorrhagic features, all coagulation tests are normal.
- iv) The vessel wall shows leucocytoclastic vasculitis as seen by viable and necrotic neutrophils.
- v) Circulating immune complexes are deposited in the vessel wall consisting of IgA, C3 and fibrin, and in some cases, properdin suggesting activation of alternate complement pathway as the trigger event.

2. Haemolytic-uraemic syndrome Haemolytic-uraemic syndrome is a disease of infancy and early childhood in which there is bleeding tendency and varying degree of acute renal failure. The disorder remains confined to the kidney where hyaline thrombi are seen in the glomerular capillaries.

3. Simple easy bruising (Devil's pinches) Easy bruising of unknown cause is a common phenomenon in women of child-bearing age group.

4. Infection Many infections cause vascular haemorrhages either by causing toxic damage to the endothelium or by DIC. These are especially prone to occur in septicaemia and severe measles.

5. Drug reactions Certain drugs form antibodies and produce hypersensitivity (or leucocytoclastic) vasculitis responsible for abnormal bleeding.

6. Steroid purpura Long-term steroid therapy or Cushing's syndrome may be associated with vascular purpura due to defective vascular support.

7. Senile purpura Atrophy of the supportive tissue of cutaneous blood vessels in old age may cause senile atrophy, especially in the dorsum of forearm and hand.

8. Scurvy Deficiency of vitamin C causes defective collagen synthesis which causes skin bleeding as well as bleeding into muscles, and occasionally into the gastrointestinal and genitourinary tracts.

**GIST BOX 11.3****Haemorrhagic Diathesis due to Vascular Disorders**

- ▣ These are commonly called vascular purpuras because the cause lies in the vascular wall—damaged endothelium, abnormality in subendothelial matrix, abnormal formation of blood vessels.
- ▣ Examples of inherited vascular purpuras are hereditary haemorrhagic telangiectasia, connective tissue matrix disorders.
- ▣ Acquired causes are Henoch-Schonlein purpura, haemolytic-uraemic syndrome, simple easy bruising, certain bacterial and viral infection, intake of some drugs and steroids, senility, scurvy etc

HAEMORRHAGIC DIATHESSES DUE TO PLATELET DISORDERS

Disorders of platelets produce bleeding disorders by one of the following 3 mechanisms:

- A. *Due to reduction in the number of platelets* i.e. various forms of thrombocytopenias.
- B. *Due to rise in platelet count* i.e. thrombocytosis.
- C. *Due to defective platelet functions.*

A. THROMBOCYTOPENIAS

Thrombocytopenia is defined as a reduction in the peripheral blood platelet count below the lower limit of normal i.e. below 150,000/ μ l. Thrombocytopenia is associated with abnormal bleeding that includes spontaneous skin purpura and mucosal haemorrhages as well as prolonged bleeding after trauma. However, spontaneous haemorrhagic tendency becomes clinically evident only after severe depletion of the platelet count to level below 20,000/ μ l.

Thrombocytopenia may result from 4 main groups of causes:

1. Impaired platelet production
2. Accelerated platelet destruction
3. Splenic sequestration
4. Dilutional loss

A list of causes of thrombocytopenia is given in **Table 11.2**. Three of the common and important causes—drug-induced thrombocytopenia, idiopathic thrombocytopenic purpura (ITP), and thrombotic thrombocytopenic purpura (TTP), are discussed below.

Drug-induced Thrombocytopenia

Many commonly used drugs cause thrombocytopenia by depressing megakaryocyte production. In most cases, an

Table 11.2 Causes of thrombocytopenia.

I. IMPAIRED PLATELET PRODUCTION

1. *Generalised bone marrow failure e.g.*

Aplastic anaemia, leukaemia, myelofibrosis, megaloblastic anaemia, marrow infiltrations (carcinomas, lymphomas, multiple myeloma, storage diseases).

2. *Selective suppression of platelet production e.g.*

Drugs (quinine, quinidine, sulfonamides, PAS, rifampicin, anticancer drugs, thiazide diuretics), (heparin, diclofenac, acyclovir), alcohol intake.

II. ACCELERATED PLATELET DESTRUCTION

1. *Immunologic thrombocytopenias e.g.*

ITP (acute and chronic), neonatal and post-transfusion (isoimmune), drug-induced, secondary immune thrombocytopenia (post-infection, SLE, AIDS, CLL, lymphoma).

2. *Increased consumption e.g.*

DIC, TTP, giant haemangiomas, microangiopathic haemolytic anaemia.

III. SPLENIC SEQUESTRATION

Splenomegaly

IV. DILUTIONAL LOSS

Massive transfusion of old stored blood to bleeding patients

immune mechanism by formation of drug-antibody complexes is implicated in which the platelet is damaged as an 'innocent bystander'. Drug-induced thrombocytopenia is associated with many commonly used drugs and includes: chemotherapeutic agents (alkylating agents, anthracyclines, antimetabolites), certain antibiotics (sulfonamides, PAS, rifampicin, penicillins), drugs used in cardiovascular diseases (digitoxin, thiazide diuretics), diclofenac, acyclovir, heparin and excessive consumption of ethanol.

Clinically, the patient presents with acute purpura. The platelet count is markedly lowered, often below 10,000/ μ l and the bone marrow shows normal or increased number of megakaryocytes.

The immediate treatment is to stop or replace the suspected drug with instruction to the patient to avoid taking the offending drug in future. Occasional patients may require temporary support with glucocorticoids, plasmapheresis or platelet transfusions.

Heparin-induced Thrombocytopenia

Thrombocytopenia due to administration of heparin is distinct from that caused by other drugs in following ways:

i) Thrombocytopenia is generally not so severe to fall to level below 20,000/ μ l.

ii) Unlike drug-induced thrombocytopenia, heparin-induced thrombocytopenia is not associated with bleeding but instead these patients are more prone to develop thrombosis.

The underlying mechanism of heparin-induced thrombocytopenia is formation of antibody against platelet factor 4 (PF-4)-heparin complex. This specific antibody activates the endothelial cells and initiates thrombus formation.

It occurs in a small proportion of cases after the patient has received heparin for 5-10 days.

Diagnosis is made by a combination of laboratory and clinical features with 4 *T*s: thrombocytopenia, thrombosis, time of fall of platelet count, absence of other causes of thrombocytopenia.

Immune Thrombocytopenic Purpura (ITP)

Idiopathic (or immune) thrombocytopenic purpura (ITP), is characterised by immunologic destruction of platelets and normal or increased megakaryocytes in the bone marrow.

PATHOGENESIS On the basis of duration of illness, ITP is classified into acute and chronic forms, both of which have different pathogenesis.

Acute ITP This is a self-limited disorder, seen most frequently in children following recovery from a viral illness (e.g. hepatitis C, infectious mononucleosis, CMV infection, HIV infection) or an upper respiratory illness. The onset of acute ITP is sudden and severe thrombocytopenia but recovery occurs within a few weeks to 6 months. The mechanism of acute ITP is by formation of *immune complexes* containing viral antigens, and by formation of *antibodies* against viral antigens which crossreact with platelets and lead to their immunologic destruction.

Chronic ITP Chronic ITP occurs more commonly in adults, particularly in women of child-bearing age (20-40 years). The disorder develops insidiously and persists for several years. Though chronic ITP is idiopathic, similar immunologic thrombocytopenia may be seen in association with SLE, AIDS and autoimmune thyroiditis. The pathogenesis of chronic ITP is explained by formation of *anti-platelet autoantibodies*, usually by platelet-associated IgG humoral antibodies synthesised mainly in the spleen. These antibodies are directed against target antigens on the platelet glycoproteins, Gp IIb-IIIa and Gp Ib-IX complex. Some of the antibodies directed against platelet surface also interfere in their function. The mechanism of platelet destruction is similar to that seen in autoimmune haemolytic anaemias. Sensitised platelets are destroyed mainly in the spleen and rendered susceptible to phagocytosis by cells of the reticuloendothelial system.

CLINICAL FEATURES The clinical manifestation of ITP may develop abruptly in cases of acute ITP, or the onset may be insidious as occurs in majority of cases of chronic ITP. The usual manifestations are petechial haemorrhages, easy bruising, and mucosal bleeding such as menorrhagia in women, nasal bleeding, bleeding from gums, melaena and haematuria. Intracranial haemorrhage is, however, rare. Splenomegaly and hepatomegaly may occur in cases with chronic ITP but lymphadenopathy is quite uncommon in either type of ITP.

LABORATORY FINDINGS The diagnosis of ITP can be suspected on clinical features after excluding the known causes of thrombocytopenia and is supported by the following haematologic findings:

1. *Platelet count* is markedly reduced, usually in the range of 10,000-50,000/ μ l.
2. *Blood film* shows only occasional platelets which are often large in size (**Fig. 11.6, A**).
3. *Bone marrow* shows increased number of megakaryocytes which have large non-lobulated single nuclei and may have reduced cytoplasmic granularity and presence of vacuoles (**Fig. 11.6, B**).

4. With sensitive techniques, *anti-platelet IgG antibody* can be demonstrated on platelet surface or in the serum of patients.
5. *Platelet survival studies* reveal markedly reduced platelet lifespan, sometimes less than one hour, as compared with normal lifespan of 7-10 days.

PRINCIPLES OF TREATMENT Spontaneous recovery occurs in 90% cases of acute ITP, while only less than 10% cases of chronic ITP recover spontaneously. Treatment is directed at reducing the level and source of autoantibodies and reducing the rate of destruction of sensitised platelets. This is possible by corticosteroid therapy, immunosuppressive drugs (e.g. vincristine, cyclophosphamide and azathioprine) and splenectomy. Beneficial effects of splenectomy in chronic ITP are due to both removal of the major site of platelet destruction and the major source of autoantibody synthesis. Platelet transfusions are helpful as a palliative measure only in patients with severe haemorrhage.

Thrombotic Thrombocytopenic Purpura (TTP) and Haemolytic-Uraemic Syndrome (HUS)

Thrombotic thrombocytopenic purpura (TTP) and haemolytic-uraemic syndrome (HUS) are a group of thrombotic microangiopathies which are essentially characterised by triad of *thrombocytopenia, microangiopathic haemolytic anaemia and formation of hyaline fibrin microthrombi* within the microvasculature throughout the body. These are often fulminant and lethal disorders occurring in young adults. The intravascular microthrombi are composed predominantly of platelets and fibrin. The widespread presence of these platelet microthrombi is responsible for thrombocytopenia due to increased consumption of platelets, microangiopathic haemolytic anaemia and protean clinical manifestations involving different organs and tissues throughout the body.

PATHOGENESIS Unlike DIC, a clinicopathologically related condition, activation of the clotting system is not the primary event in formation of microthrombi. TTP is initiated by endothelial injury followed by release of von Willebrand factor and other procoagulant material from endothelial cells, leading to the formation of microthrombi. Trigger for the endothelial injury comes from immunologic damage by diverse conditions such as in pregnancy, metastatic cancer, high-dose chemotherapy, HIV infection, and mitomycin C.

CLINICAL FEATURES The clinical manifestations of TTP are due to microthrombi in the arterioles, capillaries and venules throughout the body. Besides features of thrombocytopenia and microangiopathic haemolytic anaemia, characteristic findings include fever, transient neurologic deficits and renal failure. The spleen may be palpable.

LABORATORY FINDINGS The diagnosis can be made from the following findings:

1. Thrombocytopenia.
2. Microangiopathic haemolytic anaemia with negative Coombs' test.
3. Leucocytosis, sometimes with leukaemoid reaction.

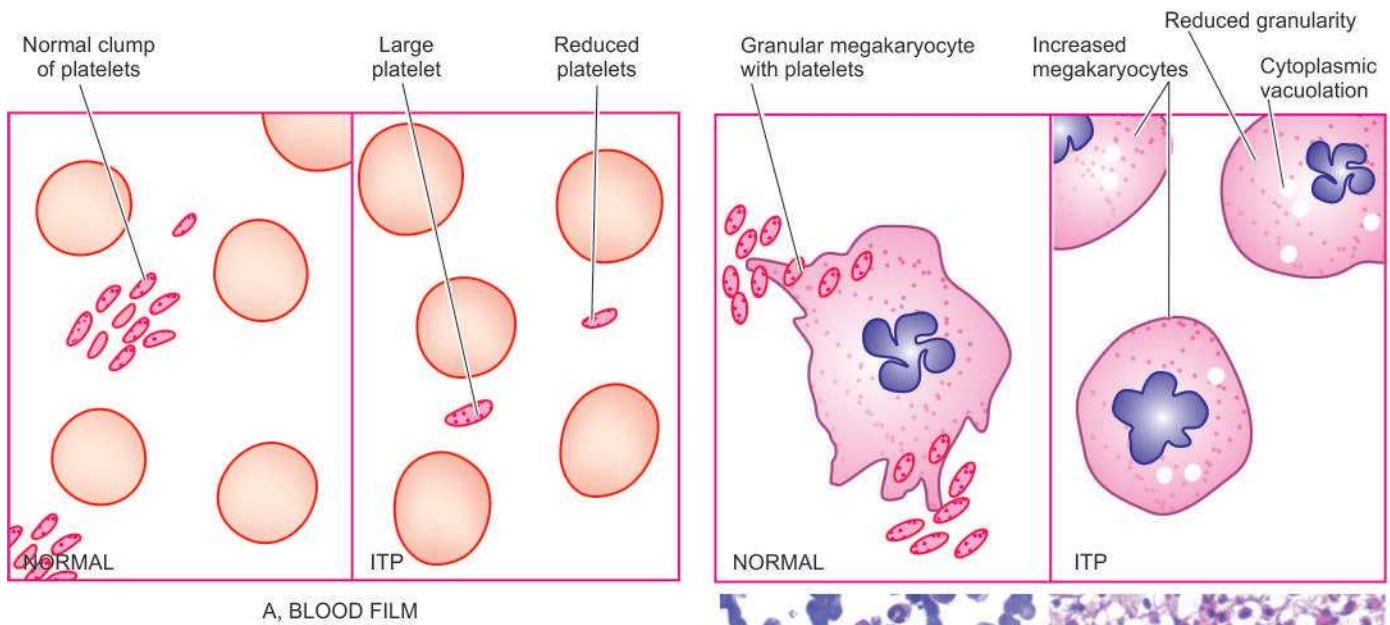

Figure 11.6 Laboratory findings of ITP contrasted with those found in a normal individual. A, Peripheral blood in ITP shows presence of reduced number of platelets which are often large. B, C, Bone marrow aspirate and trephine in ITP show characteristically increased number of megakaryocytes with single non-lobulated nuclei and reduced cytoplasmic granularity.

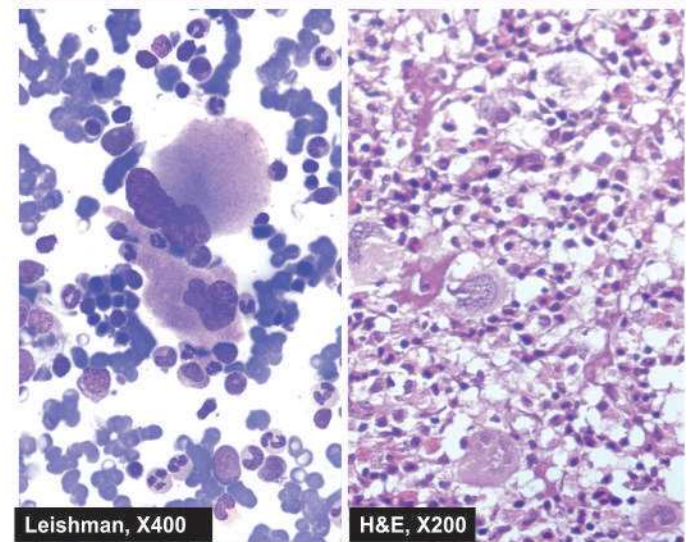

4. Bone marrow examination reveals normal or slightly increased megakaryocytes accompanied with some myeloid hyperplasia.

5. Diagnosis is, however, established by examination of biopsy (e.g. from gingiva) which demonstrates typical microthrombi in arterioles, capillaries and venules, unassociated with any inflammatory changes in the vessel wall.

B. THROMBOCYTOSIS

Thrombocytosis is defined as platelet count in excess of 4,00,000/ μl . While essential or primary thrombocytosis or thrombocythaemia is discussed under myeloproliferative disorders in the next chapter, secondary or reactive thrombocytosis can occur following massive haemorrhage, iron deficiency, severe sepsis, marked inflammation, disseminated cancers, haemolysis, or following splenectomy. Thrombocytosis causes bleeding or thrombosis but how it produces is not clearly known.

As such, transitory and secondary thrombocytosis does not require any separate treatment other than treating the cause.

B, BONE MARROW ASPIRATE C, BONE MARROW TREPHINE

C. DISORDERS OF PLATELET FUNCTIONS

Defective platelet function is suspected in patients who show skin and mucosal haemorrhages and have prolonged bleeding time but a normal platelet count. These disorders may be hereditary or acquired.

Hereditary Disorders

Depending upon the predominant functional abnormality, inherited disorders of platelet functions are classified into the following 3 groups:

1. DEFECTIVE PLATELET ADHESION These are as under:
i) *Bernard-Soulier syndrome* is an autosomal recessive disorder with inherited deficiency of a platelet membrane glycoprotein which is essential for adhesion of platelets to vessel wall.

ii) *In von Willebrand's disease*, there is defective platelet adhesion as well as deficiency of factor VIII (page 314).

2. DEFECTIVE PLATELET AGGREGATION In *thrombasthenia (Glanzmann's disease)*, there is failure of primary platelet aggregation with ADP or collagen due to inherited deficiency of two of platelet membrane glycoproteins.

3. DISORDERS OF PLATELET RELEASE REACTION These disorders are characterised by normal initial aggregation of platelets with ADP or collagen but the subsequent release of ADP, prostaglandins and 5-HT is defective due to complex intrinsic deficiencies.

Acquired Disorders

Acquired defects of platelet functions include the following clinically significant examples:

1. ASPIRIN THERAPY Prolonged use of aspirin leads to easy bruising and abnormal bleeding time. This is because aspirin inhibits the enzyme cyclooxygenase, and thereby suppresses the synthesis of prostaglandins which are involved in platelet aggregation as well as release reaction. The anti-platelet effect of aspirin is clinically applied in preventing major thromboembolic disease in recurrent myocardial infarction.

2. OTHERS Several other acquired disorders are associated with various abnormalities in platelet functions at different levels. These include: uraemia, liver disease, multiple myeloma, Waldenström's macroglobulinaemia and various myeloproliferative disorders.

GIST BOX 11.4

Haemorrhagic Diathesis due to Platelet Disorders

- ☐ Platelet disorders may be due to reduction or increased number, or defective functions.
- ☐ Thrombocytopenia may result from impaired production, accelerated destruction, splenic sequestration or dilutional loss.
- ☐ Idiopathic (or immune) thrombocytopenic purpura (ITP), is characterised by immunologic destruction of platelets and normal or increased megakaryocytes in the bone marrow. It may be acute or chronic.
- ☐ Thrombotic thrombocytopenic purpura (TTP) and haemolytic-uraemic syndrome have thrombocytopenia and hyaline fibrin microthrombi within the microvasculature throughout the body.
- ☐ Defective platelet functions may be hereditary (platelet adhesion, aggregation, release reaction) or acquired (aspirin, uraemia, liver disease etc).

COAGULATION DISORDERS

The physiology of normal coagulation is described in Chapter 4 together with relatively more common coagulation disorders of arterial and venous thrombosis and embolism. A deficiency of each of the thirteen known plasma coagulation factors has been reported, which may be inherited or acquired. In general, coagulation disorders are less common as compared with other bleeding disorders. The type of bleeding in coagulation disorders is different from that seen in vascular and platelet abnormalities. Instead of spontaneous appearance of petechiae and purpuras, the plasma coagulation defects manifest more often in the form of large ecchymoses, haematomas and bleeding into muscles, joints, body cavities, GIT and urinary tract. For establishing the diagnosis, *screening tests for coagulation* (whole blood coagulation time, bleeding time, activated partial thromboplastin time and prothrombin time) are carried out, followed by *coagulation factor assays* as discussed already on page 308.

Disorders of plasma coagulation factors may have hereditary or acquired origin.

Hereditary coagulation disorders Most of the inherited plasma coagulation disorders are due to qualitative or quantitative defect in a single coagulation factor. Out of defects in various coagulation factors, two of the most common inherited coagulation disorders are the sex-(X)-linked disorders—*classic haemophilia or haemophilia A* (due to inherited deficiency of factor VIII), and *Christmas disease or haemophilia B* (due to inherited deficiency of factor IX). Another common and related coagulation disorder, *von Willebrand's disease* (due to inherited defect of von Willebrand's factor), is also discussed here.

Acquired coagulation disorders The acquired coagulation disorders, on the other hand, are usually characterised by deficiencies of multiple coagulation factors. The most common acquired clotting abnormalities are: vitamin K deficiency, coagulation disorder in liver diseases, fibrinolytic defects and disseminated intravascular coagulation (DIC).

Common hereditary and acquired coagulation disorders are discussed below.

1. CLASSIC HAEMOPHILIA (HAEMOPHILIA A)

Classic haemophilia or haemophilia A is the most common hereditary coagulation disorder occurring due to deficiency or reduced activity of factor VIII (anti-haemophilic factor). The disorder is inherited as a sex-(X-) linked recessive trait and, therefore, manifests clinically in males, while females are usually the carriers. However, rarely there may be true female haemophilics (homozygous state) arising from consanguinity within the family e.g. daughter born to haemophilic father and carrier mother. The chances of a proven carrier mother passing on the abnormality to her children are 50:50 for each son and 50:50 for each daughter. A haemophilic father cannot transmit the disorder to his sons (as they inherit his Y chromosome only that does not carry the genetic abnormality) while all his daughters will be asymptomatic carriers. However, cases without family history of haemophilia are due to spontaneous somatic mutations of gene coding for factor VIII.

The disease has been known since ancient times but Schönlein in 1839 gave this bleeder's disease its present name haemophilia. In 1952, it was found that haemophilia was not always due to deficiency of factor VIII as was previously considered but instead blood of some patients was deficient in factor IX (Christmas factor or plasma thromboplastin component). Currently, *haemophilia A (classic haemophilia)* is inherited deficiency of factor VIII due to mutation in F8 gene, and *haemophilia B (Christmas disease)* is inherited deficiency of factor IX due to mutation in F9 gene.

The frequency of haemophilia varies in different races, the highest incidence being in populations of Britain, Northern Europe and Australia. Haemophilia A comprises about 80% cases. Western literature reports give an overall incidence of haemophilia A in 1 in 10,000 male births. Another interesting facet of the haemophilia which has attracted investigators and researchers is the prevalence of this disorder in the blood of royal families in Great Britain and some European countries.

PATHOGENESIS Haemophilia A is caused by quantitative reduction of factor VIII in 90% of cases, while 10% cases have normal or increased level of factor VIII with reduced activity.

Factor VIII is synthesised in hepatic parenchymal cells and regulates the activation of factor X in intrinsic coagulation pathway. Factor VIII circulates in blood complexed to another larger protein, von Willebrand's factor (vWF), which comprises 99% of the factor VIII-vWF complex. The genetic coding, synthesis and functions of vWF are different from those of factor VIII and are considered separately below under von Willebrand's disease. Normal haemostasis requires 25% factor VIII activity. Though occasional patients with 25% factor VIII level may develop bleeding, most symptomatic haemophilic patients have factor VIII levels below 5%.

CLINICAL FEATURES Patients of haemophilia suffer from bleeding for hours or days after the injury. The clinical severity of the disease correlates well with plasma level of factor VIII activity. Haemophilic bleeding can involve any organ but occurs most commonly as recurrent painful haemarthroses and muscle haematomas, and sometimes as haematuria. Spontaneous intracranial haemorrhage and oropharyngeal bleeding are rare, but when they occur they are the most feared complications.

LABORATORY FINDINGS The following tests are abnormal:

- i) Whole blood coagulation time is prolonged in severe cases only.
- ii) Prothrombin time is usually normal.
- iii) Activated partial thromboplastin time (APTT or PTTK) is typically prolonged.
- iv) Specific assay for factor VIII shows lowered activity. The diagnosis of *female carriers* is made by the findings of about half the activity of factor VIII, while the *manifest disease* is associated with factor VIII activity below 25%.

PRINCIPLES OF TREATMENT Symptomatic patients with bleeding episodes are treated with factor VIII replacement therapy, consisting of factor VIII concentrates or plasma cryoprecipitates. With the availability of this treatment, the life expectancy of even severe haemophilic patients was approaching normal but the occurrence of AIDS in multitransfused haemophilic patients has adversely affected the life expectancy.

2. CHRISTMAS DISEASE (HAEMOPHILIA B)

Inherited deficiency of factor IX (Christmas factor or plasma thromboplastin component) produces Christmas disease or haemophilia B. Haemophilia B is rarer than haemophilia A constituting about 20% cases; its estimated incidence is 1 in 100,000 male births. The inheritance pattern and clinical features of factor IX deficiency are indistinguishable from those of classic haemophilia but accurate laboratory diagnosis is critical since haemophilia B requires treatment with different plasma fraction. The usual screening tests for coagulation are similar to those in classic haemophilia but bioassay of factor IX reveals lowered activity.

PRINCIPLES OF TREATMENT Therapy in symptomatic haemophilia B consists of infusion of either fresh frozen plasma or a plasma enriched with factor IX. Besides the expected possibilities of complications of hepatitis, chronic liver disease and AIDS, the replacement therapy in factor IX deficiency may activate the coagulation system and cause thrombosis and embolism.

3. VON WILLEBRAND'S DISEASE

DEFINITION AND PATHOGENESIS von Willebrand's disease (vWD) is the most common hereditary coagulation disorder occurring due to qualitative or quantitative defect in von Willebrand's factor (vWF). Its incidence is estimated to be 1 in 1,000 individuals of either sex. The vWF comprises the larger fraction of factor VIII-vWF complex which circulates in the blood. Though the two components of factor VIII-vWF complex circulate together as a unit and perform the important function in clotting and facilitate platelet adhesion to subendothelial collagen, vWF differs from factor VIII in the following respects:

- i) The *gene* for vWF is located at chromosome 12, while that of factor VIII is in X-chromosome. Thus, vWD is inherited as an autosomal dominant trait which may occur in either sex, while factor VIII deficiency (haemophilia A) is a sex (X-) linked recessive disorder.
- ii) The vWF is *synthesised* in the endothelial cells, megakaryocytes and platelets but not in the liver cells, while the principal site of synthesis of factor VIII is the liver.
- iii) The main *function* of vWF is to facilitate the adhesion of platelets to subendothelial collagen, while factor VIII is involved in activation of factor X in the intrinsic coagulation pathway.

CLINICAL FEATURES Clinically, the patients of vWD are characterised by spontaneous bleeding from mucous membranes and excessive bleeding from wounds. There are 3 major types of vWD:

Type I disease is the most common and is characterised by mild to moderate decrease in plasma vWF (50% activity). The synthesis of vWF is normal but the release of its multimers is inhibited.

Type II disease is much less common and is characterised by normal or near normal levels of vWF which is functionally defective.

Type III disease is extremely rare and is the most severe form of the disease. These patients have no detectable vWF activity and may have sufficiently low factor VIII levels.

Bleeding episodes in vWD are treated with cryoprecipitates or factor VIII concentrates.

LABORATORY FINDINGS These are as under:

- i) Prolonged bleeding time.
- ii) Normal platelet count.
- iii) Reduced plasma vWF concentration.
- iv) Defective platelet aggregation with ristocetin, an antibiotic.
- v) Reduced factor VIII activity.

4. VITAMIN K DEFICIENCY

Vitamin K is a fat-soluble vitamin which plays important role in haemostasis since it serves as a cofactor in the formation of 6 prothrombin complex proteins (*vitamin K-dependent coagulation factors*) synthesised in the liver: factor II, VII, IX, X, protein C and protein S. Vitamin K is obtained from green vegetables, absorbed in the small intestine and stored in the liver (page 245). Some quantity of vitamin K is endogenously synthesised by the bacteria in the colon.

Vitamin K deficiency may present in the newborn or in subsequent childhood or adult life:

- i) **Neonatal vitamin K deficiency** Deficiency of vitamin K in the newborn causes haemorrhagic disease of the newborn.

Liver cell immaturity, lack of gut bacterial synthesis of the vitamin and low quantities in breast milk, all contribute to vitamin K deficiency in the newborn and may cause haemorrhage on 2nd to 4th day of life. Routine administration of vitamin K to all newly born infants has led to disappearance of neonatal vitamin K deficiency.

ii) **Vitamin K deficiency in children and adult** There are 3 major causes of vitamin K deficiency in childhood or adult life:

- Inadequate dietary intake.
- Intestinal malabsorption.
- Loss of storage site due to hepatocellular disease.

With the onset of vitamin K deficiency, the plasma levels of all the 6 vitamin K-dependent factors (prothrombin complex proteins) fall. This, in turn, results in prolonged PT and PTTK. Parenteral administration of vitamin K rapidly restores vitamin K levels in the liver.

5. COAGULATION DISORDERS IN LIVER DISEASE

Since liver is the major site for synthesis and metabolism of coagulation factors, liver disease often leads to multiple haemostatic abnormalities. The liver also produces inhibitors of coagulation such as antithrombin III and protein C and S and plays a role in the clearance of activated factors and fibrinolytic enzymes. Thus, patients with liver disease may develop hypercoagulability and are predisposed to develop DIC and systemic fibrinolysis.

The major causes of bleeding in liver diseases are as under:

A. Morphologic lesions:

- Portal hypertension e.g. varices, splenomegaly with secondary thrombocytopenia
- Peptic ulceration
- Gastritis

B. Hepatic dysfunctions:

- Impaired hepatic synthesis of coagulation factors
- Impaired hepatic synthesis of coagulation inhibitors: protein C, protein S and antithrombin III
- Impaired absorption and metabolism of vitamin K
- Failure to clear activated coagulation factors causing DIC and systemic fibrinolysis

C. Complications of therapy:

- Following massive transfusion leading to dilution of platelets and coagulation factors.
- Infusion of activated coagulation proteins.
- Following heparin therapy.

Many a times, the haemostatic abnormality in liver disease is complex but most patients have prolonged PT and PTTK, mild thrombocytopenia, normal fibrinogen level and decreased hepatic stores of vitamin K.

GIST BOX 11.5 Coagulation Disorders

- ☐ Disorders of coagulation factors may be hereditary or acquired.
- ☐ Common hereditary coagulation disorders are haemophilia A (due to deficiency or reduced activity of factor VIII), haemophilia B (due to deficiency of factor IX), and von Willebrand disease (due to qualitative or quantitative defect in von Willebrand's factor (vWF))
- ☐ Common acquired causes are vitamin K deficiency in different ages and liver diseases causing reduced synthesis of coagulation factors.

OTHER BLEEDING AND COAGULATION DISORDERS

HAEMORRHAGIC DIATHESSES DUE TO FIBRINOLYTIC DEFECTS

Normally, fibrinolysis consisting of plasminogen-plasmin and fibrin degradation products (FDPs) is an essential protective physiologic mechanism to limit the blood coagulation in the body. However, unchecked and excessive fibrinolysis may sometimes be the cause of bleeding. The causes of *primary pathologic fibrinolysis* leading to haemorrhagic defects are as under:

- Deficiency of α_2 -plasmin inhibitor following trauma or surgery.
- Impaired clearance of tissue plasminogen activator such as in cirrhosis of liver.

At times, it may be difficult to distinguish primary pathologic fibrinolysis from secondary fibrinolysis accompanying DIC.

HYPERCOAGULABLE STATE

As discussed in Chapter 4, hypercoagulability or thrombophilia is a state of increased risk of thrombosis due to abnormality in haemostatic equilibrium i.e. reverse of abnormal bleeding (page 102). It may occur due to inherited or acquired disorders as under:

I. Inherited factors:

- Antithrombin III deficiency
- Protein C deficiency
- Protein S deficiency
- Activated protein C resistance (Factor V Leiden)
- Inherited disorders of fibrinolytic pathways e.g. dysfibrinogenemia, dysplasminogenemia
- Increased prothrombin production

II. Acquired factors:

- Antiphospholipid antibodies (APLA) e.g. lupus anticoagulant, anticardiolipin antibodies
- Impaired venous return due to stasis
- Oral contraceptives
- Disseminated malignancy
- Nephrotic syndrome
- Postoperative cases

DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

Disseminated intravascular coagulation (DIC), also termed defibrination syndrome or consumption coagulopathy, is a complex thrombo-haemorrhagic disorder (intravascular coagulation and haemorrhage) occurring as a secondary complication in some systemic diseases.

Etiology

Although there are numerous conditions associated with DIC, most frequent causes are listed below:

- Massive tissue injury** In obstetrical syndromes (e.g. abruptio placentae, amniotic fluid embolism, retained dead foetus), massive trauma, metastatic malignancies, surgery.
- Infections** Especially endotoxaemia, gram-negative and meningococcal septicaemia, certain viral infections, malaria, aspergillosis.
- Widespread endothelial damage** In aortic aneurysm, haemolytic-uraemic syndrome, severe burns, acute glomerulonephritis.

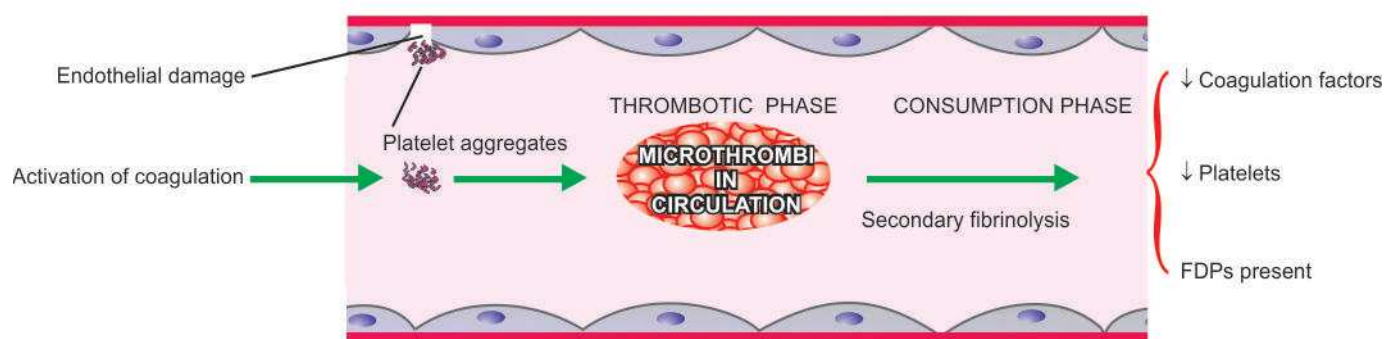

Figure 11.7 The pathogenesis of disseminated intravascular coagulation.

4. Miscellaneous: Snake bite, shock, acute intravascular haemolysis, heat stroke.

Pathogenesis

Although in each case, a distinct triggering mechanism has been identified, the sequence of events, in general, can be summarised as under (**Fig. 11.7**):

1. Activation of coagulation The etiologic factors listed above initiate widespread activation of coagulation pathway by release of tissue factor.

2. Thrombotic phase Endothelial damage from the various thrombogenic stimuli causes generalised platelet aggregation and adhesion with resultant deposition of small thrombi and emboli throughout the microvasculature.

3. Consumption phase The early thrombotic phase is followed by a phase of consumption of coagulation factors and platelets.

4. Secondary fibrinolysis As a protective mechanism, fibrinolytic system is secondarily activated at the site of intravascular coagulation. Secondary fibrinolysis causes breakdown of fibrin resulting in formation of FDPs in the circulation.

Pathophysiology of DIC is summed up schematically in **Fig. 11.8**.

Clinical Features

There are 2 main features of DIC—*bleeding* as the most common manifestation, and *organ damage* due to ischaemia caused by the effect of widespread intravascular thrombosis such as in

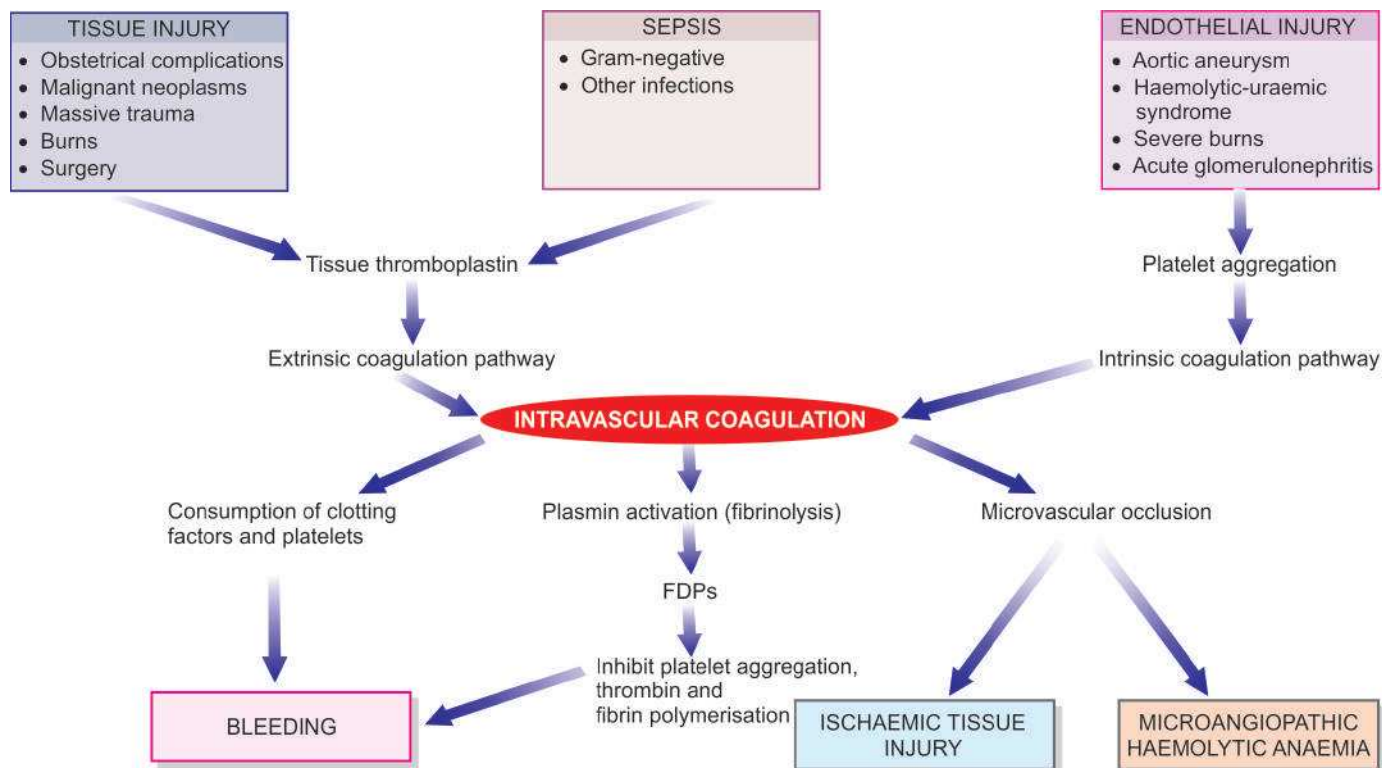

Figure 11.8 Pathophysiology of disseminated intravascular coagulation.

Table 11.3 Major laboratory findings in common haemostatic disorders.

| DISORDER | PLATELET COUNT | BT | PT | APTT | TT | FDPS | F-VIII | F-IX |
|-----------------------------------|----------------|----|----|------|----|---------|--------|------|
| I. VASCULAR DISORDERS | | | | | | | | |

| IV. DIC | ↓ | ↑ | ↑ | ↑ | ↑ | Present | ↓ | ↓ |

the kidney and brain. Less common manifestations include: microangiopathic haemolytic anaemia and thrombosis in larger arteries and veins.

Laboratory Findings

The laboratory investigations include the following:

1. The platelet count is low.
2. Blood film shows the features of microangiopathic haemolytic anaemia. There is presence of schistocytes and fragmented red cells due to damage caused by trapping and passage through the fibrin thrombi.
3. Prothrombin time, thrombin time and activated partial thromboplastin time, are all prolonged.
4. Plasma fibrinogen levels are reduced due to consumption in microvascular coagulation.
5. Fibrin degradation products (FDPs) are raised due to secondary fibrinolysis.

A summary of important laboratory findings in common causes of haemostatic abnormalities is summed up in **Table 11.3**.

GIST BOX 11.6

Other Bleeding and Coagulation Disorders

- ☐ Uncontrolled and excessive fibrinolysis may sometimes be the cause of bleeding.
- ☐ Hypercoagulability or thrombophilia is increased risk of thrombosis due to abnormality in haemostatic equilibrium i.e. reverse of abnormal bleeding. It may be from inherited or acquired disorders.
- ☐ Disseminated intravascular coagulation (DIC) is a complex of intravascular coagulation and haemorrhage. It may occur from various causes e.g. massive bleeding, fulminant infections etc.
- ☐ DIC passes through phases of activation of coagulation, thrombotic phase, consumptive phase and secondary fibrinolysis.
- ☐ Major findings in DIC are thrombocytopenia, prolonged prothrombin time, reduced fibrinogen, and presence of FDPs.

BLOOD GROUPS AND BLOOD TRANSFUSION

BLOOD GROUP ANTIGENS AND ANTIBODIES

Karl Landsteiner described the existence of major human blood groups in 1900 and was awarded Nobel Prize in 1930. The term *blood group* is applied to any well-defined system of red blood cell antigens which are inherited characteristics. Over 20 blood group systems having approximately 400 blood group antigens are currently recognised. The ABO and Rhesus (Rh) blood group systems are of major clinical significance. Other minor and clinically less important blood group systems are: Lewis system, P system, I system, MNS system, Kell and Duffy system, and Lutheran system.

Individuals who lack the corresponding antigen and have not been previously transfused have *naturally-occurring antibodies* in their serum. The most important are anti-A and anti-B antibodies, usually of IgM class. *Immune antibodies*, on the other hand, are acquired in response to transfusion and by transplacental passage during pregnancy. These are warm antibodies, usually of IgG class.

ABO SYSTEM This system consists of 3 major allelic genes: A, B and O, located on the long arm of chromosome 9. These genes control the synthesis of blood group antigens A and B. The serum of an individual contains naturally-occurring antibodies to A and/or B antigen, whichever antigen is lacking in the person's red cells (**Table 11.4**). Two subgroups of A—A₁ and A₂, and thus of AB also, A₁B and A₂B, are recognised but are

Table 11.4 The ABO blood groups.

| BLOOD GROUP | ANTIGENS ON RED CELLS | NATURALLY-OCCURRING SERUM ANTIBODIES |
|-------------|-----------------------|--------------------------------------|
| AB | AB | None |
| A | A | Anti-B |
| B | B | Anti-A |
| O | O | Anti-A, Anti-B |

of minor clinical significance. In routine practice, the ABO type is determined by testing the red blood cells with anti-A and anti-B and by testing the serum against A, B and O red blood cells.

Red blood cells of type O and A₂ have large amounts of another antigen called *H substance* which is genetically different from ABO but is a precursor of A and B antigens. An O group individual who inherits A or B genes but fails to inherit H gene from either parent is called O_h *phenotype or Bombay blood group*. In such rare individual, despite the presence of all the three antibodies in serum (anti-A, anti-B and anti-H), the red cells are not agglutinated by the antisera.

RHESUS SYSTEM The Rhesus (Rh) blood group system was first discovered on human red cells by the use of antisera prepared by immunising rabbits with red cells from a Rhesus monkey. The Rh allelic genes are *C or c*, *D or d* and *E or e*, located on chromosome 1. One set of 3 genes is inherited from each parent giving rise to various complex combinations. The corresponding antigens are similarly named *Cc*, *Ee* and only *D* since no *d* antigen exists.

However, out of all these, *D* antigen is most strongly immunogenic and, therefore, clinically most important. In practice, Rh grouping is performed with anti-D antiserum. Individuals who are D-positive are referred to as *Rh-positive* and those who lack D antigen are termed *Rh-negative*.

Practically, there are no naturally-occurring Rh antibodies. All Rh antibodies in Rh-negative individuals are acquired from immunisation such as by transfusion and during pregnancy, resulting in fatal haemolytic transfusion reaction and haemolytic disease of the newborn (described later).

BLOOD TRANSFUSION

Blood transfusion goes through following sequential steps:

1. *Healthy blood donor selection* with haemoglobin more than 12.5 g/dl and free of infectious diseases.
2. *Blood collection by phlebotomy* in a sterile plastic blood bag containing anticoagulant, commonly acid citrate, mixing blood and coagulant gently while blood is flowing in to the bag.
3. *Storage of blood bag* in refrigerator at 2° to 6° C.
4. *Donor testing* for ABO-Rh grouping, and for infectious organism (HBV, HBsAg, HCV, syphilis and malaria).
5. *Blood grouping* (ABO-Rh) of the recipient.
6. *Pre-transfusion compatibility testing* of donor and recipient as under:
 - i) *Antibody screening* of the patient's serum to detect the presence of clinically significant antibodies.
 - ii) *Cross-matching* the patient's serum against donor red cells to confirm donor-recipient compatibility.
7. *Supervised blood transfusion* to observe reactions if any.

The indications for blood transfusion are acute blood loss and various haematologic disorders considered already. In addition to the whole blood transfusion, the modern blood-banking techniques have made it possible to transfuse blood components such as packed red blood cells, platelets, white blood cell concentrates, plasma components and plasmapheresis in specific situations.

COMPLICATIONS OF BLOOD TRANSFUSION

A carefully prepared and supervised blood transfusion is quite safe. However, in 5-6% of transfusions, untoward complications

occur, some of which are minor while others are more serious and at times fatal.

Transfusion reactions are generally classified into 2 types: immune and non-immune.

A. *Immunologic transfusion reactions* may be against red blood cells (haemolytic reactions), leucocytes, platelets or immunoglobulins.

B. *Non-immune transfusion reactions* include circulatory overload, massive transfusion, or transmission of an infectious agent.

These transfusion reactions are considered below.

A. Immunologic Transfusion Reactions

These are as under:

1. Haemolytic transfusion reactions Haemolytic transfusion reaction may be *immediate* or *delayed*, *intravascular* or *extravascular*.

♦ Very rapid cell destruction associated with *intravascular haemolysis* is usually due to ABO incompatibility since both naturally-occurring antibodies, anti-A and anti-B, are capable of fixing complement. The symptoms include restlessness, anxiety, flushing, chest or lumbar pain, tachypnoea, tachycardia and nausea, followed by shock and renal failure.

♦ *Extravascular haemolysis* is more often due to immune antibodies of the Rh system. The clinical manifestations are relatively less severe and usually consist of malaise and fever but shock and renal failure may rarely occur. Some patients develop delayed reactions in which the patient develops anaemia due to destruction of red cells in the RE system about a week after transfusion. Such delayed reactions are generally the result of previous transfusion or pregnancy (anamnesic reaction).

2. Transfusion-related acute lung injury (TRALI) This is an uncommon reaction resulting from transfusion of donor plasma containing high levels of anti-HLA antibodies which bind to leucocytes of recipient. These leucocytes then aggregate in pulmonary micromutation and release mediators of increased vascular permeability resulting in acute pulmonary oedema and signs and symptoms of respiratory failure.

3. Other allergic reactions Besides haemolytic transfusion reaction, other reactions are as follows:

- i) *Febrile reaction* which is usually attributed to immunologic reaction against white blood cells, platelets, or IgA class immunoglobulins.
- ii) Patients with antibodies against IgA molecule sometimes develop *anaphylactic shock* on transfusion of blood from other human subjects.
- iii) *Allergic reactions* such as urticaria may occur.
- iv) Transfusion-related *graft-versus-host disease* mediated by donor T lymphocytes may occur.

B. Nonimmune Transfusion Reactions

This category includes the following adverse effects:

1. Circulatory overload Circulatory overload resulting in pulmonary congestion and acute heart failure is the most important and most common complication that may result in death following transfusion. The risk of circulatory overload is particularly high in patients with chronic anaemia, and in infants and the elderly. The onset may be immediate, or may be delayed up to 24 hours.

2. Massive transfusion When the volume of stored blood transfused to bleeding patients exceeds their normal blood volume, it results in dilutional thrombocytopenia and dilution of coagulation factors.

3. Transmission of infection Many diseases can be transmitted by transfusion of an infected blood. These include: hepatitis (HBV, HCV), CMV infection, syphilis, malaria, toxoplasmosis, infectious mononucleosis, brucellosis and AIDS (HIV infection). The incidence increases in patients who receive multiple transfusions such as cases of haemophilia, thalassaemia major, acute leukaemias, acute severe haemorrhage etc. It has, therefore, been mandatory that prior to any human transfusion, every unit of blood must be screened for the serologic testing of HIV, HBV, HCV and syphilis and for the presence of malarial parasite.

4. Air embolism Air embolism is unlikely to occur if the blood transfusion is carried out with plastic bags with negative pressure as is the usual practice nowadays. A debilitated person may develop symptomatic air embolism even if a small volume (10-40 ml) makes its way into the circulation, whereas a healthy individual is at lesser risk.

5. Thrombophlebitis The complication of thrombophlebitis is more commonly associated with venesection for blood transfusion, especially if it is done in the saphenous vein of the ankle rather than the veins of the arm. The risk of developing thrombophlebitis is further enhanced if the transfusion is continued longer than 12 hours at a single site.

6. Transfusion haemosiderosis Post-transfusion iron overload with deposition of iron in the tissues of the body occurs after repeated transfusions in the absence of any blood loss e.g. in thalassaemia major and in severe chronic refractory anaemias. The body has no other means of getting rid of extra iron except iron excretion at the rate of 1 mg per day. A unit of whole blood (400 ml) contains about 250 mg of iron. After approximately 100 units, the liver, myocardium and endocrine glands are all damaged.

BLOOD COMPONENTS

Blood from donors is collected as whole blood in a suitable anticoagulant. Nowadays it is a common practice to divide whole blood into components which include: packed RBCs, platelets, fresh-frozen plasma (FFP) and cryoprecipitate.

The procedure consists of initial centrifugation at low speed to separate whole blood into two parts: *packed RBCs* and *platelet-rich plasma (PRP)*. Subsequently, PRP is centrifuged at high speed to yield two parts: *random donor platelets* and *FFP*. *Cryoprecipitates* are obtained by thawing of FFP followed by centrifugation. *Apheresis* is the technique of direct collection of large excess of platelets from a single donor.

Applications of these blood components in clinical use are as under:

1. Packed RBCs These are used to raise the oxygen-carrying capacity of blood and are used in normovolaemic patients of anaemia without cardiac disease. One unit of packed RBCs may raise haemoglobin by 1 g/dl.

2. Platelets Transfusion of platelets is done in patients of thrombocytopenia who have haemorrhage. Optimally, platelet transfusions can be given to a patient with platelet count below 10,000/ μ l. Each unit of platelets can raise platelet count by 5,000 to 10,000/ μ l.

3. Fresh frozen plasma FFP contains plasma proteins and coagulation factors that include albumin, protein C and S and antithrombin. FFP transfusion is indicated in patients of coagulation failure and TTP. Each unit of FFP raises coagulation factors by about 2%.

4. Cryoprecipitate Cryoprecipitate is a source of insoluble plasma proteins, fibrinogen, factor VIII and vWF. Indications for transfusion of cryoprecipitate are for patients requiring fibrinogen, factor VIII and vWF. Transfusion of single unit of cryoprecipitate yields about 80 IU of factor VIII.

GIST BOX 11.7

Blood Groups and Blood Transfusion

- ☐ ABO system consists of A, B and O allelic genes, which control the synthesis of blood group antigens A and B. The serum of an individual contains naturally-occurring antibodies to A and/or B antigen.
- ☐ D antigen is strongly immunogenic and an individuals may be D-positive (i.e. Rh-positive) or D-negative (i.e. Rh-negative) but there are no naturally-occurring Rh antibodies.
- ☐ Complications of blood transfusion may be immunologic reactions (e.g. haemolytic reactions, acute lung injury) or non-immunologic (e.g. circulatory overload, infections, air embolism, thrombophlebitis etc).
- ☐ Nowadays it is a common practice to divide whole unit of blood into components for optimum utilisation such as packed RBCs, platelets, fresh-frozen plasma (FFP) and cryoprecipitate.

HAEMOLYTIC DISEASE OF NEWBORN

Haemolytic disease of the newborn (HDN) results from the passage of IgG antibodies from the maternal circulation across the placenta into the circulation of the foetal red cells. Besides pregnancy, sensitisation of the mother may result from previous abortions and previous blood transfusion.

HDN can occur from incompatibility of ABO or Rh blood group system. ABO incompatibility is much more common but the HDN in such cases is usually mild, while Rh-D incompatibility results in more severe form of the HDN.

PATHOGENESIS

The pathogenesis of the two main forms of HDN is different.

HDN due to Rh-D incompatibility Rh incompatibility occurs when a Rh-negative mother is sensitised to Rh-positive blood. This results most often from a Rh-positive foetus by passage of Rh-positive red cells across the placenta into the circulation of Rh-negative mother. Normally, during pregnancy very few foetal red cells cross the placenta but haemorrhage during parturition causes significant sensitisation of the mother. Sensitisation is more likely if the mother and foetus are ABO compatible rather than ABO incompatible. Though approximately 95% cases of Rh-HDN are due to anti-D, some cases are due to combination of anti-D with other immune antibodies of the Rh system such as anti-C and anti-E, and rarely anti-C alone.

It must be emphasised here that the risk of sensitisation of a Rh-negative woman married to Rh-positive man is small in first pregnancy but increases during successive pregnancies

if prophylactic anti-D immunoglobulin is not given within 72 hours after the first delivery. If both the parents are Rh-D positive (homozygous), all the newborns will be Rh-D positive, while if the father is Rh-D positive (heterozygous), there is a 50% chance of producing a Rh-D negative child.

HDN due to ABO incompatibility About 20% pregnancies with ABO incompatibility between the mother and the foetus develop the HDN. Naturally-occurring anti-A and anti-B antibodies which are usually of IgM class do not cross the placenta, while immune anti-A and anti-B antibodies which are usually of IgG class may cross the placenta into foetal circulation and damage the foetal red cells. ABO HDN occurs most frequently in infants born to group O mothers who possess anti-A and/or anti-B IgG antibodies. ABO-HDN differs from Rh(D)-HDN, in that it occurs in first pregnancy, Coombs' (antiglobulin) test is generally negative, and is less severe than the latter.

CLINICAL FEATURES

The HDN due to Rh-D incompatibility in its *severest form* may result in intrauterine death from *hydrops foetalis*. *Moderate disease* produces a baby born with severe anaemia and jaundice due to unconjugated hyperbilirubinaemia. When the level of unconjugated bilirubin exceeds 20 mg/dl, it may result in deposition of bile pigment in the basal ganglia of the CNS called *kernicterus* and result in permanent brain damage. *Mild disease*, however, causes only severe anaemia with or without jaundice.

LABORATORY FINDINGS

The haematologic findings in cord blood and mother's blood are as under:

1. *Cord blood* shows variable degree of anaemia, reticulocytosis, elevated serum bilirubin and a positive direct Coombs' test if the cord blood is Rh-D positive.
2. *Mother's blood* is Rh-D negative with high plasma titre of anti-D.

COURSE AND PROGNOSIS

The course in HDN may range from death, to minimal haemolysis, to mental retardation. The practice of administration of anti-Rh immunoglobulin to the mother before or after delivery has reduced the incidence of HDN as well as protects the mother before the baby's RBCs sensitise the mother's blood. Exchange transfusion of the baby is done to remove the antibodies, remove red cells susceptible to haemolysis and also to lower the bilirubin level.

GIST BOX 11.8

Haemolytic Disease of Newborn

- Haemolytic disease of newborn results from the passage of IgG antibodies from the maternal circulation across the placenta into the circulation of the foetal red cells.
- It could be due to incompatibility of Rh or ABO groups.
- Cord blood shows anaemia and is Rh-D positive while mother's blood is Rh-D negative.

CLINICAL CASE 6

A 30 years old female reports to physician with complaints of appearance of petechial haemorrhages on the skin of her legs and arms for the last 2 days. She further gives history of four episodes of epistaxis in the last 6 months. She has also been having heavy periods for the last 6-7 cycles.

On examination, the petechiae are purpuric and blanch on pressing. No jaundice is seen. On abdominal examination, the spleen is just palpable but the liver is not enlarged. There is no lymphadenopathy.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 908 (Appendix II)

12

Disorders of Leucocytes and Lymphoreticular Tissues

As illustrated in Fig. 10.3, haematopoietic stem cells in the bone marrow differentiate into two types of progenitors—*lymphoid* (immune system) stem cells, and *non-lymphoid or myeloid* (trilineage) stem cells. The former develop into T, B and NK cells while the latter differentiate into 3 types of cell lines—granulocyte-monocyte progenitors (producing neutrophils, eosinophils, basophils and monocytes), erythroid progenitors (producing red cells, discussed in Chapter 10), and megakaryocytes (as the source of platelets, discussed in Chapter 11). In this chapter, we will discuss the abnormalities pertaining to leucocyte pool of two cell lines (granulocyte-monocyte cell line and the lymphoid cell lines), besides discussion on all haematopoietic neoplasms.

Leucocyte pool in the body lies at two distinct locations: in circulating blood and in the tissues. This concept holds more true for lymphoid cells in particular, which are present in circulation as well as are distributed in the lymphoid tissues of the body (lymph nodes, spleen, mucosa-associated lymphoid tissue—MALT, pharyngeal lymphoid tissue). B, T and NK lymphoid cells are formed after differentiation from lymphopoietic precursor cells in the bone marrow undergo further maturation in peripheral lymphoid organs and thymus (Chapter 3). Thus, relationship of haematopoietic tissues and lymphoreticular tissues is quite close. In fact, current WHO classification of lymphoma-leukaemia does not consider diseases of lymphocytes in the blood and in the lymphoid tissues as separate disorders; instead these diseases are seen to represent different stages of the same biologic process. Thus, in current times, diseases of leucocytes are studied together with diseases of lymphoreticular tissues of the body.

Accordingly, following topics have been covered in this chapter:

1. Lymph nodes: Normal and reactive
2. White blood cells: Normal and reactive
3. Lymphohaematopoietic malignancies (Leukaemias-lymphomas): General
4. Myeloid neoplasms
5. Lymphoid neoplasms: General
6. Hodgkin's disease
7. Non-Hodgkin's lymphomas-leukaemias
8. Plasma cell disorders
9. Histiocytic neoplasms (Langerhans cell histiocytosis)
10. Spleen
11. Thymus

LYMPH NODES: NORMAL AND REACTIVE

NORMAL STRUCTURE

The lymph nodes are bean-shaped or oval structures varying in length from 1 to 2 cm and form the part of lymphatic network distributed throughout the body. Each lymph node is covered

by a connective tissue *capsule*. At the convex surface of the capsule several *afferent lymphatics* enter which drain into the peripheral *subcapsular sinus*, branch into the lymph node and terminate at the concavity (hilum) as a single *efferent lymphatic* vessel. These lymphatic vessels are lined by mononuclear phagocytic cells.

The inner structure of the lymph node is divided into a peripheral cortex and central medulla. The *cortex* consists of several rounded aggregates of lymphocytes called *lymphoid follicles*. The follicle has a pale-staining germinal centre surrounded by small dark-staining lymphocytes called the mantle zone. The deeper region of the cortex or *paracortex* is the zone between the peripheral cortex and the inner medulla. The *medulla* is predominantly composed of cords of plasma cells and some lymphocytes. The capsule and the structure within the lymph node are connected by supportive delicate reticulin framework (Fig. 12.1,A).

Functionally, the lymph node is divided into T and B lymphocyte zones:

◆ *B-cell zone* lies in the follicles in the cortex, the mantle zone and the interfollicular space, while *plasma cells* are also present in the interfollicular zone.

◆ *T-cell zone* is predominantly present in the medulla.

There are two main functions of the lymph node—to mount immune response in the body, and to perform the function of active phagocytosis for particulate material. Besides T- and B-cells, the follicular centre has *dendritic histiocytes* and antigen-presenting *Langerhans' histiocytes* (formerly together called tingible body macrophages due to engulfment of particulate material by them) and *endothelial cells*. The follicular centre is a very active zone where lymphocytes from peripheral blood continuously enter and leave, interact with macrophage-histiocytes and endothelial cells and undergo maturation and transformation. Lymphocytes and endothelial cells have surface molecules which interact and serve as 'addresses' so that endothelial cells can direct the lymphocytes; these molecules are appropriately termed as *addressins* or *homing receptors*. Peripheral blood B and T lymphocytes on entering the lymph node are stimulated immunologically which transforms them to undergo cytoplasmic and nuclear maturation which may be in the follicular centre or paracortex as per following sequence and schematically depicted in Fig. 12.1,B:

- i) Follicular centre, small non-cleaved cells or centroblasts
- ii) Follicular centre, small cleaved cells or centrocytes
- iii) Follicular centre, large cleaved cells
- iv) Follicular centre, large non-cleaved cells
- v) Immunoblasts (in paracortex)
- vi) Convolved cells or lymphoblasts (in paracortex)
- vii) Plasma cells.

Lymph nodes are secondarily involved in a variety of systemic diseases, local injuries and infections, and are also

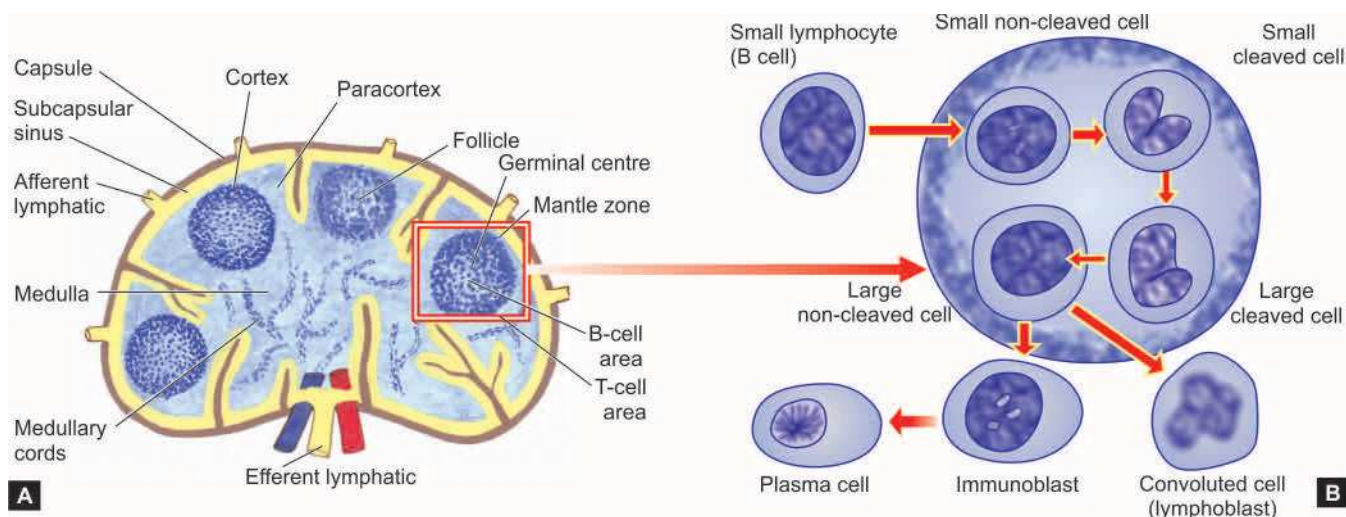

Figure 12.1 Normal lymph node. A, The anatomic structure and functional zones of a lymph node. B, Maturation of lymphoid cells in the follicle.

the site for some important primary neoplasms. Many of these diseases such as tuberculosis, sarcoidosis, histoplasmosis, typhoid fever, viral infections etc. have been considered elsewhere in the textbook along with description of these primary diseases. Reactive lymphadenitis is discussed below while the subject of lymphoid neoplasms including plasma cell disorders and Langerhans' cell histiocytosis is discussed under haematologic neoplasms.

REACTIVE LYMPHADENITIS

Lymph nodes undergo reactive changes in response to a wide variety of stimuli which include microbial infections, drugs, environmental pollutants, tissue injury, immune-complexes and malignant neoplasms. However, the most common causes of lymph node enlargement are inflammatory and immune reactions, aside from primary malignant neoplasms and metastatic tumour deposits. Those due to primary inflammatory reaction are termed *reactive lymphadenitis*, and those due to primary immune reactions are referred to as *lymphadenopathy*.

Reactive lymphadenitis is a nonspecific response and is categorised into acute and chronic types, each with a few variant forms.

ACUTE NONSPECIFIC LYMPHADENITIS

All kinds of acute inflammations may cause acute nonspecific lymphadenitis in the nodes draining the area of inflamed tissue. Most common causes are microbiologic infections or their breakdown products, and foreign bodies in the wound or into the circulation etc. Most frequently involved lymph nodes are: *cervical* (due to infections in the oral cavity), *axillary* (due to infection in the arm), *inguinal* (due to infection in the lower extremities), and *mesenteric* (due to acute appendicitis, acute enteritis etc).

Acute lymphadenitis is usually mild and transient but occasionally it may be more severe. Acutely inflamed nodes are enlarged, tender, and if extensively involved, may be fluctuant. The overlying skin is red and hot. After control of infection, majority of cases heal completely without leaving any scar. If the inflammation does not subside, acute lymphadenitis changes into chronic lymphadenitis.

MORPHOLOGIC FEATURES *Grossly*, the affected lymph nodes are enlarged 2-3 times their normal size and may show abscess formation if the involvement is extensive.

Microscopically, the sinusoids are congested, widely dilated and oedematous and contain numerous neutrophils. The lymphoid follicles are prominent with presence of many mitoses and phagocytosis. In more severe cases, necrosis may occur and neutrophil abscesses may form.

CHRONIC NONSPECIFIC LYMPHADENITIS

Chronic nonspecific lymphadenitis, commonly called *reactive lymphoid hyperplasia*, is a common form of inflammatory reaction of draining lymph nodes as a response to antigenic stimuli such as repeated attacks of acute lymphadenitis and lymph from malignant tumours.

Depending upon the pattern in chronic nonspecific lymphadenitis, three types are distinguished, each having its own set of causes. These are: *follicular hyperplasia*, *paracortical hyperplasia* and *sinus histiocytosis*. However, mixed patterns may also be seen in which case one of the patterns predominates over the others.

MORPHOLOGIC FEATURES *Grossly*, the affected lymph nodes are usually enlarged, firm and non-tender.

Microscopically, the features of 3 patterns of reactive lymphoid hyperplasia are as under:

1. Follicular hyperplasia This is the most frequent pattern, particularly encountered in children. Besides nonspecific stimulation, a few specific causes are: rheumatoid arthritis, toxoplasmosis, syphilis and AIDS. The microscopic features are as follows (**Fig. 12.2**):

- i) There is marked enlargement and prominence of the germinal centres of lymphoid follicles (proliferation of B-cell areas) due to the presence of numerous mitotically active lymphocytes and proliferation of phagocytic cells containing phagocytosed material.
- ii) Parafollicular and medullary regions are more cellular and contain plasma cells, histiocytes, and some neutrophils and eosinophils.

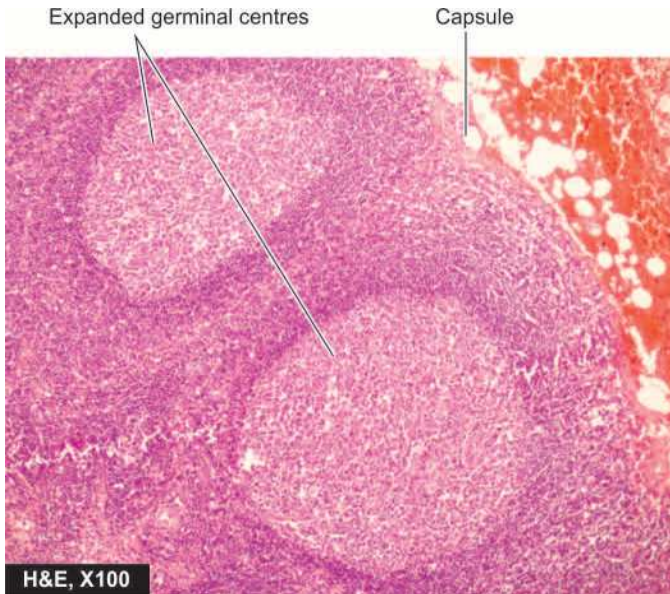

Figure 12.2 Reactive lymphadenitis, follicular hyperplasia type.

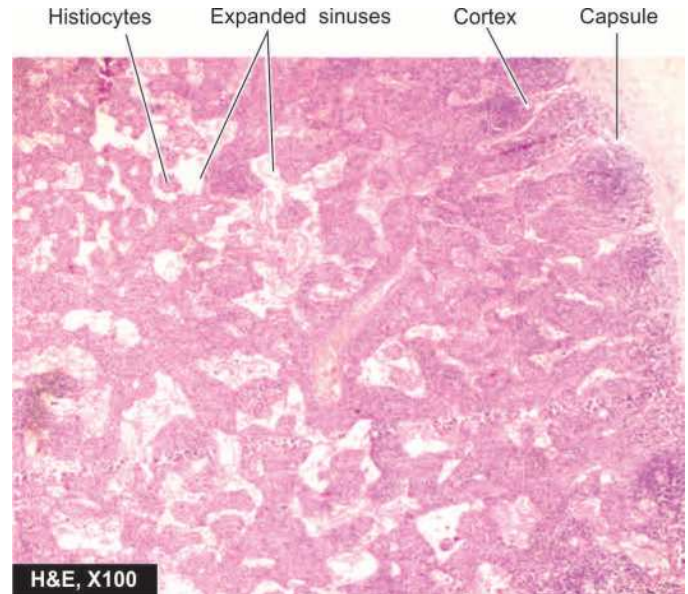

Figure 12.3 Reactive lymphadenitis, sinus histiocytosis type.

iii) There is hyperplasia of mononuclear phagocytic cells lining the lymphatic sinuses in the lymph node.

◆ *Angiofollicular lymphoid hyperplasia* or *Castleman's disease* is a clinicopathologic variant of follicular hyperplasia. The condition may occur at any age and possibly has an association with Epstein-Barr virus infection. Two histologic forms are distinguished:

i) *Hyaline-vascular type* is more common (90% cases) and is characterised by the presence of hyalinised arterioles in small lymphoid follicles and proliferation of vessels in the interfollicular area.

ii) *Plasma cell form* is less common and is characterised by plasma cell hyperplasia and vascular proliferation in the interfollicular region.

2. Paracortical lymphoid hyperplasia This is due to hyperplasia of T-cell-dependent area of the lymph node. Amongst the important causes are immunologic reactions due to drugs (e.g. dilantin), vaccination, viruses (e.g. infectious mononucleosis) and autoimmune disorders. Its histologic features are:

i) Expansion of the paracortex (T-cell area) with increased number of T-cell transformed immunoblasts.

ii) Encroachment by the enlarged paracortex on the lymphoid follicles, sometimes resulting in their effacement.

iii) Hyperplasia of the mononuclear phagocytic cells in the lymphatic sinuses.

Variants of paracortical lymphoid hyperplasia are angio-immunoblastic lymphadenopathy, dermatopathic lymphadenopathy, dilantin lymphadenopathy and post-vaccinal lymphadenopathy.

◆ *Angioimmunoblastic lymphadenopathy* is characterised by diffuse hyperplasia of immunoblasts rather than paracortical hyperplasia only, and there is proliferation of blood vessels. The condition occurs in elderly patients with generalised lymph node enlargement and hypergammaglobulinaemia.

◆ *Dermatopathic lymphadenopathy* occurs in lymph node draining an area of skin lesion. Besides the hyperplastic paracortex, there is presence of dark melanin pigment within the macrophages in the lymph node.

3. Sinus histiocytosis or sinus hyperplasia This is a very common type found in regional lymph nodes draining inflammatory lesions, or as an immune reaction of the host to a draining malignant tumour or its products. The hallmark of histologic diagnosis is the expansion of the sinuses by proliferating large histiocytes containing phagocytosed material (**Fig. 12.3**). The presence of sinus histiocytosis in the draining lymph nodes of carcinoma such as in breast carcinoma has been considered by some workers to confer better prognosis in such patients due to good host immune response.

◆ *Sinus histiocytosis with massive lymphadenopathy* is characterised by marked enlargement of lymph nodes, especially of the neck, in young adolescents. It is associated with characteristic clinical features of painless but massive lymphadenopathy with fever and leucocytosis and usually runs a benign and self-limiting course.

HIV-RELATED LYMPHADENOPATHY

HIV infection and AIDS have already been discussed in Chapter 3; here one of the frequent finding in early cases of AIDS, **persistent generalised lymphadenopathy (PGL)**, is described. The presence of enlarged lymph nodes of more than 1 cm diameter at two or more extra-inguinal sites for more than 3 months without any other obvious cause is frequently the earliest symptom of primary HIV infection.

Histologically, the findings at biopsy of involved lymph node vary depending upon the stage of HIV infection:

1. *In the early stage* marked follicular hyperplasia is the dominant finding and reflects the polyclonal B-cell proliferation.

2. *In the intermediate stage*, there is a combination of follicular hyperplasia and follicular involution. However, adenopathic form of Kaposi's sarcoma too may develop at this stage (page 395).

3. *In the last stage*, there is decrease in the lymph node size indicative of prognostic marker of disease progression. Microscopic findings of node at this stage reveal follicular involution and lymphocyte depletion. At this stage, other stigmata of AIDS in the lymph node may also appear e.g. lymphoma, mycobacterial infection, toxoplasmosis, systemic fungal infections etc.

GIST BOX 12.1 Lymph Nodes—Normal and Reactive

- ▣ A normal lymph node has T-cell zone in the medulla and B-cell zone in the follicles of cortex.
- ▣ Reactive lymphadenitis is enlargement of lymph node in response to stimuli e.g. microbes, drugs, pollutants, immune complexes etc.
- ▣ Reactive lymphadenitis may be acute or chronic.
- ▣ Chronic reactive lymphadenitis is more common and may be follicular hyperplasia or sinus histiocytosis type.

WHITE BLOOD CELLS: NORMAL AND REACTIVE

The leucocytes of the peripheral blood are of 2 main varieties, distinguished by the presence or absence of granules: *granulocytes* and *nongranular leucocytes*. The granulocytes, according to the appearance of nuclei, are subdivided into polymorphonuclear leucocytes and monocytes. Further, depending upon the colour and content of granules, polymorphonuclear leucocytes are of 3 types: neutrophils, eosinophils and basophils. The nongranular leucocytes are 3 types of lymphocytes: T, B and natural killer (NK) cells.

GRANULOPOIESIS

SITE OF FORMATION AND KINETICS

All forms of granulocytes are produced in the bone marrow and are termed, '*myeloid series*'. Myeloid series include maturing stages: myeloblast (most primitive precursor), promyelocyte, myelocyte, metamyelocyte, band forms and segmented granulocyte (mature form). It takes about 12 days for formation of mature granulocytes from the myeloblast. These maturing cells are further divided into:

- ◆ '*proliferative or mitotic pool*' comprised by myeloblast, promyelocyte and myelocyte; and
- ◆ '*mature or post-mitotic pool*' composed of metamyelocyte, band forms and segmented granulocytes).

Normally the bone marrow contains more myeloid cells than the erythroid cells in the ratio of 2:1 to 15:1 (average 3:1), the largest proportion being that of metamyelocytes, band forms and segmented neutrophils. The bone marrow storage compartment contains about 10-15 times the number of granulocytes found in the peripheral blood. Following their release from the bone marrow, granulocytes spend about 10 hours in the circulation before they move into the tissues, where they perform their respective functions. The blood pool of granulocytes consists of 2 components of about equal size—

the *circulating pool* that is included in the blood count, and the *marginating pool* that is not included in the blood count. Granulocytes spend about 4-5 days in the tissues before they are either destroyed during phagocytosis or die due to senescence. To control the various compartments of granulocytes, a 'feed-back system' exists between the circulating and tissue granulocytes on one side, and the marrow granulocytes on the other. The presence of a humoral regulatory substance, 'granulopoietin' analogous to erythropoietin has also been identified by *in vitro* studies of colony-forming units (CFU) and is characterised as G-CSF (granulocyte colony-stimulating factor) and GM-CSF (granulocyte-monocyte colony-stimulating factor).

The kinetics of monocytes is less well understood than that of other myeloid cells. Monocytes spend about 20-40 hours in the circulation after which they leave the blood to enter extravascular tissues where they perform their main function of active phagocytosis. The extravascular lifespan of tissue macrophages which are the transformed form of blood monocytes, may vary from a few months to a few years.

MYELOID SERIES

The development of myeloid cells from myeloblast takes place in the following sequence (**Fig. 12.4**):

1. MYELOBLAST The myeloblast is the earliest recognisable precursor of the granulocytes, normally comprising about 2% of the total marrow cells. The myeloblast varies considerably in size (10-18 μm in diameter), having a large round to oval nucleus nearly filling the cell, has fine nuclear chromatin and contains 2-5 well-defined pale nucleoli. The thin rim of cytoplasm is deeply basophilic and devoid of granules. The myeloblasts of acute myeloid leukaemia may, however, show the presence of rod-like cytoplasmic inclusions called *Auer's rods* which represent abnormal derivatives of primary azurophilic granules.

The nuclei of successive stages during their development from myeloblast become progressively coarser and lose their nucleoli and the cytoplasm loses its blue colour. As the cells become mature lysosomal granules appear; firstly non-specific primary or azurophilic granules appear which are followed by specific or secondary granules that differentiate the neutrophils, eosinophils and basophils.

2. PROMYELOCYTE The promyelocyte is slightly larger than the myeloblast (12-18 μm diameter). It possesses a round to oval nucleus, having fine nuclear chromatin which is slightly condensed around the nuclear membrane. The nucleoli are present but are less prominent and fewer than those in the myeloblast. The main distinction of promyelocyte from myeloblast is in the cytoplasm which contains azurophilic (primary or non-specific) granules.

3. MYELOCYTE The myelocyte is the stage in which specific or secondary granules appear in the cytoplasm, and accordingly, the cell can be identified at this stage as belonging to the neutrophilic, eosinophilic or basophilic myelocyte. Primary granules also persist at this stage but formation of new primary granules stops. The nucleus of myelocyte is eccentric, round to oval, having somewhat coarse nuclear chromatin and no visible nucleoli. The myeloid cells up to the myelocyte stage continue to divide and, therefore, are included in *mitotic or proliferative pool*.

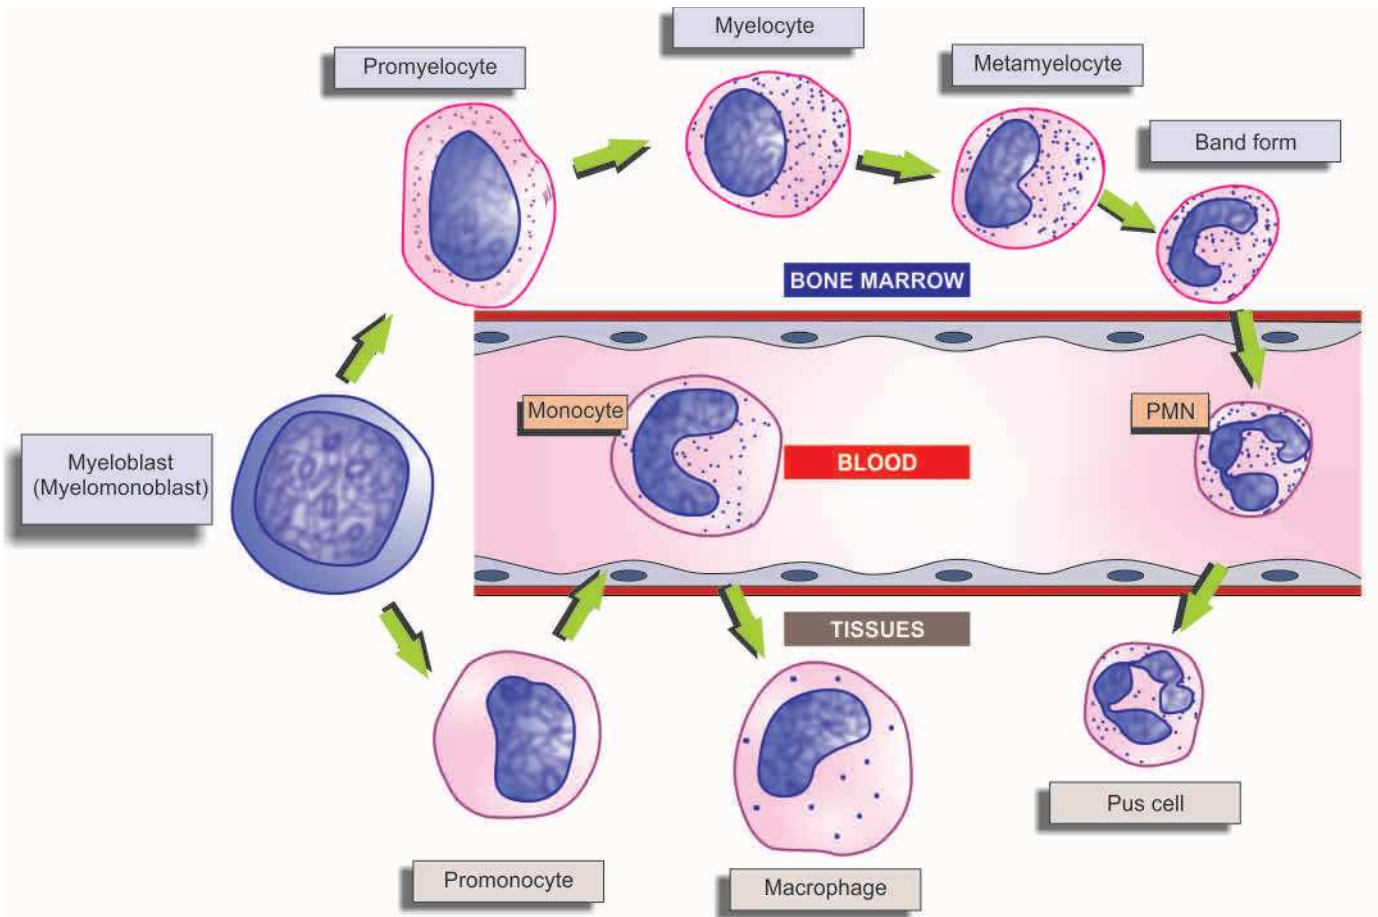

Figure 12.4 Granulopoiesis and the cellular compartments of myeloid cells in the bone marrow, blood and tissues.

4. METAMYELOCYTE The metamyelocyte stage is 10–18 μm in diameter and is characterised by a clearly indented or horseshoe-shaped nucleus without nucleoli. The nuclear chromatin is dense and clumped. The cytoplasm contains both primary and secondary granules. The metamyelocytes are best distinguished from the monocytes by the clumped nuclear chromatin while the latter have fine chromatin.

5. BAND FORMS Band form is juvenile granulocyte, 10–16 μm in diameter, characterised by further condensation of nuclear chromatin and transformation of nuclear shape into band configuration of uniform thickness.

6. SEGMENTED GRANULOCYTES The mature polymorphonuclear leucocytes, namely: the neutrophils, eosinophils and basophils, are described separately below.

Common surface markers for all stages of myeloid series of cells are CD33, CD13 and CD15. However, stages from myelocytes to mature neutrophils also carry CD11b and CD14. Band forms and mature neutrophils have further CD 10 and CD16.

MONOCYTE-MACROPHAGE SERIES

The monocyte-macrophage series of cells, though comprise a part of myeloid series along with other granulocytic series, but are described separately here in view of different morphologic stages in their maturation (**Fig. 12.4**).

1. MONOBLAST The monoblast is the least mature of the recognisable cell of monocyte-macrophage series. It is very similar in appearance to myeloblast except that it has ground-glass cytoplasm with irregular border and may show phagocytosis as indicated by the presence of engulfed red cells in the cytoplasm. However, differentiation from myeloblast at times may be difficult even by electron microscopy and, therefore, it is preferable to call the earliest precursor of granulocytic series as *myelomonoblast*.

2. PROMONOCYTE The promonocyte is a young monocyte, about 20 μm in diameter and possesses a large indented nucleus containing a nucleolus. The cytoplasm is basophilic and contains no azurophilic granules but may have fine granules which are larger than those in the mature monocyte.

3. MONOCYTE The mature form of monocytic series is described below, while the transformed stages of these cells in various tissues (i.e. macrophages) are a part of RE system discussed in Chapter 3.

Monocyte-macrophage series having specialised function of phagocytosis secrete active products such as lysozyme, neutral proteases, acid hydrolases, components of complement, transferrin, fibronectin, nucleosides and several cytokines (TNF- α , IL-1, IL-8, IL-12, IL-18). They express lineage-specific molecules CD 14, cell surface LPS receptors etc.

SITES OF FORMATION AND KINETICS

The lymphocytes and the plasma cells are immunocompetent cells of the body. In humans, the bone marrow and the thymus are the *primary lymphopoietic organs* where lymphoid stem cells undergo spontaneous division independent of antigenic stimulation. The *secondary or reactive lymphoid tissue* is comprised by the lymph nodes, spleen and gut-associated lymphoid tissue (GALT). These sites actively produce lymphocytes from the germinal centres of lymphoid follicles as a response to antigenic stimulation. Lymphocytes pass through a series of developmental changes in the course of their evolution into lymphocyte subpopulations and subsets. It includes migration of immature lymphocytes to other organs such as the thymus where locally-produced factors act on them.

Functionally, the lymphocytes are divided into T, B and natural killer (NK) cells depending upon whether they are immunologically active in cell-mediated immunity (T cells), in humoral antibody response (B cells) or form part of the natural or innate immunity and act as killer of some viruses (NK cells). In human beings, the B cells are derived from the bone marrow stem cells, while in birds they mature in the bursa of Fabricius. After antigenic activation, B cells proliferate and mature into plasma cells which secrete specific immunoglobulin antibodies. The T cells are also produced in the bone marrow and possibly in the thymus. NK cells do not have B or T cell markers, nor are these cells dependent upon thymus for development. The concept of T, B and NK cells along with lymphocyte subpopulations and their functions is discussed in Chapter 3.

LYMPHOID SERIES

The maturation stages in production of lymphocytes are illustrated in [Fig. 12.5](#) and are as under:

1. LYMPHOBLAST The lymphoblast is the earliest identifiable precursor of lymphoid cells and is a rapidly dividing cell. It is a large cell, 10-18 μm in diameter, containing a large round to oval nucleus having slightly clumped or stippled nuclear chromatin. The nuclear membrane is denser and the number of nucleoli is fewer (1-2) as compared with those in myeloblast (2-5). The cytoplasm is scanty, basophilic and non-granular.

The distinguishing morphologic features between the myeloblast and lymphoblast are summarised in [Table 12.1](#).

2. PROLYMPHOCYTE This stage is an intermediate stage between the lymphoblast and mature lymphocyte. These young lymphocytes are 9-18 μm in diameter, contain round

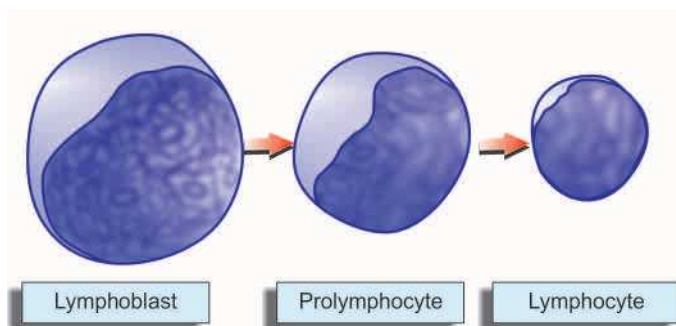

Figure 12.5 The formation of lymphoid series of cells.

Table 12.1 Morphologic characteristics of the blast cells in Romanowsky stains.

| FEATURE | MYELOBLAST | LYMPHOBLAST |
|----------------------|--|-------------------------------|
| 1. Size | 10-18 μm | 10-18 μm |
| 2. Nucleus | Round or oval | Round or oval |
| 3. Nuclear chromatin | Fine meshwork | Slightly clumped |
| 4. Nuclear membrane | Very fine | Fairly dense |
| 5. Nucleoli | 2-5 | 1-2 |
| 6. Cytoplasm | Scanty, blue, agranular, Auer rods may be seen | Scanty, clear blue, agranular |

to indented nucleus with slightly stippled or coarse chromatin and may have 0-1 nucleoli.

3. LYMPHOCYTE The mature lymphocytes are described below.

MATURE LEUCOCYTES IN HEALTH AND REACTIVE PROLIFERATION IN DISEASE

Normally, only mature leucocytes namely: polymorphs, lymphocytes, monocytes, eosinophils and basophils, are found in the peripheral blood. The normal range of total and differential leucocyte count (TLC and DLC expressed sequentially as P, L, M, E, B) in health in adults and children is given in [Table 12.2](#). White cell count tends to be higher in infants and children than in adults. It also normally undergoes minor degree of diurnal variation with a slight rise in the afternoon. The total white cell count is normally high in pregnancy and following delivery, usually returning to normal within a week. Pathological variations in white cell values together with brief review of their morphology and functions are considered below ([Fig. 12.6](#)):

POLYMORPHS (NEUTROPHILS)

MORPHOLOGY A polymorphonuclear neutrophil (PMN), commonly called polymorph or neutrophil, is 12-15 μm in diameter. It consists of a characteristic dense nucleus, having 2-5 lobes and pale cytoplasm containing numerous fine violet-pink granules. These lysosomal granules contain several enzymes and are of 2 types:

Table 12.2 Normal white blood cell counts in health.

| | ABSOLUTE COUNT |
|---------------------------------|------------------------------|
| TLC | |
| Adults | 4,000–11,000/ μl |
| Infants (Full term, at birth) | 10,000–25,000/ μl |
| Infants (1 year) | 6,000–16,000/ μl |
| Children (4–7 years) | 5,000–15,000/ μl |
| Children (8–12 years) | 4,500–13,500/ μl |
| DLC IN ADULTS | |
| Polymorphs (neutrophils) 40–75% | 2,000–7,500/ μl |
| Lymphocytes 20–50% | 1,500–4,000/ μl |
| Monocytes 2–10% | 200–800/ μl |
| Eosinophils 1–6% | 40–400/ μl |
| Basophils <1% | 10–100/ μl |

Figure 12.6 Morphology of normal mature leucocytes in peripheral blood.

Primary or azurophilic granules are large and coarse and appear early at the promyelocyte stage. These granules contain hydrolases, elastase, myeloperoxidase, cathepsin-G, cationic proteins, permeability increasing protein, and microbicidal protein called defensins.

Secondary or specific granules are smaller and more numerous. These appear later at myelocyte stage, are MPO-negative and contain lactoferrin, NADPH oxidase, histaminase, vitamin B₁₂ binding protein, and receptors for chemoattractants and for laminin.

The normal **functions** of neutrophils are as under:

1. **Chemotaxis** or cell mobilisation in which the cell is attracted towards bacteria or at the site of inflammation.
2. **Phagocytosis** in which the foreign particulate material of tiny sizes is phagocytosed by actively motile neutrophils; thus PMNs act as microphages compared to function of monocytes as macrophages.
3. **Killing** of the microorganism is mediated by oxygen-dependent and oxygen-independent pathways (page 121).

PATHOLOGIC VARIATIONS Pathologic variations in neutrophils include variations in count, morphology and defective function.

VARIATION IN COUNT An increase in neutrophil count (*neutrophil leucocytosis* or *neutrophilia*) or a decrease in count (*neutropenia*) may occur in various diseases.

Neutrophil leucocytosis An increase in circulating neutrophils above 7,500/ μ l is the commonest type of leucocytosis and occurs most commonly as a response to acute bacterial infections. Some common causes of neutrophilia are as under:

1. **Acute infections, local or generalised**, especially by cocci but also by certain bacilli, fungi, spirochaetes, parasites and some viruses. For example: pneumonia, cholecystitis, salpingitis, meningitis, diphtheria, plague, peritonitis, appendicitis, actinomycosis, poliomyelitis, abscesses, furuncles, carbuncles, tonsillitis, otitis media, osteomyelitis etc.
2. **Other inflammations** e.g. tissue damage resulting from burns, operations, ischaemic necrosis (such as in MI), gout, collagen-vascular diseases, hypersensitivity reactions etc.
3. **Intoxication** e.g. uraemia, diabetic ketosis, eclampsia, poisonings by chemicals and drugs.
4. **Acute haemorrhage**, internal or external.
5. **Acute haemolysis**.
6. **Disseminated malignancies**.
7. **Myeloproliferative disorders** e.g. myeloid leukaemia, polycythaemia vera, myeloid metaplasia.

8. **Miscellaneous** e.g. following corticosteroid therapy, idiopathic neutrophilia.

Neutropenia When the absolute neutrophil count falls below 2,500/ μ l, the patient is said to have neutropenia and is prone to develop recurrent infections. Some common causes of neutropenia (and hence leucopenia) are as follows:

1. **Certain infections** e.g. typhoid, paratyphoid, brucellosis, influenza, measles, viral hepatitis, malaria, kala-azar etc.
2. **Overwhelming bacterial infections** especially in patients with poor resistance e.g. miliary tuberculosis, septicaemia.
3. **Drugs, chemicals and physical agents** which induce aplasia of the bone marrow cause neutropenia, e.g. antimetabolites, nitrogen mustards, benzene, ionising radiation. Occasionally, certain drugs produce neutropenia due to individual sensitivity such as: anti-inflammatory (amidopyrine, phenylbutazone), antibacterial (chloramphenicol, cotrimoxazole), anticonvulsants, antithyroids, hypoglycaemics and anti-histaminics.
4. **Certain haematological and other diseases** e.g. pernicious anaemia, aplastic anaemia, cirrhosis of the liver with splenomegaly, SLE, Gaucher's disease.
5. **Cachexia and debility**.
6. **Anaphylactoid shock**.
7. **Certain rare hereditary, congenital or familial disorders** e.g. cyclic neutropenia, primary splenic neutropenia, idiopathic benign neutropenia.

VARIATIONS IN MORPHOLOGY Some of the common variations in neutrophil morphology are shown in **Fig. 12.7**. These are as under:

1. **Granules** Heavy, dark staining, coarse toxic granules are characteristic of bacterial infections.
2. **Vacuoles** In bacterial infections such as in septicaemia, cytoplasmic vacuolation may develop.
3. **Döhle bodies** These are small, round or oval patches, 2-3 μ m in size, in the cytoplasm. They are mostly seen in bacterial infections.
4. **Nuclear abnormalities** These include the following:
 - i) **Sex chromatin** is a normal finding in 2-3% of neutrophils in female sex. It consists of a drumstick appendage of chromatin, about 1 μ m across, and attached to one of the nuclear lobes by a thin chromatin strand. Their presence in more than 20% of PMNs is indicative of female sex chromosomes.
 - ii) A '**shift-to-left**' is the term used for appearance of neutrophils with decreased number of nuclear lobes in the peripheral blood e.g. presence of band and stab forms and

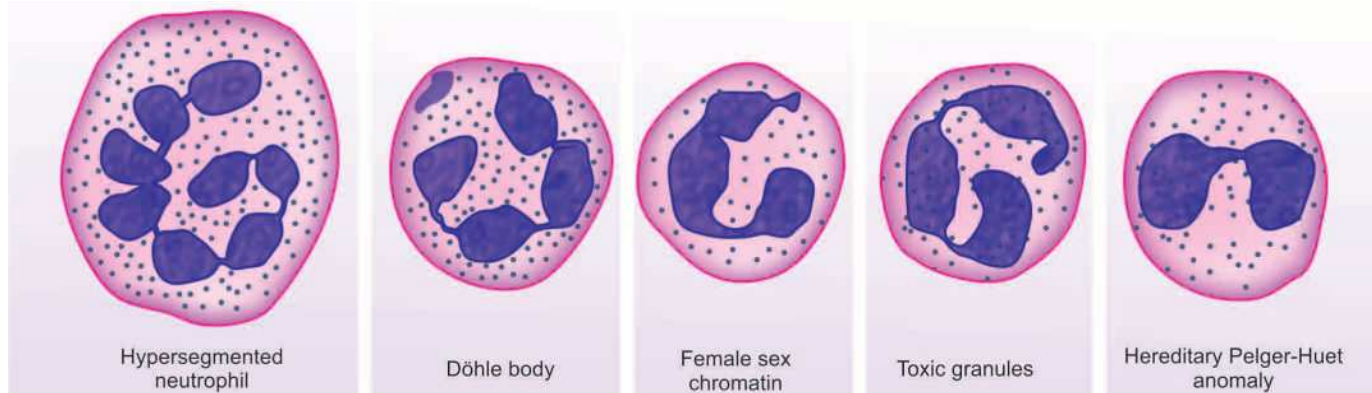

Figure 12.7 Common variations in neutrophil morphology.

a few myelocytes in the peripheral blood. It is seen in severe infections, leucoerythroblastic reaction or leukaemia.

iii) A 'shift-to-right' is appearance of hypersegmented (more than 5 nuclear lobes) neutrophils in the peripheral blood such as in megaloblastic anaemia, uraemia, and sometimes in leukaemia.

iv) *Pelger-Huët anomaly* is an uncommon autosomal dominant inherited disorder in which nuclei in majority of neutrophils are distinctively bilobed (spectacle-shaped) and coarsely staining chromatin. Acquired pseudo-Pelger-Huët abnormality may occur in acute infections or in MDS. However, the physiologic role of multilobed nucleus of neutrophils is unknown and the bilobed anomaly is an innocuous condition.

DEFECTIVE FUNCTIONS The following abnormalities in neutrophil function may sometimes be found:

- 1. Defective chemotaxis** e.g. in a rare congenital abnormality called lazy-leucocyte syndrome; following corticosteroid therapy, aspirin ingestion, alcoholism, and in myeloid leukaemia.
- 2. Defective phagocytosis** due to lack of opsonisation e.g. in hypogammaglobulinaemia, hypocomplementaemia, after splenectomy, in sickle cell disease.
- 3. Defective killing** e.g. in chronic granulomatous disease, Chédiak-Higashi syndrome, myeloid leukaemias.

LYMPHOCYTES

MORPHOLOGY Majority of lymphocytes in the peripheral blood are *small* (9-12 μm in diameter) but *large* lymphocytes (12-16 μm in diameter) are also found. Both small and large lymphocytes have round or slightly indented nucleus with coarsely-clumped chromatin and scanty basophilic cytoplasm. Plasma cells are derived from B lymphocytes under the influence of appropriate stimuli. The nucleus of plasma cell is eccentric and has cart-wheel pattern of clumped nuclear chromatin. The cytoplasm is characteristically deeply basophilic with a pale perinuclear zone. Plasma cells are normally not present in peripheral blood but their pathological proliferation occurs in myelomatosis. Reactive lymphocytes (or Turk cells or plasmacytoid lymphocytes) are seen in certain viral infections and have sufficiently basophilic cytoplasm that they resemble plasma cells.

As discussed in Chapter 3, functionally, there are 3 types of lymphocytes and possess distinct surface markers called clusters of differentiation (CD) which aid in identification of stage of their differentiation:

T lymphocytes i.e. thymus-dependent lymphocytes, which mature in the thymus and are also known as thymocytes. They are mainly involved in direct action on antigens and are therefore involved in *cell-mediated immune (CMI)* reaction by its subsets such as cytotoxic (killer) T cells (CD3+), CD8+ T cells, and *delayed hypersensitivity reaction* by CD4+ T cells.

B lymphocytes i.e. bone marrow-dependent or bursa-equivalent lymphocytes as well as their derivatives, plasma cells, are the source of specific immunoglobulin antibodies. They are, therefore, involved in *humoral immunity (HI)* or *circulating immune reactions*.

NK cells i.e. natural killer cells are those lymphocytes which morphologically have appearance of lymphocytes but do not possess functional features of T or B cells. As the name indicates they are identified with '*natural*' or innate immunity and bring about direct '*killing*' of microorganisms (particularly certain viruses) or lysis of foreign body.

PATHOLOGIC VARIATIONS A rise in the absolute count of lymphocytes exceeding the upper limit of normal (above 4,000/ μm) is termed *lymphocytosis*, while absolute lymphocyte count below 1,500/ μm is referred to as *lymphopenia*.

Lymphocytosis Some of the common causes of lymphocytosis are as under:

- 1. Certain acute infections** e.g. pertussis, infectious mononucleosis, viral hepatitis, infectious lymphocytosis.
- 2. Certain chronic infections** e.g. brucellosis, tuberculosis, secondary syphilis.
- 3. Haematopoietic disorders** e.g. lymphocytic leukaemias, lymphoma, heavy chain disease.
- 4. Relative lymphocytosis** is found in viral exanthemas, convalescence from acute infections, thyrotoxicosis, conditions causing neutropenia.

Lymphopenia Lymphopenia is uncommon and occurs in the following conditions:

- 1. Most acute infections.**
- 2. Severe bone marrow failure.**
- 3. Corticosteroid and immunosuppressive therapy.**
- 4. Widespread irradiation.**

MONOCYTES

MORPHOLOGY The monocyte is the largest mature leucocyte in the peripheral blood measuring 12-20 μm in diameter. It possesses a large, central, oval, notched or indented or horseshoe-shaped nucleus which has characteristically fine reticulated chromatin network. The cytoplasm is abundant, pale blue and contains many fine dust-like granules and vacuoles.

The main **functions** of monocytes are as under:

1. *Phagocytosis* of antigenic material or microorganisms.
2. Immunologic function as *antigen-presenting cells* and present the antigen to lymphocytes to deal with further.
3. As *mediator of inflammation*, they are involved in release of prostaglandins, stimulation of the liver to secrete acute phase reactants.

Tissue macrophages of different types included in RE system are derived from blood monocytes (page 46).

PATHOLOGIC VARIATIONS A rise in the blood monocytes above 800/ μl is termed *monocytosis*. Some common causes of monocytosis are as follows:

1. *Certain bacterial infections* e.g. tuberculosis, subacute bacterial endocarditis, syphilis.
2. *Viral infections*.
3. *Protozoal and rickettsial infections* e.g. malaria, typhus, trypanosomiasis, kala-azar.
4. *Convalescence from acute infection*.
5. *Haematopoietic disorders* e.g. monocytic leukaemia, lymphomas, myeloproliferative disorders, multiple myeloma, lipid storage disease.
6. *Malignancies* e.g. cancer of the ovary, stomach, breast.
7. *Granulomatous diseases* e.g. sarcoidosis, inflammatory bowel disease.
8. *Collagen-vascular diseases*.

EOSINOPHILS

MORPHOLOGY Eosinophils are similar to segmented neutrophils in size (12-15 μm in diameter), and have coarse, deep red staining granules in the cytoplasm and have usually two nuclear lobes. Granules in eosinophils contain basic protein and stain more intensely for peroxidase than granules in the neutrophils. In addition, eosinophils also contain cell adhesion molecules, cytokines (IL-3, IL-5), and a protein that precipitates Charcot-Leyden crystals in lung tissues in asthmatic patients.

Eosinophils are involved in reactions to foreign proteins and to antigen-antibody reactions.

PATHOLOGIC VARIATIONS An increase in the number of eosinophilic leucocytes above 400/ μl is referred to as *eosinophilia* and below 40/ μl is termed as *eosinopenia*.

Eosinophilia. The causes are as under:

1. Allergic disorders e.g. bronchial asthma, urticaria, angio-neurotic oedema, hay fever, drug hypersensitivity.
2. *Parasitic infestations* e.g. trichinosis, echinococcosis, intestinal parasitism.
3. *Skin diseases* e.g. pemphigus, dermatitis herpetiformis, erythema multiforme.

4. *Löffler's syndrome*.
5. *Pulmonary infiltration with eosinophilia* (PIE) syndrome.
6. *Tropical eosinophilia*.
7. *Haematopoietic diseases* e.g. CML, polycythaemia vera, pernicious anaemia, Hodgkin's disease, following splenectomy.
8. *Malignant diseases* with metastases.
9. *Irradiation*.
10. *Miscellaneous disorders* e.g. polyarteritis nodosa, rheumatoid arthritis, sarcoidosis.

Eosinopenia Adrenal steroids and ACTH induce eosinopenia in man.

BASOPHILS

MORPHOLOGY Basophils resemble the other mature granulocytes but are distinguished by coarse, intensely basophilic granules which usually fill the cytoplasm and often overlie and obscure the nucleus.

The granules of circulating basophils (as well as their tissue counterparts as mast cells) contain heparin, histamine and 5-HT. Mast cells or basophils on degranulation are associated with histamine release.

PATHOLOGIC VARIATIONS Basophil leucocytosis or *basophilia* refers to an increase in the number of basophilic leucocytes above 100/ μl . Basophilia is unusual and is found in the following conditions:

1. Chronic myeloid leukaemia
2. Polycythaemia vera
3. Myelosclerosis
4. Myxoedema
5. Ulcerative colitis
6. Following splenectomy
7. Hodgkin's disease
8. Urticaria pigmentosa.

INFECTIOUS MONONUCLEOSIS

Infectious mononucleosis (IM) or glandular fever is a benign, self-limiting lymphoproliferative disease caused by Epstein-Barr virus (EBV), one of the herpesviruses. Infection may occur from childhood to old age but the classical acute infection is more common in teenagers and young adults. The infection is transmitted by person-to-person contact such as by kissing with transfer of virally-contaminated saliva. Groups of cases occur particularly in young people living together in boarding schools, colleges, camps and military institutions. Primary infection in childhood is generally asymptomatic, while 50% of adults develop clinical manifestations. The condition is so common that by the age of 40, most people have been infected and developed antibodies. It may be mentioned here that EBV is oncogenic as well and is strongly implicated in the African (endemic) Burkitt's lymphoma and nasopharyngeal carcinoma as discussed in Chapter 7.

PATHOGENESIS

EBV, the etiologic agent for IM, is a B lymphotropic herpesvirus. The disease is characterised by fever, generalised lymphadenopathy, hepatosplenomegaly, sore throat, and appearance in blood of atypical 'mononucleosis cells.' The pathogenesis of these pathologic features is outlined below:

1. In a susceptible sero-negative host who lacks antibodies, the virus in the contaminated saliva *invades and replicates within epithelial cells* of the salivary gland and then enters B cells in the lymphoid tissues which possess receptors for EBV. The infection spreads throughout the body via bloodstream or by infected B cells.

2. Viraemia and death of infected B cells cause an acute febrile illness and appearance of specific humoral antibodies which peak about 2 weeks after the infection and persist throughout life. The appearance of antibodies marks the *disappearance of virus from the blood*.

3. Though the viral agent has disappeared from the blood, the EBV-infected B cells continue to be present in the circulation as latent infection. *EBV-infected B cells undergo polyclonal activation and proliferation*. These cells perform two important roles which are the characteristic diagnostic features of IM:

i) They secrete *antibodies*—initially IgM but later IgG class antibodies appear. IgM antibody is the heterophile anti-sheep antibody used for diagnosis of IM while IgG antibody persists for life and provides immunity against re-infection.

ii) They *activate CD8+ T lymphocytes*—also called cytotoxic T cells (or CTL) or suppressor T cells. CD8+ T cells bring about killing of B cells and are pathognomonic atypical lymphocytes seen in blood in IM.

4. The proliferation of these cells is responsible for *generalised lymphadenopathy and hepatosplenomegaly*.

5. The *sore throat* in IM may be caused by either necrosis of B cells or due to viral replication within the salivary epithelial cells in early stage.

Besides the involvement of EBV in the pathogenesis of IM, its role in neoplastic transformation in nasopharyngeal carcinoma and Burkitt's lymphoma is discussed in Chapter 7 and diagrammatically depicted in **Fig. 12.8**.

CLINICAL FEATURES

The incubation period of IM is 30-50 days in young adults, while children have shorter incubation period. A prodromal period of 3-5 days is followed by frank clinical features lasting for 1-3 weeks, and subsequently complete recovery occurs after 2 months. The usual clinical features are as under:

1. During prodromal period (first 3-5 days), the symptoms are mild such as malaise, myalgia, headache and fatigue.

2. Frank clinical features (next 7-21 days) seen commonly are fever (90%), sore throat (80%) and bilateral cervical lymphadenopathy (95%). Other features are splenomegaly (50% patients), hepatomegaly (10% cases), transient erythematous maculopapular rash on the trunk and extremities (10%), periorbital oedema (10%) and jaundice (5%).

3. Complications Although most cases of IM run a self-limited course, complications may develop in some cases as under:

- Neurologic manifestations in children.
- Splenic rupture due to splenitis.
- Upper airway obstruction due to hypertrophied adenotonsillitis.
- Autoimmune haemolytic anaemia, cold antibody type.
- Bacterial superinfection.
- Rarely, myocarditis, hepatitis, pneumonia.

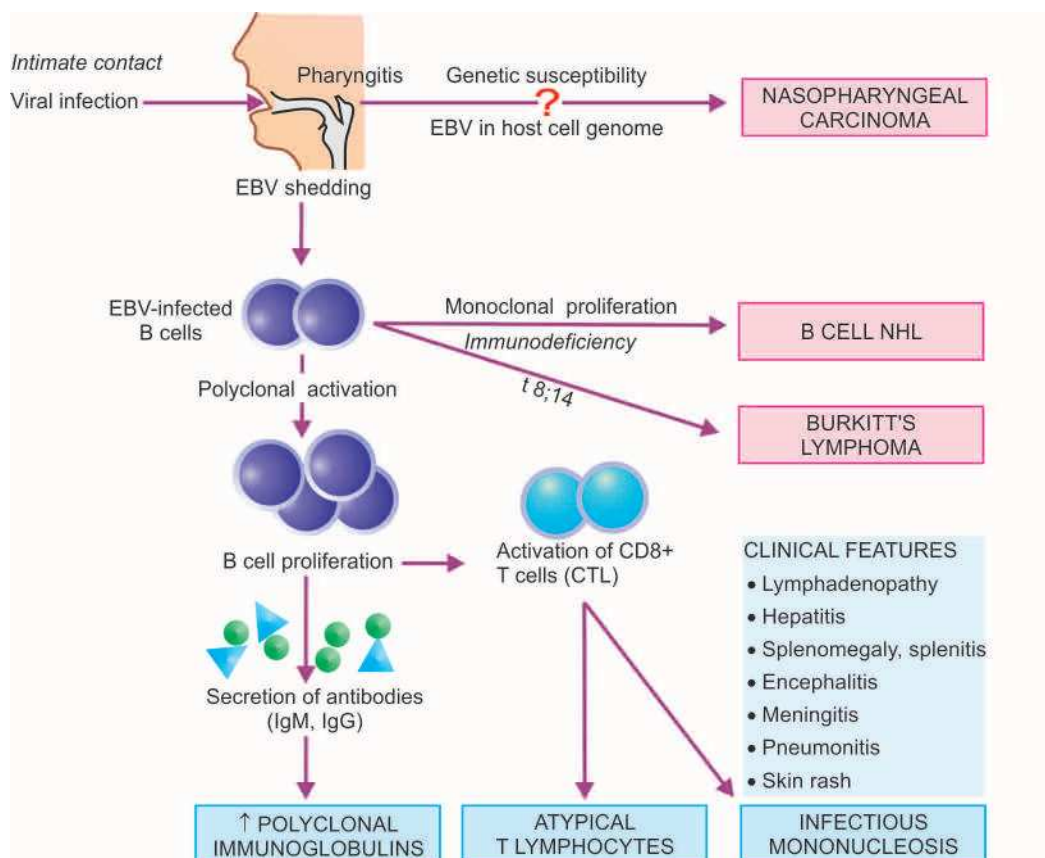

Figure 12.8 The role of EBV in the pathogenesis of infectious mononucleosis, nasopharyngeal carcinoma and Burkitt's lymphoma.

LABORATORY FINDINGS

The diagnosis of IM is made by characteristic haematologic and serologic findings.

I. HAEMATOLOGIC FINDINGS Major abnormalities in blood are as under:

i) TLC There is a moderate rise in total white cell count (10,000-20,000/ μ l) during 2nd to 3rd week after infection.

ii) DLC There is an absolute lymphocytosis. The lymphocytosis is due to rise in normal as well as atypical T lymphocytes. There is relative neutropenia.

iii) Atypical T cells Essential to the diagnosis of IM is the presence of at least 10-12% *atypical T cells (or mononucleosis cells)* lying in peripheral blood lymphocytosis (**Fig. 12.9**). The mononucleosis cells are variable in appearance and are classed as Downey type I, II and III, of which Downey type I are found most frequently. These atypical T lymphocytes are usually of the size of large lymphocytes (12-16 μ m diameter). The nucleus, rather than the usual round configuration, is oval, kidney-shaped or slightly lobate due to indentation of nuclear membrane and contains relatively fine chromatin without nucleoli, suggesting an immature pattern but short of leukaemic features. The cytoplasm is more abundant, basophilic and finely granular and may contain vacuoles. The greatest number of atypical lymphocytes is found between 7th to 10th day of the illness and these cells may persist in the blood for up to 2 months.

iv) CD4+ and CD8+ T cell counts There is reversal of CD4+/CD8+ T cell ratio. There is marked decrease in CD4+ T cells while there is substantial rise in CD8+ T cells.

v) Platelets There is generally thrombocytopenia in the first 4 weeks of illness.

2. SEROLOGIC DIAGNOSIS The second characteristic laboratory finding is the demonstration of antibodies in the serum of infected patient. These are as under:

i) Test for heterophile antibodies Heterophile antibody test (Paul-Bunnell test) is used for making the diagnosis of IM. In this test, patient's serum is absorbed with guinea pig kidney. Serum dilutions are prepared which are used for agglutination of red cells of sheep, horse or cow and are reported as heterophile titer of test serum. A high serum titer of 40 or more times is diagnostic of acute IM infection in symptomatic case in the first week. Heterophile antibodies peak during the 3rd week in 80-90% cases. The test remains positive for about 3 months after the illness started. Thus, the test has to be repeatedly performed. Similar antibody is also produced in patients suffering from serum sickness and has to be distinguished by differential absorption studies. Heterophile antibodies are not demonstrable in children under 5 years of age or in quite elderly. Currently, more sensitive and rapid kit-based test for heterophile antibodies, monospot, is also available.

ii) EBV-specific antibody tests Specific antibodies against the viral capsid and nucleus of EBV can be demonstrated in patients who are negative for heterophile antibody test:

a) Specific antibody against EBV capsid antigen show elevated titers in over 90% cases during acute infection. IgM class antibody appears early and is thus most useful for diagnosis of acute infection. IgG class antibody appears later

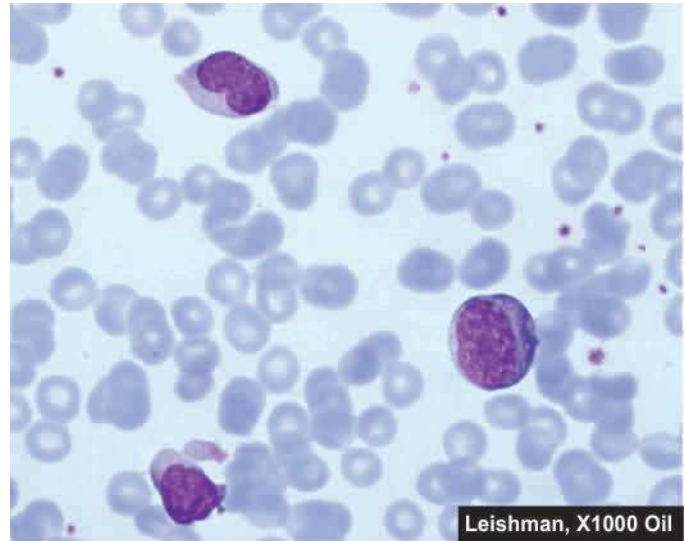

Figure 12.9 Peripheral blood film showing atypical lymphocytes in infectious mononucleosis.

and persists throughout life; thus it does not have diagnostic value but is instead used for assessing the past exposure to EBV infection.

b) Antibodies against EBV nuclear antigen are detected 3 to 6 weeks after infection and, like IgG class antibodies, persist throughout life.

c) Antibodies to early antigens may be elevated but are less useful for making diagnosis of IM. However, titers of these antibodies remain elevated for 3 to 6 months and their levels are high in cases of nasopharyngeal carcinoma and African Burkitt's lymphoma.

d) IgA antibodies to EBV antigen are seen in patients of nasopharyngeal carcinoma or those who are at high risk of developing this EBV-induced cancer.

iii) EBV antigen detection Detection of EBV DNA or proteins can be done in blood or CSF by PCR method.

3. LIVER FUNCTION TESTS In addition, abnormalities of the liver function test are found in about 90% of cases. These include elevated serum levels of transaminases (SGOT and SGPT), rise in serum alkaline phosphatase and mild elevation of serum bilirubin.

LEUKAEMOID REACTIONS

Leukaemoid reaction is defined as a reactive excessive leucocytosis in the peripheral blood resembling that of leukaemia in a subject who does not have leukaemia. In spite of confusing blood picture, the clinical features of leukaemia such as splenomegaly, lymphadenopathy and haemorrhages are usually absent and the features of underlying disorder causing the leukaemoid reaction are generally obvious.

Leukaemoid reaction may be myeloid or lymphoid; the former is much more common.

MYELOID LEUKAEMOID REACTION

CAUSES Majority of leukaemoid reactions involve the granulocyte series. It may occur in association with a wide variety of diseases. These are as under:

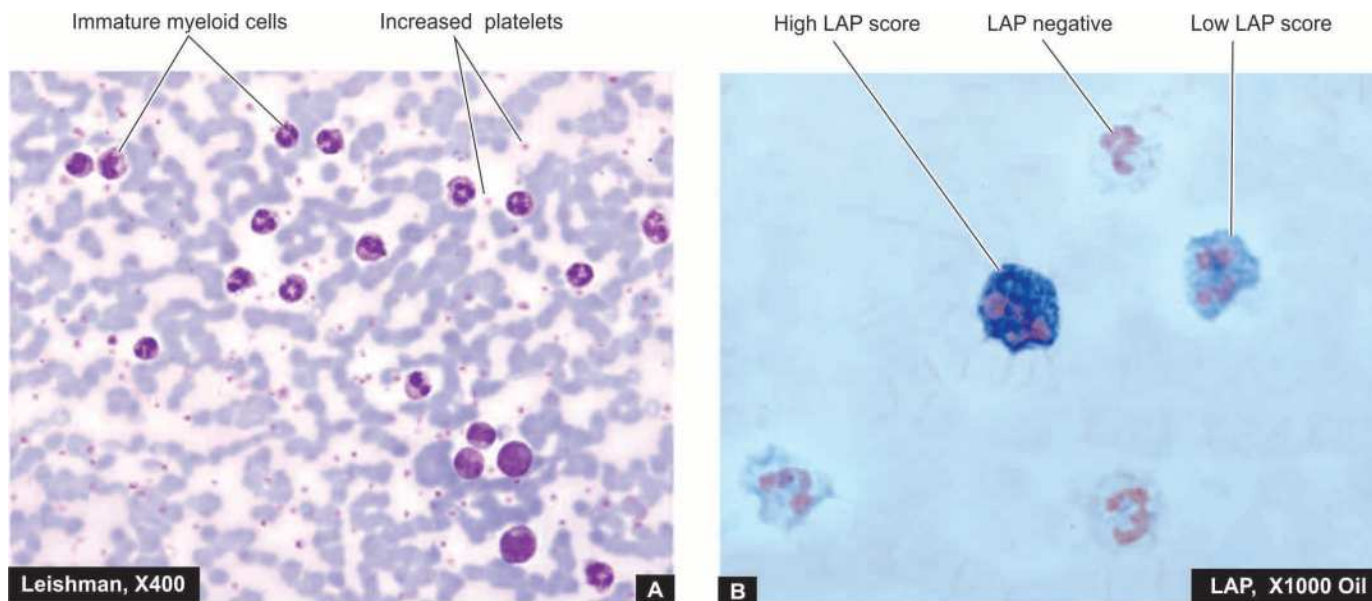

Figure 12.10 Leukaemoid reaction. A, Peripheral blood film showing marked neutrophilic leucocytosis accompanied with late precursors of myeloid series. B, Neutrophil (or leucocyte) alkaline phosphatase (NAP or LAP) activity is higher as demonstrated by this cytochemical stain.

1. *Infections* e.g. staphylococcal pneumonia, disseminated tuberculosis, meningitis, diphtheria, sepsis, endocarditis, plague, infected abortions etc.
2. *Intoxication* e.g. eclampsia, mercury poisoning, severe burns.
3. *Malignant diseases* e.g. multiple myeloma, myelofibrosis, Hodgkin's disease, bone metastases.
4. *Severe haemorrhage and severe haemolysis.*

LABORATORY FINDINGS Myeloid leukaemoid reaction is characterised by the following laboratory features:

1. *Leucocytosis*, usually moderate, not exceeding 100,000/ μ l.

2. Proportion of *immature cells* mild to moderate, comprised by metamyelocytes, myelocytes (5-15%), and blasts fewer than 5% i.e. the blood picture simulates somewhat with that of CML (**Fig. 12.10, A**).
3. Infective cases may show *toxic granulation and Döhle bodies* in the cytoplasm of neutrophils.
4. *Neutrophil (or Leucocyte) alkaline phosphatase (NAP or LAP) score* in the cytoplasm of mature neutrophils in leukaemoid reaction is characteristically high and is very useful to distinguish it from chronic myeloid leukaemia in doubtful cases (**Fig. 12.10, B**).

Table 12.3 Contrasting features of leukaemoid reaction and chronic myeloid leukaemia.

| FEATURE | LEUKAEMOID REACTION | CML |
|--|---|--|
| 1. <i>TLC</i> | 25,000-100,000/ μ l | \geq 100,000/ μ l |
| 2. <i>DLC</i> | i) Dominant cells PMN's ii) Immature cells predominantly metamyelocytes and myelocytes (5-15%), myeloblasts and promyelocytes \geq 5% iii) Basophils normal | i) All maturation stages ii) Immature cells all stages, myeloblasts and promyelocytes \leq 10% iii) Basophilia present |
| 3. <i>NAP score</i> | Elevated | Reduced |
| 4. <i>Philadelphia chromosome</i> | Absent | Present |
| 5. <i>ABL-BCR fusion gene</i> | Absent | Present |
| 6. <i>Major etiology</i> | Infections, intoxication, disseminated malignancy, severe haemorrhage | RNA viruses, HTLV oncogenesis, genetic factors, radiations, certain drugs and chemicals |
| 7. <i>Additional haematologic findings</i> | i) Anaemia ii) Normal to raised platelet count iii) Myeloid hyperplasia in bone marrow | Anaemia Normal to raised platelet count Myeloid hyperplasia in bone marrow |
| 8. <i>Organ infiltration</i> | Absent | May be present |
| 9. <i>Massive splenomegaly</i> | Absent | Present |

5. *Cytogenetic studies* may be helpful in exceptional cases which reveal negative Philadelphia chromosome i.e. t (9; 22) or BCR-ABL fusion gene in myeloid leukaemoid reaction but positive in cases of CML.

6. *Additional features* include anaemia, normal-to-raised platelet count, myeloid hyperplasia of the marrow and absence of infiltration by immature cells in organs and tissues.

Table 12.3 sums up the features to distinguish myeloid leukaemoid reaction from chronic myeloid leukaemia.

LYMPHOID LEUKAEMOID REACTION

CAUSES Lymphoid leukaemoid reaction may be found in the following conditions:

1. *Infections* e.g. infectious mononucleosis, cytomegalovirus infection, pertussis (whooping cough), chickenpox, measles, infectious lymphocytosis, tuberculosis.
2. *Malignant diseases* may rarely produce lymphoid leukaemoid reaction.

LABORATORY FINDINGS The blood picture is characterised by the following findings:

1. Leucocytosis not exceeding 100,000/ μL .
2. The differential white cell count reveals mostly mature lymphocytes simulating the blood picture found in cases of CLL.

GIST BOX 12.2

White Blood Cells—Normal and Reactive

- ▣ Granulopoiesis occurs under the influence of regulatory hormone granulopoietin having G-CSF and GM-CSF.
- ▣ Myeloid series of cells include myeloblasts, promyelocyte, myelocyte, metamyelocyte, band form and mature granulocytes (polymorph, eosinophil, basophil).
- ▣ Monocytic series are formed from monoblast and lymphoid cells from lymphoblasts.
- ▣ Peripheral blood normally contains mature leucocytes expressed as total and differential cell counts which remain within normal range.
- ▣ Pathologic variation in count of leucocytes is given as leucocytosis and may be due to neutrophilia (e.g. acute bacterial infections), lymphocytosis (e.g. viral infections), monocytosis (e.g. chronic bacterial or viral infections), eosinophilia (e.g. allergic disorders) and basophilia (e.g. CML).
- ▣ Infectious mononucleosis or glandular fever is a self-limited viral infection caused by EB virus producing fever, soar throat, lymphadenopathy and abnormal atypical T lymphocytes.
- ▣ Leukaemoid reaction is due to reactive proliferation of leucocytes, which may be myeloid or lymphoid. Myeloid leukaemoid reaction is more common and is due to an underlying cause. It requires distinction from CML—myeloid leukaemoid reaction has high LAP scores and is Philadelphia chromosome negative.

LYMPHOHAEMATOPOIETIC MALIGNANCIES (LEUKAEMIAS-LYMPHOMAS): GENERAL

CLASSIFICATION: HISTORY AND CURRENT CONCEPTS

Neoplastic proliferations of white blood cells are termed leukaemias and lymphomas and are the most important group of leucocyte disorders.

Historically, **leukaemias** have been classified on the basis of cell types predominantly involved into *myeloid* and *lymphoid*, and on the basis of natural history of the disease, into *acute* and *chronic*. Thus, the main types of leukaemias have been: *acute myeloblastic leukaemia* and *acute lymphoblastic leukaemia* (AML and ALL), and *chronic myeloid leukaemia* and *chronic lymphocytic leukaemias* (CML and CLL); besides there are some other uncommon variants. In general, acute leukaemias are characterised by predominance of undifferentiated leucocyte precursors or leukaemic blasts and have a rapidly downhill course. Chronic leukaemias, on the other hand, have easily recognisable late precursor series of leucocytes circulating in large number as the predominant leukaemic cell type and the patients tend to have more indolent behaviour. The incidence of both acute and chronic leukaemias is higher in men than in women. ALL is primarily a disease of children and young adults, whereas AML occurs at all ages. CLL tends to occur in the elderly, while CML is found in middle age.

Similarly, over the years, **lymphomas** which are malignant tumours of lymphoreticular tissues have been categorised into two distinct clinicopathologic groups: *Hodgkin's lymphoma* or *Hodgkin's disease (HD)* characterised by pathognomonic presence of Reed-Sternberg cells, and a heterogeneous group of *non-Hodgkin's lymphomas (NHL)*.

Over the last 50 years, several classification systems have been proposed for leukaemias and lymphomas—clinicians favouring an approach based on clinical findings while pathologists have been interested in classifying them on morphologic features. Newer classification schemes have been based on cytochemistry, immunophenotyping, cytogenetics and molecular markers which have become available to pathologists and haematologists. The last classification scheme proposed by the World Health Organization (WHO) in 2008 combines all tumours of haematopoietic and lymphoid tissues together. The basis of the WHO classification is the *cell type of the neoplasm* as identified by combined approach of clinical features and morphologic, cytogenetic and molecular characteristics, *rather than location of the neoplasm* (whether in blood or in tissues) because of the fact that haematopoietic cells are present in circulation as well as in tissues in general, and lymphoreticular tissues in particular.

As per WHO classification scheme, neoplasms of haematopoietic and lymphoid tissues are considered as a unified group and are divided into 3 broad categories:

I. Myeloid neoplasms This group includes neoplasms of myeloid cell lineage and therefore includes neoplastic proliferations of red blood cells, platelets, granulocytes and monocytes. There are 5 categories under myeloid series of neoplasms: myeloproliferative disorders, myeloproliferative/myelodysplastic diseases, myelodysplastic syndromes (MDS),

and acute myeloid leukaemia (AML), acute biphenotypic leukaemias.

II. Lymphoid neoplasms Neoplasms of lymphoid lineage include leukaemias and lymphomas of B, T or NK cell origin. This group is thus divided into Hodgkin's disease and non-Hodgkin's lymphomas; the latter includes B cell neoplasms (including plasma cell disorders), T cell neoplasms, and rarely NK cell neoplasms.

III. Histiocytic neoplasms This group is of interest mainly due to neoplastic proliferations of histiocytes in Langerhans cell histiocytosis.

Besides the WHO classification, the FAB (French-American-British) Cooperative Group classification of lymphomas and leukaemias based on morphology and cytochemistry is also widely used.

These as well as other classification schemes have been tabulated and discussed later under separate headings of myeloid and lymphoid malignancies.

ETIOLOGY OF LYMPHOHAEMATOPOIETIC MALIGNANCIES

The exact etiology of leukaemias and lymphomas is not known. However, a number of factors have been implicated:

1. HEREDITY There is evidence to suggest that there is role of family history, occurrence in identical twins and predisposition of these malignancies in certain genetic syndromes:

i) Identical twins There is high concordance rate among identical twins if acute leukaemia develops in the first year of life. Hodgkin's disease is 99 times more common in identical twin of an affected case compared with general population, implicating genetic origin strongly.

ii) Family history Families with excessive incidence of leukaemia have been identified.

iii) Genetic disease association Acute leukaemia occurs with increased frequency with a variety of congenital disorders such as Down's, Bloom's, Klinefelter's and Wiskott-Aldrich's syndromes, Fanconi's anaemia and ataxia telangiectasia. Hodgkin's disease has familial incidence and with certain HLA type.

2. INFECTIONS There is evidence to suggest that certain infections, particularly viruses, are involved in development of lymphomas and leukaemias (Chapter 7):

i) Human T cell leukaemia-lymphoma virus I (HTLV-I) implicated in etiology of adult T cell leukaemia-lymphoma (ATLL).

ii) HTLV II for T cell variant of hairy cell leukaemia.

iii) Epstein-Barr virus (EBV) implicated in the etiology of Hodgkin's disease (mixed cellularity type and nodular sclerosis type), endemic variety of Burkitt's lymphoma, post-transplant lymphoma.

iv) HIV in diffuse large B-cell lymphoma and Burkitt's lymphoma.

v) Hepatitis C virus (HCV) in lymphoplasmacytic lymphoma.

vi) Human herpes virus 8 (HHV-8) in primary effusion lymphoma.

vii) Helicobacter pylori bacterial infection of gastric mucosa in MALT lymphoma of the stomach.

3. ENVIRONMENTAL FACTORS Certain environmental factors are known to play a role in the etiology of leukaemias and lymphomas:

i) Ionising radiation Damage due to radiation exposure has been linked to development of leukaemias and lymphomas. Individuals exposed to occupational radiation exposure, patients receiving radiation therapy, and Japanese survivors of the atomic bomb explosions have been found to be at higher risk of developing haematopoietic malignancies, particularly prone to development of CML, AML and ALL but not to CLL or hairy cell leukaemia.

ii) Chemical carcinogens Benzene, tobacco smoking, alcohol, use of certain hair dyes and exposure to agriculture chemicals are associated with increased risk of development of haematopoietic malignancies.

iii) Certain drugs Long-term exposure to certain drugs such as phenytoin, alkylating agents and other chemotherapeutic agents is associated with increased incidence of leukaemias and lymphomas. Patients treated for Hodgkin's disease can develop NHL.

4. ASSOCIATION WITH DISEASES OF IMMUNITY Since lymphoid cells are the immune cells of the body, diseases with derangements of the immune system have higher incidence of haematopoietic malignancies:

i) Immunodeficiency diseases Various inherited and acquired immunodeficiency diseases including AIDS and iatrogenic immunosuppression induced by chemotherapy or radiation, are associated with subsequent development of lymphomatous transformation.

ii) Autoimmune disease association A few autoimmune diseases such as Sjögren's syndrome, nontropical sprue, rheumatoid arthritis and SLE are associated with higher incidence of NHL.

PATHOGENESIS

It needs to be emphasised that since haematopoietic cells have a rapid turnover, they are more vulnerable to chromosomal damages and cytogenetic changes under influence of various etiologic factors listed above.

1. Genetic damage to single clone of target cells Leukaemias and lymphomas arise following malignant transformation of a single clone of cells belonging to myeloid or lymphoid series, followed by proliferation of the transformed clone. Basic mechanism of malignant transformation is genetic damage to the DNA of the target white cells followed by proliferation, disrupting normal growth and differentiation. The heritable genetic damage may be induced by various etiologic agents listed above (e.g. RNA viruses HTLV-I, EBV etc) and causes insertional mutagenesis for which oncogenes may play a role (page 221). The evolution of leukaemia is multi-step process, and in many cases, acute leukaemia may develop after a pre-existing myelodysplastic or myeloproliferative disorder.

2. Chromosomal translocations A number of cytogenetic abnormalities have been detected in cases of leukaemias-lymphomas, most consistent of which are chromosomal translocations. In NHL, translocation involving antigen receptor genes, immunoglobulin genes, or overexpression of *BCL-2* protein may be seen. The most consistent chromosomal abnormality in various forms of acute and chronic leukaemias

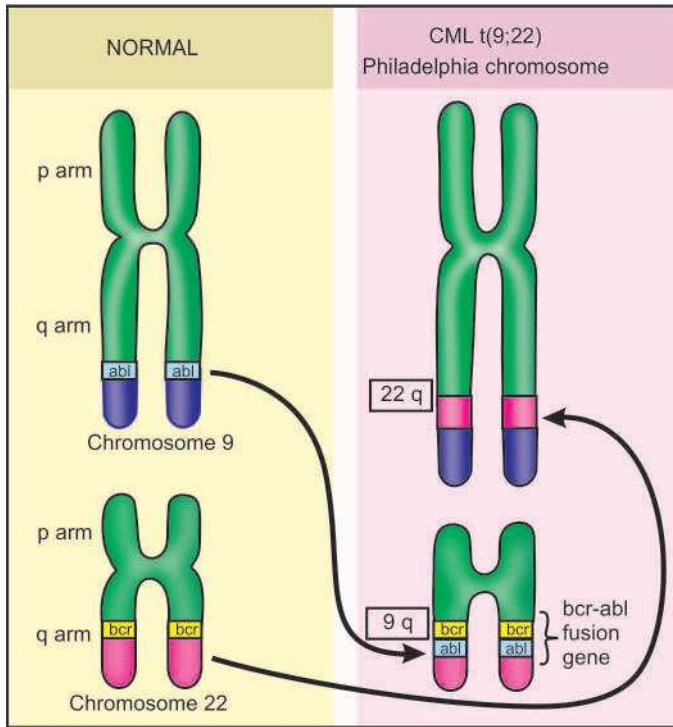

Figure 12.11 The Philadelphia (Ph) chromosome. There is reciprocal translocation of the part of the long arms of chromosome 22 to the long arms of chromosome 9 written as t(9;22).

is Philadelphia (Ph) chromosome seen in 70-90% cases with CML, involving reciprocal translocation of parts of long arm of chromosome 22 to the long arm of chromosome 9 i.e. t(9;22) (Fig. 12.11).

3. Maturation defect In acute leukaemia, the single most prominent characteristic of the leukaemic cells is a defect in maturation beyond the myeloblast or promyelocyte level in AML, and the lymphoblast level in ALL. It needs to be emphasised that it is the maturation defect in leukaemic blasts rather than rapid proliferation of leukaemic cells responsible for causing acute leukaemia. In fact, the generation time of leukaemic blasts is somewhat prolonged rather than shortened.

4. Myelosuppression As the leukaemic cells accumulate in the bone marrow, there is suppression of normal haematopoietic stem cells, partly by physically replacing the normal marrow precursors, and partly by inhibiting normal haematopoiesis via cell-mediated or humoral mechanisms. This is based on the observation that some patients with acute leukaemia have a hypocellular marrow indicating that marrow failure is not due to overcrowding by leukaemic cells alone. Nevertheless, some normal haematopoietic stem cells do remain in the marrow which are capable of proliferating and restoring normal haematopoiesis after effective anti-leukaemic treatment.

5. Organ infiltration The leukaemic cells proliferate primarily in the bone marrow, circulate in the blood and infiltrate into other tissues such as lymph nodes, liver, spleen, skin, viscera and the central nervous system.

6. Cytokines Presence of reactive inflammatory cells in the Hodgkin's disease is due to secretion of cytokines from the Reed Sternberg cells e.g. IL-5 (growth factor for eosinophils), IL-13 (for autocrine stimulation of RS cells) and transforming growth factor- β (for fibrogenesis).

GIST BOX 12.3

Lymphohaematopoietic Malignancies (Leukaemias-Lymphomas)—General

- ▣ As per current concepts, neoplasms of haematopoietic and lymphoid tissues are considered as a unified group and are divided into neoplasms of myeloid, lymphoid and histiocytic cells.
- ▣ Although the exact etiology of leukaemias and lymphomas is not known, a number of factors have been implicated e.g. heredity, viral and certain bacterial infections, ionising radiations, chemical carcinogens, certain drugs, immunodeficiency, and autoimmune diseases.
- ▣ Pathogenesis of these cancers evolves through genetic damage to single clone of target cells, chromosomal translocations, maturation defect and myelosuppression and secretion of certain cytokines.

MYELOID NEOPLASMS

Based on the cell line of differentiation of the pluripotent stem cell, the WHO classification divides all haematopoietic neoplasms into 2 groups: myeloid and lymphoid neoplasms. Since myeloid trilineage stem cells further differentiate into 3 series of progenitor cells: erythroid, granulocyte-monocyte, and megakaryocytic series, therefore all examples of myeloid neoplasms fall into these three categories of cell-lines. Based on this concept, myeloid neoplasms has following 5 groups (Fig. 12.12):

- I. Myeloproliferative diseases
- II. Myelodysplastic/myeloproliferative diseases
- III. Myelodysplastic syndrome (MDS)
- IV. Acute myeloid leukaemia (AML)
- V. Acute biphenotypic leukaemia

Each of these groups is subclassified into further types as shown in Table 12.4. Important examples within each group are discussed below.

MYELOPROLIFERATIVE DISEASES

The myeloproliferative disorders are a group of neoplastic proliferation of multipotent haematopoietic stem cells. Besides their common stem cell origin, these disorders are closely related, occasionally leading to evolution of one entity into another during the course of the disease.

The WHO classification of myeloproliferative disorders includes 7 types as shown in Table 12.4. Classic and common examples are chronic myeloid leukaemia (CML), polycythaemia vera (PV), and essential thrombocytosis (ET), each one representing corresponding excess of granulocytes, red blood cells, and platelets, respectively. The group as a whole has slow and insidious onset of clinical features and indolent clinical behaviour.

CHRONIC MYELOID LEUKAEMIA (CML)

Definition and Pathophysiology

By WHO definition, CML is established by identification of the clone of haematopoietic stem cell that possesses the balanced reciprocal translocation between chromosomes 9 and 22, forming Philadelphia chromosome (Fig. 12.11). The t(9;22) involves fusion of BCR (breakpoint cluster region) gene on

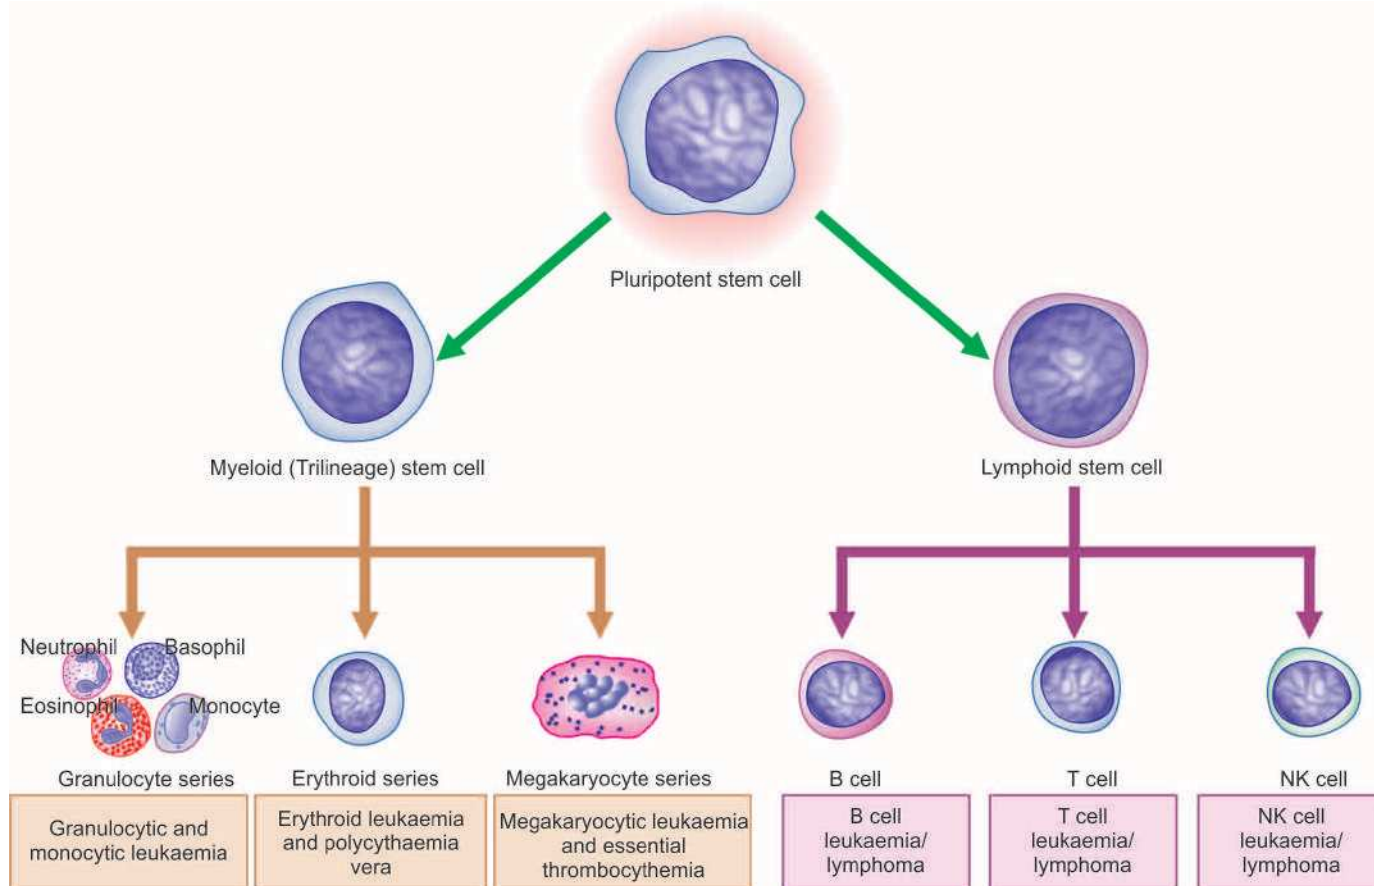

Figure 12.12 Maturation stages of myeloid cells in relation to corresponding types of myeloid neoplasms.

chromosome 22q11 with ABL (named after Abelson murine leukaemia virus) gene located on chromosome 9q34. The fusion product so formed is termed “Ph chromosome t(9;22) (q34;11), BCR/ABL” which should be positive for making the diagnosis of CML. This identification may be done by PCR or by FISH. The underlying pathophysiologic mechanism of human CML is based on the observation that BCR/ABL fusion product proteins are capable of transforming haematopoietic progenitor cells *in vitro* and form malignant clone. BCR/ABL fusion product brings about following functional changes:

- ABL protein is activated to function as a tyrosine kinase enzyme that in turn activates other kinases which *inhibits apoptosis*.
- Ability of ABL to act as *DNA-binding protein* is altered.
- Binding of ABL to *actin microfilaments* of the cytoskeleton is increased.

Exact mechanism of progression of CML to the blastic phase is unclear but following mechanisms may be involved:

- Structural alterations in tumour suppressor *p53* gene.
- Structural alterations in tumour suppressor *RB* gene.
- Alterations in *RAS* oncogene.
- Alterations in *MYC* oncogene.
- Release of cytokine *IL-1 β* .
- Functional inactivation of tumour suppressor protein, *phosphatase A2*.

Clinical Features

Chronic myeloid (myelogenous, granulocytic) leukaemia comprises about 20% of all leukaemias and its peak incidence is seen in 3rd and 4th decades of life. A distinctive variant of CML seen in children is called *juvenile CML*. Both sexes are

affected equally. The onset of CML is generally insidious. Some of the common presenting manifestations are as under:

- Features of *anaemia* such as weakness, pallor, dyspnoea and tachycardia.
- Symptoms due to *hypermetabolism* such as weight loss, lassitude, anorexia, night sweats.
- Splenomegaly* is almost always present and is frequently massive. In some patients, it may be associated with acute pain due to splenic infarction.
- Bleeding tendencies* such as easy bruising, epistaxis, menorrhagia and haematomas may occur.
- Less common features include gout, visual disturbance, neurologic manifestations and priapism.
- Juvenile CML* is more often associated with lymph node enlargement than splenomegaly. Other features are frequent infections, haemorrhagic manifestations and facial rash.

Laboratory Findings

The diagnosis of CML is generally possible on blood picture alone. However, bone marrow, cytochemical stains and other investigations are of help.

I. BLOOD PICTURE The typical blood picture in a case of CML at the time of presentation shows the following features (**Fig. 12.13**):

1. Anaemia Anaemia is usually of moderate degree and is normocytic normochromic in type. Occasional normoblasts may be present.

2. White blood cells Characteristically, there is marked leucocytosis (approximately 200,000/ μ l or more at the time

Table 12.4 WHO classification of myeloid neoplasms.

- I. MYELOPROLIFERATIVE DISEASES
 1. Chronic myeloid leukaemia (CML), {Ph chromosome t(9;22) (q34;11), BCR/ABL-positive}
 2. Chronic neutrophilic leukaemia
 3. Chronic eosinophilic leukaemia/ hypereosinophilic syndrome
 4. Chronic idiopathic myelofibrosis
 5. Polycythaemia vera (PV)
 6. Essential thrombocythaemia (ET)
 7. Chronic myeloproliferative disease, unclassifiable
- II. MYELODYSPLASTIC/MYELOPROLIFERATIVE DISEASES
 1. Chronic myelomonocytic leukaemia (CMML)
- III. MYELODYSPLASTIC SYNDROME (MDS)
 1. Refractory anaemia (RA)
 2. Refractory anaemia with ring sideroblasts (RARS)
 3. Refractory cytopenia with multilineage dysplasia (RCMD)
 4. RCMD with ringed sideroblasts (RCMD-RS)
 5. Refractory anaemia with excess blasts (RAEB-1)
 6. RAEB-2
 7. Myelodysplastic syndrome unclassified (MDS-U)
 8. MDS with isolated del 5q
- IV. ACUTE MYELOID LEUKAEMIA (AML)
 1. Acute myeloid leukaemias with recurrent genetic abnormalities
 - i. AML with t(8;21)(q22;q22); RUNX1-RUNX1T1
 - ii. AML with inv(16)(p13.1;q22) or t(16;16)(p13.1;q22); CBF & β -MYH11
 - iii. Acute promyelocytic leukaemia (M3) with t(15;17) (q22;q12); PML/RAR- α and variants
 - iv. AML with t(9;11)(p22;q23); MLLT3-MLL
 - v. AML with t(6;9)(p23;q34); DEK-NUP214
 - vi. AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2); RPN1-EVI1
 - vii. AML (megakaryoblastic) with t(1;22)(p13;q13); RBM15-MKL1
 - viii. AML with mutated NPM1
 - ix. AML with mutated CEBPA
 2. Acute myeloid leukaemia with myelodysplasia related changes
 3. Therapy related acute myeloid leukaemia
 - i. Alkylating agent related
 - ii. Topoisomerase II inhibitor related (some may be lymphoid)
 4. Acute myeloid leukaemia, not otherwise categorised
 - i. AML minimally differentiated (M0)
 - ii. AML without maturation (M1)
 - iii. AML with maturation (M2)*
 - iv. Acute myelomonocytic leukaemia (M4)
 - v. Acute monoblastic and monocytic leukaemia (M5a, M5b)
 - vi. Acute erythroid leukaemia (M6)
 - vii. Acute megakaryoblastic leukaemia (M7)
 - viii. Acute basophilic leukaemia
 - ix. Acute panmyelosis with myelofibrosis
 5. Myeloid sarcoma
 6. Myeloid proliferations related to Down's syndrome
 - i. Transient abnormal myelopoiesis
 - ii. Myeloid leukaemia associated with Down's syndrome
 7. Blastic plasmacytoid dendritic cell neoplasm
- V. ACUTE BIPHENOTYPIC LEUKAEMIA

*AML (M3) or acute promyelocyte leukaemia is listed at IV (iii) in the same table above.

of presentation). The natural history of CML consists of 3 phases—chronic, accelerated, and blastic.

◆ *Chronic phase of CML* begins as a myeloproliferative disorder and consists of excessive proliferation of myeloid cells of intermediate grade (i.e. myelocytes and metamyelocytes) and mature segmented neutrophils. Myeloblasts usually do not exceed 10% of cells in the peripheral blood and bone marrow. An increase in the proportion of basophils up to 10% is a characteristic feature of CML. A rising *basophilia* is indicative of impending blastic transformation. An *accelerated phase of CML* is also described in which there is progressively rising leucocytosis associated with thrombocytosis or thrombocytopenia and splenomegaly. Accelerated phase has increasing degree of anaemia, blast count in blood or marrow between 10-20%, marrow basophils 20% or more, and platelet count falling below 1,00,000/ μ l.

◆ *Blastic phase or blast crisis in CML* fulfills the definition of acute leukaemia in having blood or marrow blasts $\geq 20\%$. These blast cells may be myeloid, lymphoid, erythroid or undifferentiated and are established by morphology, cytochemistry, or immunophenotyping. Myeloid blast crisis in CML is more common and resembles AML. However, unlike AML, Auer rods are not seen in myeloblasts of CML in blast crisis.

3. Platelets Platelet count may be normal but is raised in about half the cases.

II. BONE MARROW EXAMINATION Examination of marrow aspiration yields the following results:

1. Cellularity Generally, there is hypercellularity with total or partial replacement of fat spaces by proliferating myeloid cells.

2. Myeloid cells The myeloid cells predominate in the bone marrow with increased myeloid-erythroid ratio. The differential counts of myeloid cells in the marrow show similar findings as seen in the peripheral blood with predominance of myelocytes.

3. Erythropoiesis Erythropoiesis is normoblastic but there is reduction in erythropoietic cells.

4. Megakaryocytes Megakaryocytes are conspicuous but are usually smaller in size than normal.

5. Cytogenetics Cytogenetic studies on blood and bone marrow cells show the characteristic chromosomal abnormality called Philadelphia (Ph) chromosome seen in 90-95% cases of CML. Ph chromosome is formed by reciprocal balanced translocation between part of long arm of chromosome 22 and part of long arm of chromosome 9{(t(9;22) (q34;11)} forming product of fusion gene, BCR/ABL (see Fig. 12.11).

III. CYTOCHEMISTRY The only significant finding on cytochemical stains is reduced scores of *neutrophil alkaline phosphatase (NAP)* which helps to distinguish CML from myeloid leukaemoid reaction in which case NAP scores are elevated (see Fig. 12.10,B, and Table 12.3). However, NAP scores in CML return to normal with successful therapy, corticosteroid administration and in infections.

IV. OTHER INVESTIGATIONS A few other accompanying findings are seen in CML:

1. Elevated serum B_{12} and vitamin B_{12} binding capacity.
2. Elevated serum uric acid (hyperuricaemia).

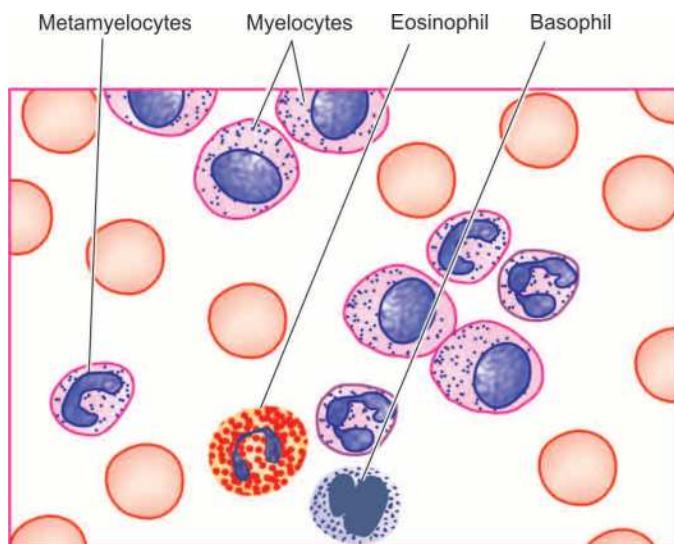

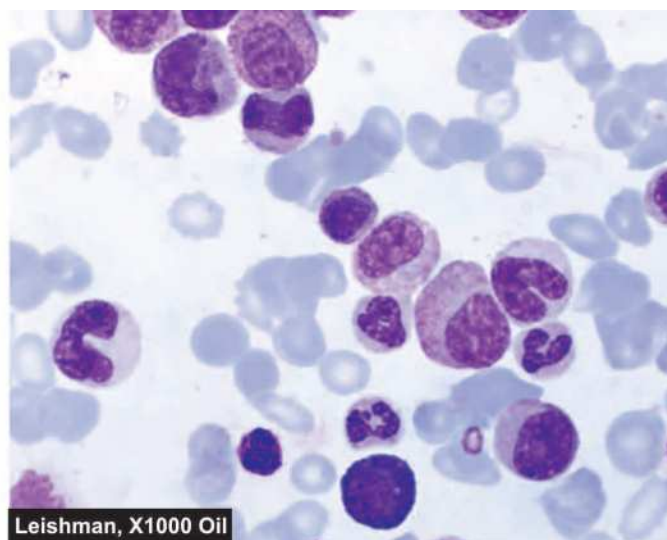

Figure 12.13 PBF findings in chronic myeloid leukaemia (CML).

General principles of Treatment and Prognosis

Insight into molecular mechanism of CML has brought about major changes in its therapy. The approach of modern therapy in CML is targeted at removal of all malignant clones of cells bearing BCR/ABL fusion protein, so that patient reverts back to prolonged non-clonal haematopoiesis i.e. molecular remission from disease. This is achievable by the following approaches:

1. Imatinib oral therapy The basic principle underlying imatinib oral treatment is to competitively inhibit ATP binding site of the ABL kinase, which in turn, inhibits signal transduction BCR/ABL fusion protein. Imatinib induces apoptosis in BCR/ABL-positive cells and thus eliminates them. Imatinib is found more effective in newly diagnosed cases of CML. Complete haematologic remission is achieved for 18 months in 97% cases treated with imatinib.

2. Allogenic bone marrow (stem cell) transplantation Although this treatment modality offers proven cure, it is complicated with mortality due to procedure and development of post-transplant graft-versus-host disease (GVHD) and, therefore, post-transplant immunosuppressive treatment has to be continued.

3. Interferon- α Prior to imatinib and allogenic transplantation, chronic phase of CML used to be treated with interferon- α was the drug of choice.

4. Chemotherapy Chemotherapeutic agents are used in treatment of CML for lowering the total population of WBCs. These include use of busulfan, cyclophosphamide (melphalan) and hydroxyurea.

5. Others Besides above, other forms of treatment include splenic irradiation, splenectomy and leucopheresis.

The most common cause of death (in 80% cases) in CML is disease acceleration and blastic transformation.

POLYCYTHAEMIA VERA

Definition and Pathophysiology

Polycythaemia vera (PV) is a clonal disorder characterised by increased production of all myeloid elements resulting in

pancytosis (i.e. increased red cells, granulocytes, platelets) in the absence of any recognisable cause.

◆ The term 'polycythaemia vera' or 'polycythaemia rubra vera' is used for *primary or idiopathic polycythaemia* only and is the most common of all the myeloproliferative disorders.

◆ *Secondary polycythaemia or erythrocytosis*, on the other hand, may occur secondary to several causes e.g.

- i) High altitude.
- ii) Cardiovascular disease.
- iii) Pulmonary disease with alveolar hypoventilation.
- iv) Heavy smoking.
- v) Inappropriate increase in erythropoietin (renal cell carcinoma, hydronephrosis, hepatocellular carcinoma, cerebellar haemangioblastoma, massive uterine leiomyoma).
- vi) Sometimes relative or spurious polycythaemia may result from plasma loss such as in burns and in dehydration from vomiting or water deprivation.

None of the secondary causes of polycythaemia is associated with splenic enlargement or increased leucocytes and platelets which are typical of PV.

The exact etiology of PV is not known but about a third of cases show inconsistent and varied chromosomal abnormalities such as 20q, trisomy 8 and 9p. Major pathogenetic mechanism is a tyrosine kinase JAK2 mutation which removes the autoinhibitory control and activates the kinases.

Clinical Features

PV is a disease of late middle life and is slightly more common in males. The disease generally runs a chronic but slowly progressive course. Clinical features are the result of hyperviscosity, hypervolaemia, hypermetabolism and decreased cerebral perfusion. These are as under:

1. Headache, vertigo, tinnitus, visual alterations syncope or even coma.
2. Increased risk of thrombosis due to accelerated atherosclerosis.
3. Increased risk of haemorrhages due to increased blood volume and intrinsic platelet dysfunction e.g. epistaxis, peptic ulcer disease.
4. Splenomegaly producing abdominal fullness.
5. Pruritus, especially after a bath.

6. Increased risk of urate stones and gout due to hyperuricaemia.

Laboratory Findings

PV is diagnosed by the following haematologic findings:

1. *Raised haemoglobin* concentration (above 17.5 g/dl in males and 15.5 g/dl in females).
2. *Erythrocytosis* (above 6 million/ μ l in males and 5.5 million/ μ l in females).
3. Haematocrit (PCV) above 55% in males and above 47% in females.
4. Mild to moderate *leucocytosis* (15,000-25,000/ μ l) with basophilia and raised neutrophil alkaline phosphatase scores.
5. *Thrombocytosis* with defective platelet function.
6. Bone marrow examination reveals erythroid hyperplasia or *panhyperplasia*.
7. *Cytogenetic abnormalities* such as 20q, trisomy 8 and 9p are found in 30% cases of PV.
8. In PV, unlike secondary polycythaemia, *erythropoietin* levels in serum and urine are reduced.

General Principles of Treatment and Prognosis

Since PV runs an indolent course, therapy is aimed at maintaining normal blood counts and relieve the patient of symptoms.

1. *Phlebotomy* (venesection) by blood letting is done at regular interval to reduce total blood cell mass and to induce a state of iron deficiency.
2. *Anticoagulant therapy* is administered in case thrombosis has occurred.
3. *Chemotherapy* may be indicated to induce myelosuppression.
4. Hyperuricaemia is treated with *uricosuric drugs*.
5. Interferon- α is associated with good results because it reduces JAK2 expression in these patients which is the underlying cytogenetic abnormality.

Patients receiving phlebotomy alone may survive for 10-12 years. About 25% patients progress to myelofibrosis. A small proportion of patients develop secondary haematologic malignancies such as AML, non-Hodgkin's lymphoma and multiple myeloma. Major complication and cause of death in PV is vascular thrombosis.

ESSENTIAL THROMBOCYTHAEMIA

Definition and Pathophysiology

Essential thrombocythaemia (ET), also termed essential thrombocytosis or primary (idiopathic) thrombocythaemia is a clonal disorder characterised by markedly elevated platelet count in the absence of any recognisable stimulus. *Secondary or reactive thrombocytosis*, on the other hand, occurs in response to known stimuli such as: chronic infection, haemorrhage, postoperative state, chronic iron deficiency, malignancy, rheumatoid arthritis and postsplenectomy.

ET is an uncommon disorder and represents an overproduction of platelets from megakaryocyte colonies without any added stimulus but no clonal marker is available to distinguish primary from secondary thrombocytosis. Though

an elevated platelet count is the dominant feature, other cell lines may also be involved in the expansion of neoplastic clone.

The underlying pathophysiologic mechanism in ET is the absence of control by thrombopoietin that regulates endomitosis in the megakaryocytes to produce platelets. The result is uncontrolled proliferation of not only megakaryocytes but also of the platelets. There is a probable role of heredity in ET since families with ET have been reported.

Clinical Features

The condition has an insidious onset and is more frequent in older people. Haemorrhagic and thrombotic events are common. These include the following:

1. Arterial or venous thrombosis.
2. Easy bruisability following minor trauma.
3. Spontaneous bleeding.
4. Transient ischaemic attack or frank stroke due to platelet aggregation in microvasculature of the CNS.

Laboratory Findings

The prominent laboratory features pertain to platelets. These include the following:

1. Sustained elevation in platelet count (above 400,000/ μ l).
2. Blood film shows many large platelets, megakaryocyte fragments and hypogranular forms.
3. Consistently abnormal platelet functions, especially abnormality in platelet aggregation.
4. Bone marrow examination reveals a large number of hyperdiploid megakaryocytes and variable amount of increased fibrosis.

General Principles of Treatment and Prognosis

ET runs a benign course and may not require any therapy. Treatment is given only if platelet count is higher than one million. Complications of ET are occurrence of acquired von Willebrand's disease and bleeding but incidence of thrombosis is not higher than matched controls.

CHRONIC IDIOPATHIC MYELOFIBROSIS

Definition and Pathophysiology

Chronic idiopathic myelofibrosis (IMF), also called agnogenic (of unknown origin) myeloid metaplasia, primary myelofibrosis and myelosclerosis, is a clonal disorder characterised by proliferation of neoplastic stem cells at multiple sites outside the bone marrow (i.e. extramedullary haematopoiesis), especially in the liver and spleen, without an underlying etiology. Secondary myelofibrosis, on the other hand, develops in association with certain well-defined marrow disorders, or it is the result of toxic action of chemical agents or irradiation.

The exact etiology is not known. Several chromosomal abnormalities have been reported but without a specific cytogenetic abnormality. *Fibrosis* in the bone marrow is due to overproduction of transforming growth factor- β , *osteosclerosis* of the bone is related to osteonectin and marrow *angiogenesis* is due to increased production of vascular endothelial growth factor (VEGF).

Clinical Features

The disease begins in the late middle life and is gradual in onset. Both sexes are affected equally. The symptomatology includes the following:

1. Anaemia with constitutional symptoms such as fatigue, weakness and anorexia.
2. Massive splenomegaly producing abdominal discomfort, pain and dyspnoea.
3. Hepatomegaly is present in half the cases.
4. Petechial and other bleeding problems are found in about 20% cases.
5. Less common findings are lymphadenopathy, jaundice, ascites, bone pain and hyperuricaemia.

Laboratory Findings

1. *Mild anaemia* is usual except in cases where features of polycythaemia vera are coexistent.
2. *Leucocytosis* at the time of presentation but later there may be leucopenia.
3. *Thrombocytosis* initially but advanced cases show thrombocytopenia.
4. *Peripheral blood smear* shows bizarre red cell shapes, tear drop poikilocytes, basophilic stippling, nucleated red cells, immature leucocytes (i.e. leucoerythroblastic reaction), basophilia and giant platelet forms.
5. *Bone marrow aspiration* is generally unsuccessful and yields 'dry tap'. Examination of trephine biopsy shows focal areas of hypercellularity and increased reticulin network and variable amount of collagen in which clusters of megakaryocytes are seen well preserved.
6. *Extramedullary haematopoiesis* can be documented by liver biopsy or splenic aspiration.

General Principles of Treatment and Prognosis

Chronic idiopathic myelofibrosis does not require any specific therapy. Anaemia and ineffective erythropoiesis cannot be readily treated and do not respond to erythropoietin, androgens. Splenectomy may be necessary in some cases. In general, chronic idiopathic myelofibrosis has poorer outcome compared with PV and ET.

GIST BOX 12.4 Myeloproliferative Diseases

- These are a group of closely-related disorders having common origin from stem cells.
- CML is identified by identification of clone of cells having reciprocal t(9;22) forming fusion gene complex BCR-ABL or Philadelphia chromosome. Clinically, CML cases have anaemia, splenomegaly and bleeding tendencies. It has a chronic phase and a more aggressive blastic phase.
- Polycythaemia vera is a clonal disorder characterised by increased production of all myeloid elements resulting in pancytosis (i.e. increased red cells, granulocytes, platelets) in the absence of any recognisable cause.
- Essential thrombocythaemia is uncommon and has over-production of platelets.
- Chronic idiopathic myelofibrosis is characterised by proliferation of stem cells outside the bone marrow i.e. extramedullary haematopoiesis.

ACUTE MYELOID LEUKAEMIA

Definition and Pathophysiology

Acute myeloid leukaemia (AML) is a heterogeneous disease characterised by infiltration of malignant myeloid cells into the blood, bone marrow and other tissues. AML is mainly a disease of adults (median age 50 years), while children and older individuals may also develop it sometimes.

AML develops due to inhibition of maturation of myeloid stem cells due to mutations. These mutations may be induced by several etiologic factors—heredity, radiation, chemical carcinogens (tobacco smoking, rubber, plastic, paint, insecticides etc) and long-term use of anti-cancer drugs but viruses do not appear to have role in the etiology of AML. The defect induced by mutations causes accumulation of precursor myeloid cells of the stage at which the myeloid maturation and differentiation is blocked. A few important examples of chromosomal mutations in AML are translocations {t(8;21)(q22;q22)} and {t(15;17)(q22;q12)} and inversions {inv(16)(p13;q22)}.

Classification

Currently, two main classification schemes for AML are followed:

FAB CLASSIFICATION According to revised FAB classification system, a leukaemia is acute if the bone marrow consists of more than 30% blasts. Based on morphology and cytochemistry, FAB classification divides AML into 8 subtypes (M0 to M7) (**Table 12.5**).

WHO CLASSIFICATION Recent WHO classification for AML differs from revised FAB classification in the following 2 ways:

- Firstly, it places limited reliance on blast morphology and cytochemistry for making the diagnosis of subtype of AML but instead takes into consideration *clinical, cytogenetic and molecular abnormalities* in different types. These features can be studied by multiparametric flow cytometry.
- Secondly, WHO classification for AML has revised and lowered the cut off percentage of *marrow blasts* to 20% from 30% in the FAB classification for making the diagnosis of AML. Latest WHO classification of AML is given in **Table 12.4**.

Both FAB as well as WHO classification schemes for AML are followed in different settings depending upon the laboratory facilities available in various centres. Moreover, most of the current clinical and laboratory data are based on FAB groupings. Hence detailed morphologic and cytochemical features of various AML groups are required to be understood well (**Table 12.5**).

Clinical Features

AML and ALL share many clinical features and the two are difficult to distinguish on clinical features alone. In approximately 25% of patients with AML, a preleukaemic syndrome with anaemia and other cytopenias may be present for a few months to years prior to the development of overt leukaemia.

Clinical manifestations of AML are divided into 2 groups: those *due to bone marrow failure*, and those *due to organ infiltration*.

Table 12.5 Revised FAB classification of acute myeloblastic leukaemias.

| FAB CLASS | OLD NAME | PERCENT CASES | MORPHOLOGY | CYTOCHEMISTRY |
|-----------|---|---------------|---|--|
| M0: | <i>Minimally differentiated AML</i> | 5 | Blasts lack definite cytologic and cytochemical features but have myeloid lineage antigens | Myeloperoxidase – |
| M1: | <i>AML without maturation</i> | 20 | Myeloblasts predominate; few if any granules or Auer rods | Myeloperoxidase + |
| M2: | <i>AML with maturation</i> | 30 | Myeloblasts with promyelocytes predominate; Auer rods may be present | Myeloperoxidase +++ |
| M3: | <i>Acute promyelocytic leukaemia</i> | 10 | Hypergranular promyelocytes; often with multiple Auer rods per cell | Myeloperoxidase +++ |
| M4: | <i>Acute myelomonocytic leukaemia (Naegeli type)</i> | 20 | Mature cells of both myeloid and monocytic series in peripheral blood; myeloid cells resemble M2 | Myeloperoxidase ++ Non-specific esterase + |
| M5: | <i>Acute monocytic leukaemia (Schilling type)</i> | 10 | Two subtypes: M5a shows poorly-differentiated monoblasts, M5b shows differentiated promonocytes and monocytes | Non-specific esterase ++ |
| M6: | <i>Acute erythroleukaemia (Di Guglielmo's syndrome)</i> | 4 | Erythroblasts predominate (>50%); myeloblasts and promyelocytes also increased | Erythroblasts: PAS + Myeloblasts: myeloperoxidase + |
| M7: | <i>Acute megakaryocytic leukaemia</i> | 1 | Pleomorphic undifferentiated blasts predominate; react with antiplatelet antibodies | Platelet peroxidase + |

I. DUE TO BONE MARROW FAILURE These are as under:

1. *Anaemia* producing pallor, lethargy, dyspnoea.
2. *Bleeding manifestations* due to thrombocytopenia causing spontaneous bruises, petechiae, bleeding from gums and other bleeding tendencies.
3. *Infections* are quite common and include those of mouth, throat, skin, respiratory, perianal and other sites.
4. *Fever* is generally attributed to infections in acute leukaemia but sometimes no obvious source of infection can be found and may occur in the absence of infection.

II. DUE TO ORGAN INFILTRATION The clinical manifestations of AML are more often due to replacement of the marrow and other tissues by leukaemic cells. These features are as under:

1. *Pain and tenderness of bones* (e.g. sternal tenderness) are due to bone infarcts or subperiosteal infiltrates by leukaemic cells.
2. *Lymphadenopathy* and enlargement of the *tonsils* may occur.
3. *Splenomegaly* of moderate grade may occur. Splenic infarction, subcapsular haemorrhages, and rarely, splenic rupture may occur.
4. *Hepatomegaly* is frequently present due to leukaemic infiltration but the infiltrates usually do not interfere with the function of the liver.
5. *Leukaemic infiltration of the kidney* may be present and ordinarily does not interfere with its function unless secondary complications such as haemorrhage or blockage of ureter supervene.
6. *Gum hypertrophy* due to leukaemic infiltration of the gingivae is a frequent finding in myelomonocytic (M4) and monocytic (M5) leukaemias.
7. *Chloroma or granulocytic sarcoma* is a localised tumour-forming mass occurring in the skin or orbit due to local

infiltration of the tissues by leukaemic cells. The tumour is greenish in appearance due to the presence of myeloperoxidase.

8. *Meningeal involvement* manifested by raised intracranial pressure, headache, nausea and vomiting, blurring of vision and diplopia are seen more frequently in ALL during haematologic remission. Sudden death from massive intracranial haemorrhage as a result of leucostasis may occur.
9. *Other organ infiltrations* include testicular swelling and mediastinal compression.

Laboratory Findings

The diagnosis of AML is made by a combination of routine blood picture and bone marrow examination, coupled with cytochemical stains and other special laboratory investigations.

I. BLOOD PICTURE Findings of routine haematologic investigations are as under (**Fig. 12.14**):

1. Anaemia Anaemia is almost always present in AML. It is generally severe, progressive and normochromic. A moderate reticulocytosis up to 5% and a few nucleated red cells may be present.

2. Thrombocytopenia The platelet count is usually moderately to severely reduced (below 50,000/ μ l) but occasionally it may be normal. Bleeding tendencies in AML are usually correlated with the level of thrombocytopenia but most serious spontaneous haemorrhagic episodes develop in patients with fewer than 20,000/ μ l platelets. Acute promyelocytic leukaemia (M3) may be associated with a serious coagulation abnormality, disseminated intravascular coagulation (DIC).

3. White blood cells The total WBC count ranges from subnormal-to-markedly elevated values. In 25% of patients, the total WBC count at presentation is reduced

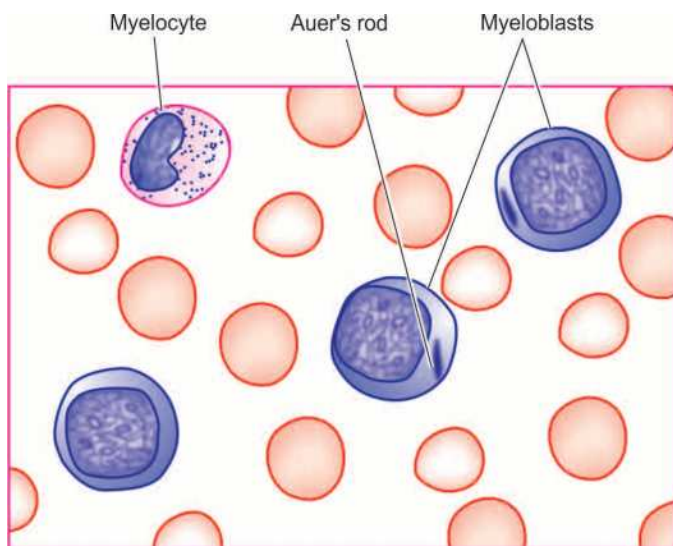

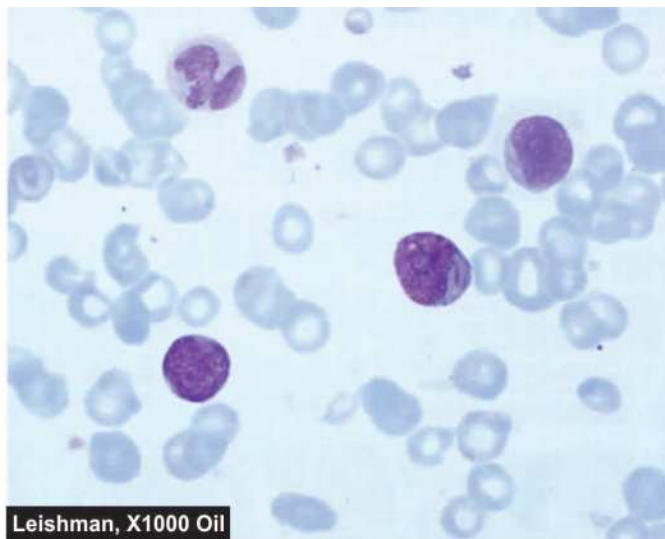

Figure 12.14 PBF findings in a case of acute myeloblastic leukaemia (AML).

to 1,000-4,000/ μ l. More often, however, there is progressive rise in white cell count which may exceed 100,000/ μ l in more advanced disease. Majority of leucocytes in the peripheral blood are blasts and there is often neutropenia due to marrow infiltration by leukaemic cells. The basic morphologic features of myeloblasts and lymphoblasts are summed up in Table 12.1. Typical characteristics of different forms of AML (M0 to M7) are given in Table 12.5. In some instances, the *identification of blast cells is greatly aided by the company they keep* i.e. by more mature and easily identifiable leucocytes in the company of blastic cells of myeloid series. Some 'smear cells' in the peripheral blood representing degenerated leucocytes may be seen.

II. BONE MARROW EXAMINATION An examination of bone marrow aspirate or trephine reveals the following features:

1. Cellularity Typically, the marrow is hypercellular but sometimes a 'blood tap' or 'dry tap' occurs. A dry tap in AML may be due to pancytopenia, but sometimes even when the marrow is so much packed with leukaemic cells that they cannot be aspirated because the cells are adhesive and enmeshed in reticulin fibres. In such cases, trephine biopsy is indicated.

2. Leukaemic cells The bone marrow is generally tightly packed with leukaemic blast cells. The diagnosis of the type of leukaemic cells, according to FAB classification, is generally possible with routine Romanowsky stains but cytochemical stains may be employed as an adjunct to Romanowsky staining for determining the type of leukaemia. The essential criteria for diagnosis of AML, as per FAB classification, was the presence of at least 30% blasts in the bone marrow. However, as per WHO classification, these criteria have been revised and lowered to 20% blasts in the marrow for labelling and treating a case as AML.

3. Erythropoiesis Erythropoietic cells are reduced. Dyserythropoiesis, megaloblastic features and ring sideroblasts are commonly present.

4. Megakaryocytes They are usually reduced or absent.

5. Cytogenetics Chromosomal analysis of dividing leukaemic cells in the marrow shows karyotypic abnormalities in 75% of cases which may have a relationship to prognosis. WHO classification emphasises on the categorisation of AML on the basis of cytogenetic abnormalities. Two of the most consistent cytogenetic abnormalities in specific FAB groups are as under:

- i) M3 cases have $t(15;17)(q22;q12)$.
- ii) M4E0 (E for abnormal eosinophils in the bone marrow) cases have $inv(16)(p13q22)$.

6. Immunophenotyping AML cells express CD13 and CD33 antigens. M7 shows CD41 and CD42 positivity.

III. CYTOCHEMISTRY Some of the commonly employed cytochemical stains, as an aid to classify the type of AML are as under (also see Table 12.5):

1. Myeloperoxidase Positive in immature myeloid cells containing granules and Auer rods but negative in M0 myeloblasts.

2. Sudan Black Positive in immature cells in AML.

3. Periodic acid-Schiff (PAS) Positive in immature lymphoid cells and in erythroleukaemia (M6).

4. Non-specific esterase (NSE) Positive in monocytic series (M4 and M5).

5. Acid phosphatase Focal positivity in leukaemic blasts in ALL and diffuse reaction in monocytic cells (M4 and M5).

IV. BIOCHEMICAL INVESTIGATIONS These may be of some help:

1. Serum muramidase Serum levels of lysozyme (i.e. muramidase) are elevated in myelomonocytic (M4) and monocytic (M5) leukaemias.

2. Serum uric acid Because of rapidly growing number of leukaemic cells, serum uric acid level is frequently increased. The levels are further raised after treatment with cytotoxic drugs because of increased cell breakdown.

General Principles of Treatment and Prognosis

The management of acute leukaemia involves the following aspects:

I. TREATMENT OF ANAEMIA AND HAEMORRHAGE

Anaemia and haemorrhage are managed by fresh blood transfusions and platelet concentrates. Patients with severe thrombocytopenia (platelet count below 20,000/ μ l) require regular platelet transfusions since haemorrhage is an important cause of death in these cases.

II. TREATMENT AND PROPHYLAXIS OF INFECTION

Neutropenia due to bone marrow replacement by leukaemic blasts and as a result of intensive cytotoxic therapy renders these patients highly susceptible to infection. The infections are predominantly bacterial but viral, fungal, and protozoal infections also occur. For prophylaxis against infection in such cases, the patient should be isolated and preferably placed in laminar airflow rooms. Efforts are made to reduce the gut and other commensal flora which are the usual source of infection. This is achieved by bowel sterilisation and by topical antiseptics. If these fail to achieve the desired results, systemic antibiotics and leucocyte concentrates are considered for therapy.

III. CYTOTOXIC DRUG THERAPY The aims of cytotoxic therapy are firstly to induce remission, and secondly to continue therapy to reduce the hidden leukaemic cell population by repeated courses of therapy. Most commonly, cyclic combinations of 2, 3 and 4 drugs are given with treatment-free intervals to allow the bone marrow to recover.

The most effective treatment of AML is a combination of 3 drugs: cytosine arabinoside, anthracyclines (daunorubicin, adriamycin) and 6-thioguanine. Another addition is amsacrine (m-AMSA) administered with cytosine arabinoside, with or without 6-thioguanine. Following remission-induction therapy, various drug combinations are given intermittently for maintenance. However, promyelocytic leukaemia (M3) is treated with tretinoin orally that reduces the leukaemic cells bearing t(15;17)(q22;q21) but development of DIC due to liberation of granules of dying cells is a problem.

IV. BONE MARROW TRANSPLANTATION Bone marrow (or stem cell) transplantation from suitable allogenic or autologous donor (HLA and mixed lymphocytes culture-matched) is increasingly being used for treating young adults with AML in first remission. The basic principle of marrow transplantation is to reconstitute the patient's haematopoietic system after total body irradiation and intensive chemotherapy have been given so as to kill the remaining leukaemic cells. Bone marrow transplantation has resulted in cure in about half the cases.

Remission rate with AML is lower (50-70%) than in ALL, often takes longer to achieve remission, and disease-free intervals are shorter. AML is most malignant of all leukaemias; median survival with treatment is 12-18 months.

GIST BOX 12.5

Acute Myeloid Leukaemia

- ☐ AML is a disease of adults characterised by infiltration of malignant myeloid cells into the blood, bone marrow and other tissues.
- ☐ According to revised FAB classification system, bone marrow in AML has more than 30% blasts. Based on

- ☐ morphology and cytochemistry, FAB classification divides AML into 8 subtypes (M0 to M7).
- ☐ WHO classification takes into account genetic and molecular features and has marrow blast count of >20% for diagnosis of AML. Accordingly, WHO classification has several newer entities.
- ☐ AML is characterised by anaemia, thrombocytopenia, and leucocytosis with blasts in blood. Bone marrow shows myeloblasts in excess of 20% and reduced megakaryocytes.

MYELOYDPLASTIC SYNDROMES

Definition and Classification

Myelodysplastic syndromes (MDS) are a heterogeneous group of haematopoietic clonal stem cell disorders having abnormal development of different marrow elements (i.e. dysmyelopoiesis), usually characterised by cytopenias, associated with cellular marrow and ineffective blood cell formation. These conditions are, therefore, also termed as preleukaemic syndromes or dysmyelopoietic syndromes.

There have been two main classification schemes for MDS:

FAB CLASSIFICATION OF MDS As per FAB (French-American-British) Cooperative Group, the marrow may contain <30% myeloblasts in MDS and this was considered as the dividing line for distinguishing cases of AML (blasts >30%) from MDS. FAB classified MDS into the following 5 groups:

1. *Refractory anaemia (RA)* Blood blasts <1%, marrow blasts <5%.
2. *Refractory anaemia with ringed sideroblasts (RARS) (primary acquired sideroblastic anaemia)* Blood blast <1%, marrow blasts <5%; ring sideroblasts \geq 15%.
3. *Refractory anaemia with excess blasts (RAEB)* Blood blasts 5%, marrow blasts 5-20%.
4. *Refractory anaemia with excess of blasts in transformation (RAEB-t)* Blood blasts 5%, marrow blasts 21-30%.
5. *Chronic myelomonocytic leukaemia (CMML)* Blood blasts, 5%, monocytosis.

WHO CLASSIFICATION OF MDS Recent WHO classification differs from FAB classification in following ways:

- i) Marrow blast count for making the diagnosis of AML has been revised and brought down to 20%.
- ii) FAB category of RAEB-t (group 4 above) cases have prognosis similar to patients of AML and thus included in AML.
- iii) CMML category of FAB (category 4) has been excluded from WHO classification of MDS since these cases behave like a myeloproliferative disorder and thus CMML has been put in the hybrid category of myelodysplastic/myeloproliferative disorder.

Thus, the WHO classification of MDS consists of following 8 categories:

1. *Refractory anaemia (RA)* Same as FAB type 1 MDS. Incidence 5-10%; characterised by anaemia without any blasts in blood; marrow may show <5% blasts.
2. *Refractory anaemia with ringed sideroblasts (RARS)* Same as FAB type 2 MDS. Incidence 10-12%.
3. *Refractory cytopenia with multilineage dysplasia (RCMD)* New entity. Incidence 24%; blood shows cytopenia

of 2 or 3 cell lineage and monocytosis but no blasts; marrow shows <5% blasts.

4. *RCMD with ringed sideroblasts (RCMD-RS)* New entity. Incidence 15%; all blood and marrow findings similar to RCMD plus in addition $\geq 15\%$ ringed sideroblasts in marrow.

5. *Refractory anaemia with excess blasts (RAEB-1)* In WHO classification, RAEB of FAB category 3 has been divided into 2 subtypes with combined incidence of 40%. RAEB-1 has blood cytopenia with <5% blasts and monocytosis; and marrow blast count 5-9%.

6. *RAEB-2* Findings of blood and marrow similar to RAEB-1 but marrow blast count is 10-19%.

7. *Myelodysplastic syndrome unclassified (MDS-U)* New entity in MDS. Blood cytopenia without any blasts; marrow shows dysplasia of myeloid and thrombocytic cell lineage and marrow blast count <5%.

8. *MDS with isolated del(5q)* New entity in MDS. Anaemia in blood and blasts <5%; marrow blasts <5%, normal or increased megakaryocytes which may be hypolobated and characteristic isolated deletion of 5q.

Pathophysiology

i) *Primary MDS* is idiopathic but factors implicated in etiology are radiation exposure and benzene carcinogen.

ii) *Secondary (therapy-related) MDS* may occur following earlier anti-cancer treatment, aplastic anaemia treated with immunosuppressive therapy and in Fanconi's anaemia.

iii) *Several cytogenetic abnormalities* are seen in about 50% of MDS which include trisomy, translocations and deletions. Cases evolving into leukaemia more often have aneuploidy.

iv) *At molecular level*, mutations are seen in *N-RAS* oncogene and *p53* anti-oncogene, which together with suppressed immunity, accelerate apoptosis in the bone marrow. Mutations in the mitochondrial genes probably account for occurrence of sideroblastic anaemia in MDS and consequently disordered iron metabolism and ineffective erythropoiesis.

Clinical Features

In general, MDS is found more frequently in older people past 6th decade of life, with slight male preponderance. Therapy-related MDS is generally not age-related and may occur about a decade after anti-cancer therapy. Clinical features are quite non-specific and MDS may be discovered during routine CBC examination done for some other cause. At presentation the patient may have following features:

1. Anaemia appreciated by pallor, fatigue and weakness.
2. Fever.
3. Weight loss.
4. Sweet syndrome having neutrophilic dermatosis seen in some cases.
5. Splenomegaly seen in 20% cases of MDS.

Laboratory Findings

Various combinations of features are seen in different types of MDS. In general, laboratory findings are as under:

BLOOD FINDINGS There is cytopenia affecting two (bi-) or all the three blood cell lines (pancytopenia):

1. *Anaemia*: Generally macrocytic or dimorphic.

2. *TLC*: Usually normal; cases of CMML may have high TLC but these cases in WHO classification of myeloid neoplasms have been put in a separate group of myelodysplastic/myeloproliferative diseases and not in MDS.

3. *DLC*: Neutrophils are hyposegmented and hypogranulated. Myeloblasts may be seen in PBF and their number correlates with marrow blasts count.

4. *Platelets*: Thrombocytopenia with large agranular platelets.

BONE MARROW FINDINGS There is constellation of findings in the marrow as under:

1. *Cellularity*: Normal to hypercellular to hypocellular.
2. *Erythroid series*: Dyserythropoiesis as seen by abnormally appearing nuclei and ring sideroblasts. Megaloblasts may be seen.
3. *Myeloid series*: Hypogranular and hyposegmented myeloid precursor cells. Myeloblasts increased depending upon the type of MDS.
4. *Megakaryocyte series*: Reduced in number and having abnormal nuclei.

General Principles of Treatment and Prognosis

MDS is difficult to treat and may not respond to cytotoxic chemotherapy. Stem cell transplantation offers cure and longer survival. Survival rates vary depending upon the type of MDS: cases of refractory anaemia with or without sideroblasts (RA and RARS) and 5q syndrome survive for years, while cases of refractory anaemia with excess blasts (RAEB-1 and 2) have poor survival for a few months only. Patients generally either succumb to infections or develop into acute myeloid leukaemia.

GIST BOX 12.6

Myelodysplastic Syndromes

- As per WHO classification of MDS, since marrow blast count for making the diagnosis of AML has been put at 20% or more, cases of MDS have blast count below 20%.
- FAB category of RAEB-t cases have been included in AML in WHO classification of MDS.
- FAB category of CMML has been included in myeloproliferative disorder in WHO scheme of MDS.
- WHO has thus divided MDS into 8 types: refractory anaemia, refractory anaemia with ring sideroblasts, refractory cytopenia with multilineage dysplasia (RCMD), RCMD with ring sideroblasts, RAEB-1 and RAEB-2, MDS unclassified, and MDS with isolated del(5q).

LYMPHOID NEOPLASMS: GENERAL

HISTORY AND CLASSIFICATION

Lymphoid cells constitute the immune system of the body. These cells circulate in the blood and also lie in the lymphoid tissues and undergo differentiation and maturation in these organs. The haematopoietic stem cells which form myeloid and lymphoid series, undergo further differentiation of lymphoid cells into B cells (including formation of plasma cells), T cells and NK cells. Lymphoid malignancies can be formed by malignant transformation of each of these cell lines. These

lymphoid malignancies can range from indolent to highly aggressive human cancers.

Conventionally, malignancies of lymphoid cells in blood have been termed as lymphatic leukaemias and those of lymphoid tissues as lymphomas. Just like myeloid leukaemias discussed earlier, lymphoid leukaemias have been classified on the basis of survival and biologic course, into chronic and acute (*CLL and ALL*). Similarly, two clinicopathologically distinct groups of lymphomas are distinguished: *Hodgkin's lymphoma* or *Hodgkin's disease (HD)* and *non-Hodgkin's lymphomas (NHL)*.

However, while HD can be identified by the pathognomonic presence of Reed-Sternberg cells, there have been controversies and confusion in classification of other lymphoid cancers (i.e. NHL and lymphoid leukaemias). In order to resolve the issue, over the years several classification schemes have emerged for lymphoid cancers due to following two main reasons:

1. Biologic course of lymphoma-leukaemia While some of the lymphoid malignancies initially present as leukaemias (i.e. in the blood and bone marrow), many others present as solid masses in the lymphoid tissues or in various other tissues, especially in the spleen, liver, bone marrow and other tissues. Still others may have initial presentation as either leukaemia or lymphomas. In fact, the line of demarcation for lymphoid malignancies is so blurred that during the biologic course of the disease, lymphoid leukaemia or lymphoma may spill over and transform to the other.

2. Technological advances In recent times, modern diagnostic tools have become available to pathologists and haematologists which go much beyond making the diagnosis of lymphomas and leukaemias on clinical grounds coupled with morphology and cytochemical stains alone. The additional tools include immunophenotyping, cytogenetics and molecular markers for the stage of differentiation of the cell of origin rather than location of the cell alone.

These aspects form the basis of current concept for WHO classification of malignancies of lymphoid cells of blood and lymphoreticular tissues as 'lymphoid neoplasms' as a unified group. However, it needs to be appreciated that in several centres in developing countries of the world, limited laboratory facilities are available. Thus, judiciously speaking, some of the older classification schemes for lymphoid malignancies need to be retained, while others can be dumped as historical. In view of this, a balanced approach of middle path has been followed in this textbook retaining relevant good points of old and adding new classification schemes of lymphoid malignancies:

I. HISTORICAL CLASSIFICATIONS These classifications can be traced as under:

Morphologic classification *Rappaport classification (1966)* proposed a clinically relevant morphologic classification based on two main features: *low-power microscopy* of the overall pattern of the lymph node architecture, and *high-power microscopy* revealing the cytology of the neoplastic cells. Based on these two features, Rappaport divided NHL into two major subtypes:

1. *Nodular or follicular lymphomas* which retain some of the features of normal lymph node in that the neoplastic cells form lymphoid 'nodules' rather than lymphoid follicles with germinal centres.

2. *Diffuse lymphomas*, on the other hand, are characterised by effacement of the normal lymph node architecture and there may be infiltration of neoplastic cells outside the capsule of the involved lymph node.

NHL was further classified according to the degree of differentiation of neoplastic cells into: *well-differentiated*, *poorly-differentiated*, and *histiocytic (large cells) types* of both nodular and diffuse lymphomas.

Immunologic classifications *Lukes-Collins classification (1974)* was proposed to correlate the type of NHL with the immune system because the identification of T and B-cells and their subpopulations had become possible in early 70s. Its subsequent modification was *Kiel classification (1981)*. Both these classifications employed immunologic markers for tumour cells, and divided all malignant lymphomas into either B-cell or T-cell origin, and rarely of macrophages. The B and T-cell tumours were further subdivided on the basis of their light microscopic characteristics. The majority of NHLs were B lymphocyte derivatives and arise from follicular centre cells (FCC). The FCC in the germinal centre undergo transformation to become large immunoblasts and pass through the four stages—*small cleaved cells* and *large cleaved cells*, *small non-cleaved cells* and *large non-cleaved cells*.

Though these classification schemes were immunologically correct, they were unclear about varying prognosis of different clinical types of NHL of either B-cell or T-cell origin.

II. OLD CLINICOPATHOLOGIC CLASSIFICATIONS In view of the objections to above pure morphologic and immunologically correct classifications, following two clinically relevant classifications were proposed which cannot be readily abandoned:

FAB classification of lymphoid leukaemia Although old FAB classification for lymphoid leukaemia based on morphology and cytochemistry divided ALL into 3 types (L1 to L3), but it was subsequently revised to include cytogenetic and immunologic features as well (**Table 12.6**). FAB classification is still followed in many centres where both pathologists and clinicians stick to labelling lymphoid leukaemia separate from lymphomas.

Working Formulations for Clinical Usage (1982) This classification proposed by a panel of experts from National Cancer Institute of the US incorporates the best features of all previous classification systems, and as the name implies, has strong clinical relevance. Based on the natural history of disease and long-term survival studies, Working Formulations divides all NHLs into following 3 prognostic groups:

- ◆ *Low-grade NHL*: 5-year survival 50-70%
- ◆ *Intermediate-grade NHL*: 5-year survival 35-45%
- ◆ *High-grade NHL*: 5-year survival 25-35%.

In this classification, no attempt is made to determine whether the tumour cells have origin from B-cells, T-cells or macrophages. Each prognostic group includes a few morphologic subtypes, and lastly, a miscellaneous group is also described.

Working Formulations classification still has many takers in several centres and is retained in **Table 12.7**.

REAL classification (1994) International Lymphoma Study Group (Harris et al) proposed another classification called revised European-American classification of lymphoid neoplasms abbreviated as REAL classification. This classification

Table 12.6 FAB classification of ALL.

| A. MORPHOLOGIC CRITERIA | | | | |
|---|---|-------------------------|---|-------------------------------|
| FAB CLASS | | PERCENT CASES | MORPHOLOGY | CYTOCHEMISTRY |
| L1: | <i>Childhood-ALL (B-ALL, and T-ALL)</i> | More common in children | Homogeneous small lymphoblasts; scanty cytoplasm, regular round nuclei, inconspicuous nucleoli | PAS ± Acid phosphatase ± |
| L2: | <i>Adult-ALL (mostly T-ALL)</i> | More frequent in adults | Heterogeneous lymphoblasts; variable amount of cytoplasm, irregular or cleft nuclei, large nucleoli | PAS ± Acid phosphatase ± |
| L3: | <i>Burkitt type-ALL (B-ALL)</i> | Uncommon | Large homogeneous lymphoblasts; round nuclei, prominent nucleoli, cytoplasmic vacuolation | PAS – Acid phosphatase – |
| B. CYTOGENETIC AND IMMUNOLOGIC CRITERIA | | | | |
| SUBTYPE | INCIDENCE | MARKERS | FAB SUBTYPE | CYTOGENETIC ABNORMALITIES |
| <i>Pre-B ALL</i> | 75% | CD10+ (90%), TdT+ | L1, L2 | t(9;22) i.e. Philadelphia+ALL |
| <i>B cell ALL</i> | 5% | CD10+ (50%), TdT- | L3 | t(8;14) (Burkitt's leukaemia) |
| <i>T cell ALL</i> | 20% | CD10+ (30%), TdT+ | L1, L2 | 14q11 |

(TdT= terminal deoxynucleotidyl transferase)

was based on the hypothesis that all forms of lymphoid malignancies (NHLs as well as lymphoblastic leukaemias) represent malignant counterparts of normal population of immune cells (B-cells, T-cells and histiocytes) present in the lymph node and bone marrow. It is believed that lymphoid malignancies arise due to arrest at the various differentiation stages of B and T-cells since tumours of histiocytic origin are quite uncommon. Accordingly, it is considered essential to understand and correlate the differentiation stages of B and T-cells with various lymphoid malignancies (Fig. 12.15). REAL classification divides all lymphoid malignancies into two broad groups, each having further subtypes:

◆ *Leukaemias and lymphomas of B-cell origin:* B-cell derivation comprises 80% cases of lymphoid leukaemias and 90% cases of NHLs. Based upon these phenotypic and genotypic features, B-cell neoplasms are of pre-B and mature B-cell origin. Based on their biologic behaviour, B-cell malignancies are further subclassified into indolent and aggressive. All these tumours express Pan-B (CD19) antigen besides other markers.

◆ *Leukaemias and lymphomas of T-cell origin:* T-cell malignancies comprise the remainder 20% cases of lymphoid leukaemia and 10% cases of NHLs. T-cell malignancies reflect the stages of T-cell ontogeny. Like B-cell malignancies, T-cell derivatives too are further categorised into indolent and aggressive T-cell malignancies. The most widely expressed T-cell antigens are CD2 and CD7.

REAL classification subsequently merged into WHO classification described below.

Table 12.7 Classification of NHL-working formulations for clinical usage (1982).

| | |
|------|---|
| I. | LOW-GRADE |
| A) | Small lymphocytic |
| B) | Follicular, predominantly small cleaved cell |
| C) | Follicular, mixed small and large cleaved cell |
| II. | INTERMEDIATE-GRADE |
| D) | Follicular, predominantly large cell |
| E) | Diffuse, small cleaved cell |
| F) | Diffuse, mixed small and large cell |
| G) | Diffuse, large, cell |
| III. | HIGH-GRADE |
| H) | Large cell, immunoblastic |
| I) | Lymphoblastic |
| J) | Small non-cleaved cell (Burkitt's) |
| IV. | MISCELLANEOUS |
| 1. | Adult T-cell leukaemia/lymphoma |
| 2. | Cutaneous T-cell lymphoma |
| 3. | Histiocytic (Histiocytic medullary reticulosis) |

III. WHO CLASSIFICATION OF LYMPHOID NEOPLASMS (2008) In view of confusion surrounding the classification schemes of lymphoid cancer, Harris et al, who described REAL classification, evolved a consensus international classification of all lymphoid neoplasms together as a unified group (lymphoid leukaemias-lymphomas) under the aegis of the WHO. Although this classification has many similarities with REAL classification as regards identification of B and T cell types (Fig. 12.15), WHO classification has more classes. WHO classification takes into account morphology, clinical features, immunophenotyping, and cytogenetic of the tumour cells. Hence, on this basis, it is possible to know the stage of maturity of the neoplastic cell and thus it has a better clinical and therapeutic relevance.

As per current WHO classification, all lymphoid neoplasms (i.e. lymphoid leukaemias and lymphomas) fall into following 5 categories (Table 12.8):

- I. Hodgkin's disease
- II. B-cell malignancies: Precursor (or immature), and peripheral (or mature)
- III. T-cell/NK cell malignancies: Precursor (or immature), and peripheral (or mature)

| | NORMAL B-CELL DIFFERENTIATION | MARKERS | B-CELL MALIGNANCIES | NORMAL T-CELL DIFFERENTIATION | MARKERS | T-CELL MALIGNANCIES |
|-------------------|---|----------------------------------|---|---|-------------------------|---|
| BONE MARROW |  | CD10, 19, 20, 22 HLA-DR+, TdT |  |  | CD2, 7, 38, 71, TdT |  |
| |  | CD19, 20, 22, 21, 5 HLA-DR+ |  |  | CD1, 2, 4, 7, 8, 38 |  |
| |  | CD19, 20, 21, 22 HLA-DR+ |  |  | CD2, 3, 4, 5, 6, 7, TCR |  |
| LYMPHOID FOLLICLE |  | CD19, 20, 21, 22 HLA-DR+ |  |  | CD2, 3, 4, 5, 6, 7, TCR |  |
| |  | CD38, 19, 20, PCA-1+ |  |  | CD2, 3, 4, 5, 6, 7, TCR |  |
| FCC | | | | | | LN AND PERIPHERAL BLOOD |

(PCA = Plasma cell antigen; TCR = T cell receptor; FCC = Follicular centre B cells; LN = Lymph node; LL = Lymphoid leukaemia)

Figure 12.15 Schematic representation of WHO-REAL classification of lymphoid neoplasms. Various immunophenotypes of B and T-cell malignancies are correlated with normal immunophenotypic differentiation/maturation stages of B and T-cells in the bone marrow, lymphoid tissue, peripheral blood and thymus.

IV. Histiocytic and dendritic cell neoplasms

V. Post-transplant lymphoproliferative disorders (PTLDs).

Thus, in the WHO classification of lymphoid neoplasms, Hodgkin's disease stands distinctive; precursor or immature lymphoid malignancies of B or T-cell origin are blastic type of leukaemias-lymphomas (i.e. B or T-cell ALL), and peripheral or mature malignancies of B or T/NK cell origin are various other forms of non-Hodgkin's lymphomas and CLL.

COMMON TO ALL LYMPHOID MALIGNANCIES

Before plunging into discussion of various common examples in the WHO classification system, a few general aspects on lymphoid neoplasms need to be understood:

1. Overall frequency Five major forms of lymphoid malignancies and their relative frequency are as under:

- NHL= 62%, *most common lymphoma*
- HD= 8%
- Plasma cell disorders = 16%
- CLL= 9%, *most common lymphoid leukaemia*
- ALL= 4%

2. Incidence of B, T, NK cell malignancies Majority of lymphoid malignancies are of B cell origin (75% of lymphoid leukaemias and 90% of lymphomas) while remaining are T cell malignancies; NK-cell lymphomas-leukaemias are rare.

Relative frequency of subtypes within various common NHLs listed in **Table 12.8** is as under:

- Diffuse large B cell lymphoma = 31%
- Follicular lymphoma = 22%
- MALT lymphoma = 8%
- Mature T cell lymphoma = 8%
- Small lymphocytic lymphoma (SLL) = 7%
- Mantle cell lymphoma = 6%
- Mediastinal large B cell lymphoma = 2.5%
- Anaplastic large cell lymphoma (ALCL) = 2.5%
- Burkitt's lymphoma = 2.5%
- Others = ~10%

3. Diagnosis The diagnosis of lymphoma (both Hodgkin's and non-Hodgkin's) can only be reliably made on examination of lymph node biopsy. While the initial diagnosis of ALL and CLL can be made on CBC examination, bone marrow biopsy is done for genetic and immunologic studies. Subsequently, clinical chemistry, electrophoresis and tests for organ involvement including CSF examination if CNS involvement is suspected, need to be carried out.

4. Staging In both HD and NHL, Ann Arbor staging is done for proper evaluation and planning treatment.

5. Ancillary studies CT scan, PET scan and gallium scan are additional imaging modalities which can be used in staging HD and NHL cases.

Table 12.8 WHO Classification of Lymphoid Malignancies (2008).

- I) HODGKIN'S DISEASE
Nodular lymphocytic predominant HD
Classic HD
1. Nodular sclerosis HD
 2. Lymphocytic rich classic HD
 3. Mixed cellularity
 4. Lymphocytic depletion HD
- II) B CELL MALIGNANCIES
Precursor (Immature) B-cell malignancies
Precursor B lymphoblastic leukaemia/lymphoma (precursor B-cell ALL)
- Peripheral (Mature) B-cell malignancies*
1. Chronic lymphocytic leukemia/small lymphocytic lymphoma (B-cell CLL/SLL)
 2. B-cell prolymphocytic leukemia
 3. Splenic marginal zone lymphoma
 4. Hairy cell leukemia and variant
 5. Splenic lymphoma/leukemia
 6. Lymphoplasmacytic lymphoma
 7. Waldenström macroglobulinemia
 8. Heavy chain diseases (α, γ, μ)
 9. Plasma cell myeloma and plasmacytoma
 10. Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)
 11. Nodal marginal zone lymphoma
 12. Follicular lymphoma
 13. Mantle cell lymphoma
 14. Diffuse large B-cell lymphoma (DLBCL), NOS
 15. T-cell/histiocyte rich large B-cell lymphoma
 16. Primary mediastinal (thymic) large B-cell lymphoma
 17. Intravascular and ALK-positive large B-cell lymphoma
 18. Plasmablastic lymphoma
 19. Primary effusion lymphoma
 20. Burkitt lymphoma/leukaemia
- III) T CELL/NK CELL MALIGNANCIES
Precursor (Immature) T-cell malignancies
Precursor T lymphoblastic lymphoma/leukaemia (Precursor T-cell ALL)
- Peripheral (Mature) T-cell and NK-cell malignancies*
1. T-cell prolymphocytic leukemia
 2. T-cell large granular lymphocytic leukemia
 3. Chronic lymphoproliferative disorder of NK cells
 4. Aggressive NK-cell leukemia
 5. Systemic EBV-positive T-cell lymphoproliferative disease of childhood
 6. Adult T-cell leukemia/lymphoma
 7. Extranodal NK/T-cell lymphoma, nasal type
 8. Enteropathy-associated T-cell lymphoma
 9. Hepatosplenic T-cell lymphoma
 10. Mycosis fungoides/ Sézary syndrome
 11. Primary cutaneous T-cell lymphoproliferative disorders
 12. Peripheral T-cell lymphoma, NOS
 13. Angioimmunoblastic T-cell lymphoma
 14. Anaplastic large cell lymphoma (ALCL), ALK-positive and ALK-negative
- IV) HISTIOCYTIC AND DENDRITIC CELL NEOPLASMS
1. Histiocytic sarcoma
 2. Langerhans cell histiocytosis
 3. Langerhans cell sarcoma
 4. Dendritic cell sarcoma, interdigitating and follicular
- V) POST-TRANSPLANTATION LYMPHOPROLIFERATIVE DISORDERS (PTLDS)

Abbreviated from Campo et al. Blood 2011.

6. Immune abnormalities Since lymphoid neoplasms arise from immune cells of the body, immune derangements pertaining to the cell of origin may accompany these cancers. This is particularly so in B-cell malignancies and include occurrence of autoimmune haemolytic anaemia, autoimmune thrombocytopenia and hypogammaglobulinaemia.

**GIST BOX 12.7****Lymphoid Neoplasms: General**

- Conventionally, malignancies of lymphoid cells in blood have been termed as lymphatic leukaemias and those of lymphoid tissues as lymphomas. However, recent WHO classification has categorised these together because these neoplasms may present initially in blood and infiltrate tissues, and vice versa.
- FAB classification, Working Formulation for Clinical Usage, and REAL classification are the other systems of classifying these malignancies, which are based on morphology, cytochemistry, clinical features and prognosis.
- WHO classification is based on immunophenotyping and cytogenetics and molecular markers.
- While CLL is the most common lymphoid leukaemia, NHL is more common than Hodgkin's disease.

HODGKIN'S DISEASE

Hodgkin's disease (HD) primarily arises within the lymph nodes and involves the extranodal sites secondarily. This group comprises about 8% of all cases of lymphoid neoplasms. The incidence of the disease has bimodal peaks—one in young adults between the age of 15 and 35 years and the other peak after 5th decade of life. The HD is more prevalent in young adult males than females. The classical diagnostic feature is the presence of *Reed-Sternberg (RS) cell* (or *Dorothy-Reed-Sternberg cell*) (described later).

CLASSIFICATION

The diagnosis of HD requires accurate microscopic diagnosis by biopsy, usually from lymph node, and occasionally from other tissues. Unlike NHL, there is only one universally accepted classification of HD i.e. *Rye classification* adopted since 1966. Rye classification divides HD into the following 4 subtypes:

1. Lymphocyte-predominance type
2. Nodular-sclerosis type
3. Mixed-cellularity type
4. Lymphocyte-depletion type.

However, the WHO classification of lymphoid neoplasms divides HD into 2 main groups:

- I. Nodular lymphocyte-predominant HD (a new type).
- II. Classic HD (includes all the 4 above subtypes in the Rye classification).

Central to the diagnosis of HD is the essential identification of *Reed-Sternberg cell* though this is not the sole criteria (see below).

The salient features of the 4 histologic subtypes of HD are summarised in [Table 12.9](#).

REED-STERNBERG CELL

The diagnosis of Hodgkin's disease rests on identification of RS cells, though uncommonly similar cells can occur in infectious

Table 12.9 Modified WHO classification of Hodgkin's disease.

| HISTOLOGIC SUBTYPE | INCIDENCE | MAIN PATHOLOGY | RS CELLS | PROGNOSIS |
|---|-----------|---|--|--|
| I. CLASSIC HD | | | | |
| <i>Lymphocyte-predominance</i> | 5% | Proliferating lymphocytes, a few histiocytes | Few, classic and polyploid type, CD15-, CD30-, CD20+ | Excellent |
| <i>Nodular sclerosis</i> | 70% | Lymphoid nodules, collagen bands | Frequent, lacunar type, CD15+, CD30+ | Very good |
| <i>Mixed cellularity</i> | 22% | Mixed infiltrate | Numerous, classic type, CD15+, CD30+ | Good |
| <i>Lymphocyte-depletion (Diffuse fibrotic and reticular variants)</i> | 1% | Scanty lymphocytes, atypical histiocytes, fibrosis | Numerous, pleomorphic type, CD15+, CD30+ | Poor |
| II. NODULAR LYMPHOCYTE-PREDOMINANT HD | | | | |
| | 2% | Proliferation of small lymphocytes, nodular pattern of growth | Sparse number of RS cells, CD45+, EMA+, CD15-, CD30- | Chronic relapsing, may transform into large B cell NHL |

mononucleosis and other forms of lymphomas. Therefore, additional cellular and architectural features of the biopsy must be given due consideration for making the histologic diagnosis.

There are several morphologic variants of RS cells which characterise different histologic subtypes of HD (**Fig. 12.16**):

1. Classic RS cell This is a large cell which has characteristically a bilobed nucleus appearing as mirror image of each other but occasionally the nucleus may be multilobed. Each lobe of the nucleus contains a prominent, eosinophilic, inclusion-like nucleolus with a clear halo around it, giving an owl-eye appearance. The cytoplasm of cell is abundant and amphophilic.

2. Lacunar type RS cell It is smaller and in addition to above features has a pericellular space or lacuna in which it lies, which is due to artefactual shrinkage of the cell cytoplasm. It is characteristically found in nodular sclerosis variety of HD.

3. Polyploid type (or popcorn or lymphocytic-histiocytic i.e. L and H) RS cells These are seen in lymphocyte predominance type of HD. This type of RS cell is larger with lobulated nucleus in the shape of popcorn.

4. Pleomorphic RS cells These are a feature of lymphocyte depletion type. These cells have pleomorphic and atypical nuclei.

The nature and origin of RS cells, which are the real neoplastic cells in HD, have been a matter of considerable debate. One main reason for this difficulty in their characterisation is that in HD, unlike most other malignancies, the number of neoplastic cells (i.e. RS cells) is very small (less than 5%) which are interspersed in the predominant reactive cells. In general, the number of RS cells is inversely proportional to the number of lymphocytes in a particular histologic subtype of HD.

Immunophenotyping of RS cells reveals monoclonal lymphoid cell origin of RS cell from B-cells of the germinal centre in most subtypes of Hodgkin's disease. RS cells in all types of Hodgkin's diseases, except in lymphocyte predominance type, express immunoreactivity for CD15 and CD30 (**Fig. 12.17**). RS cells in lymphocyte predominance type, however, are negative for both CD15 and CD30, but positive for CD20.

RS cells are invariably accompanied by variable number of *atypical Hodgkin cells* which are believed to be precursor

RS cells but are not considered diagnostic of HD. Hodgkin cells are large mononuclear cells (rather than mirror image nuclei) having nuclear and cytoplasmic similarity to that of RS cell.

MORPHOLOGIC FEATURES

Grossly, the gross appearance of Hodgkin's and non-Hodgkin's lymphoma is much the same. Any lymph node group may be involved but most commonly affected are the cervical, supraclavicular and axillary groups. Initially, the lymph nodes are discrete and separate from one another but later the lymph nodes form a large matted mass due to infiltration into the surrounding connective tissue. Extranodal involvements produce either a discrete tumour or diffuse enlargement of the affected organ. The sectioned surface of the involved lymph nodes or extranodal organ involved appears grey-white and fishflesh-like. *Nodular sclerosis type HD* may show formation of nodules due to scarring while *mixed cellularity* and *lymphocyte depletion types HD* may show abundance of necrosis. Lymphomatous involvement of the liver, spleen and other organs may be diffuse or may form spherical masses similar to metastatic carcinoma.

Microscopically, the criteria for diagnosis of histologic subtypes of HD are as under:

I. CLASSIC HD

As per WHO classification, classic group of HD includes 4 types of HD of older Rye classification:

1. Lymphocyte-predominance type (Fig. 12.16,A) The lymphocyte-predominance type of HD is characterised by proliferation of small lymphocytes admixed with a varying number of histiocytes forming nodular or diffuse pattern.

i) *Nodular form* is characterised by replacement of nodal architecture by numerous large neoplastic nodules.

ii) *Diffuse form* does not have discernible nodules but instead there is diffuse proliferation of cells.

However, currently nodular form of lymphocyte predominant HD has been categorised separately due to its distinct immunophenotyping features and prognosis (discussed below).

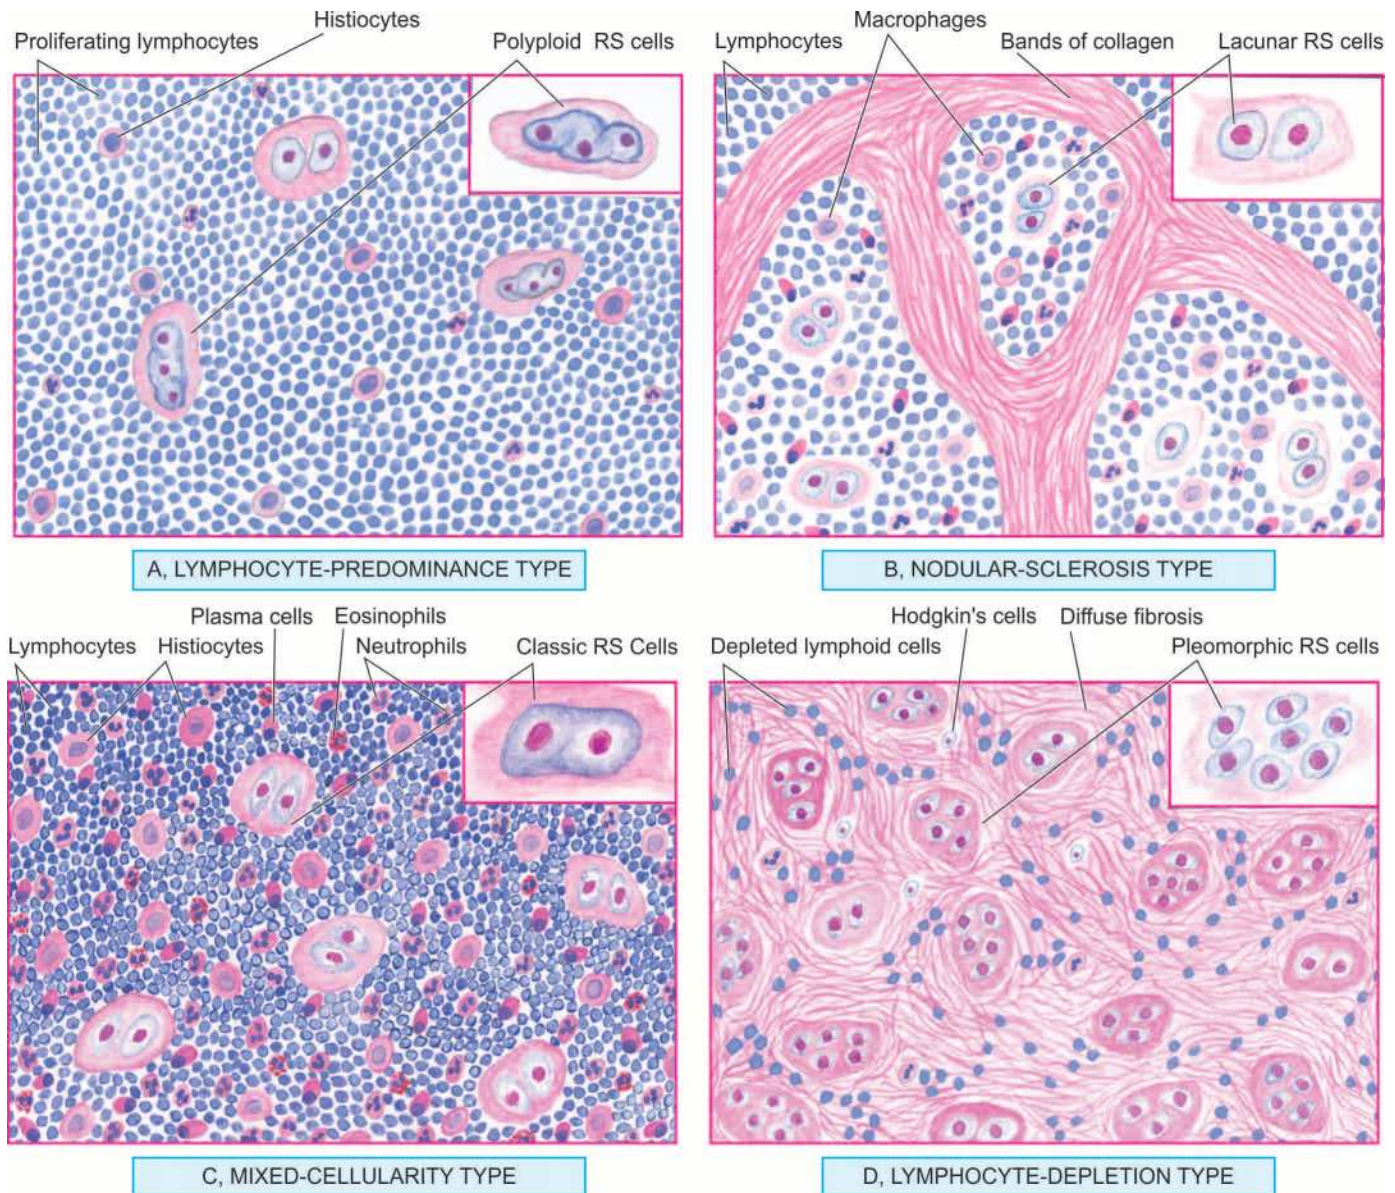

Figure 12.16 Microscopic features of 4 forms of Hodgkin's disease of lymph node. The inset on right side of each type shows the morphologic variant of RS cell seen more often in particular histologic type.

For making the diagnosis, definite demonstration of RS cells is essential which are few in number, requiring a thorough search. In addition to typical RS cells, *polyloid variant* having polyloid, and twisted nucleus (popcorn-like) may be found in some cases. This type of HD usually does not show other cells like plasma cells, eosinophils and neutrophils, nor are necrosis or fibrosis seen.

2. Nodular-sclerosis type (Fig. 12.16,B) Nodular sclerosis is the most frequent type of HD, seen more commonly in women than in men. It is characterised by two essential features (Fig. 12.18, A):

- i) *Bands of collagen*: Variable amount of fibrous tissue is characteristically present in the involved lymph nodes. Occasionally, the entire lymph node may be replaced by dense hyalinised collagen.
- ii) *Lacunar type RS cells*: Characteristic lacunar type of RS cells with distinctive pericellular halo are present. These cells appear lacunar due to the shrinkage of cytoplasm in

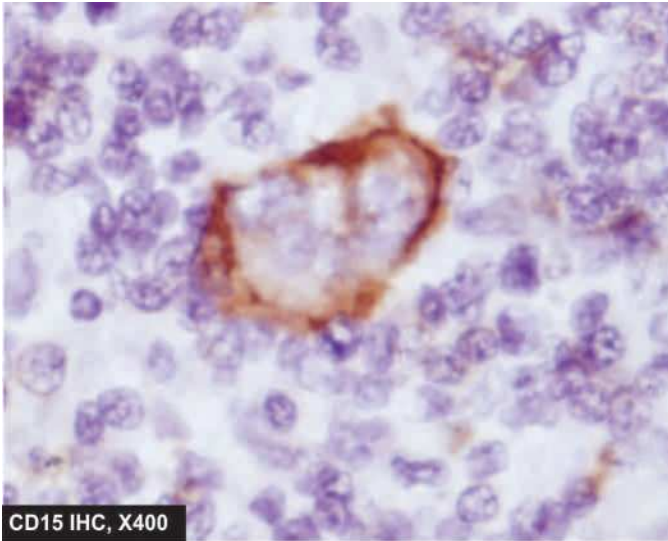

formalin-fixed tissue. The pericellular halo is not seen if the tissue is fixed in Zenker's fluid.

In addition to these 2 characteristics, the nodules between the fibrous septa consist predominantly of lymphocytes and macrophages, sometimes with foci of necrosis.

3. Mixed-cellularity type (Fig. 12.16,C) This form of HD generally replaces the entire affected lymph nodes by heterogeneous mixture of various types of apparently normal cells. These include proliferating lymphocytes, histiocytes, eosinophils, neutrophils and plasma cells. Some amount of fibrosis and focal areas of necrosis are generally present. Typical RS cells are frequent (Fig. 12.18, B).

4. Lymphocyte-depletion type (Fig. 12.16,D) In this type of HD, the lymph node is depleted of lymphocytes. There are two variants of lymphocyte-depletion HD:

- i) *Diffuse fibrotic variant* is hypocellular and the entire lymph node is replaced by diffuse fibrosis, appearing as homogeneous, fibrillar hyaline material. The area of

CD15 IHC, X400

Figure 12.17 RS cells showing positive immunostaining for CD15, a B-cell marker.

hyalinosis contains some lymphocytes, atypical histiocytes (Hodgkin cells), and numerous typical and atypical (pleomorphic) RS cells.

ii) *Reticular variant* is much more cellular and consists of large number of atypical pleomorphic histiocytes, scanty lymphocytes and a few typical RS cells.

II. NODULAR LYMPHOCYTE-PREDOMINANT HD

This is a newly described entity which is distinct from the classic HD described above. This type was previously included in lymphocyte predominant type of HD. Its peculiarities are as under:

- i) These cases of HD have a nodular growth pattern (similar to nodular sclerosis type).
- ii) Like lymphocyte-predominant pattern of classic type, there is predominance of small lymphocytes with sparse number of RS cells.

iii) These cases of HD have distinctive immunophenotyping—CD45 positive, epithelial membrane antigen (EMA) positive but negative for the usual markers for RS cells (CD15 and CD30 negative).

iv) Though generally it has a chronic relapsing course, but some cases of this type of HD may transform into large B-cell NHL.

CLINICAL FEATURES

Hodgkin's disease is particularly frequent among young and middle-aged adults. All histologic subtypes of HD, except the nodular sclerosis variety, are more common in males. The disease usually begins with superficial lymph node enlargement and subsequently spreads to other lymphoid and non-lymphoid structures.

1. Most commonly, patients present with painless, movable and firm *lymphadenopathy*. The cervical and mediastinal lymph nodes are involved most frequently. Other lymph node groups like axillary, inguinal and abdominal are involved sometimes.

2. Approximately half the patients develop *splenomegaly* during the course of the disease. *Liver enlargement* too may occur.

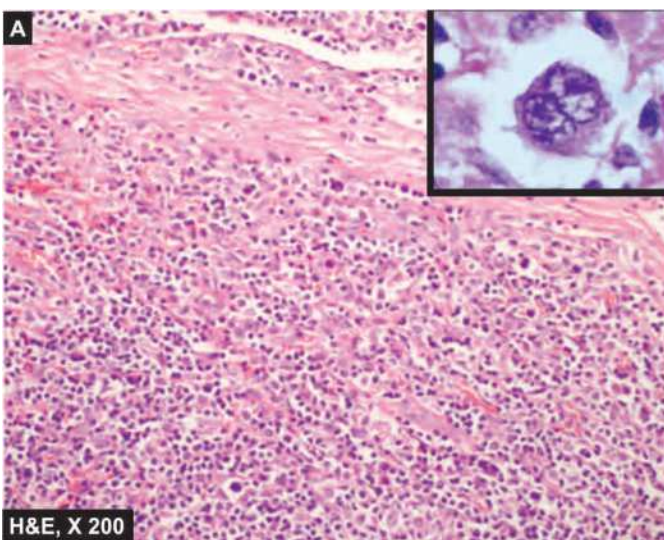

3. *Constitutional symptoms* (type B symptoms) are present in 25-40% of patients. The most common is low-grade fever with night sweats and weight loss. Other symptoms include fatigue, malaise, weakness and pruritus.

OTHER LABORATORY FINDINGS

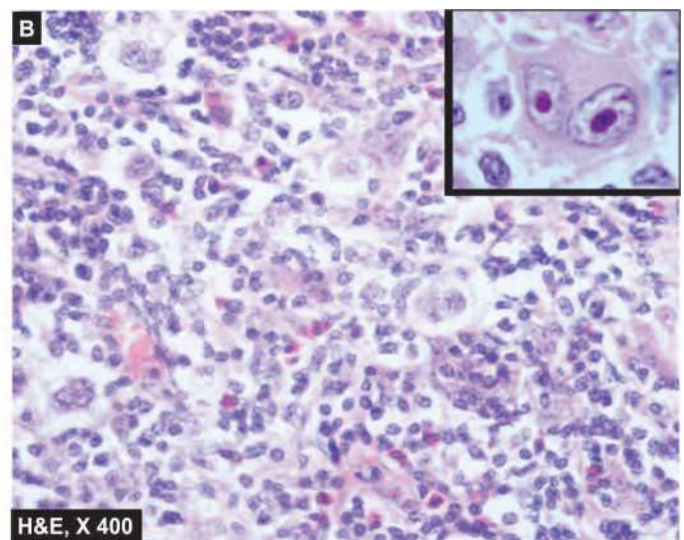

Besides clinical and pathologic findings, there are some haematologic and immunologic abnormalities in HD.

Haematologic abnormalities

1. A moderate, normocytic and normochromic *anaemia* is often present.
2. *Serum iron and TIBC* are low but marrow iron stores are normal or increased.
3. *Marrow infiltration* by the disease may produce marrow failure with leucoerythroblastic reaction.

Figure 12.18 Hodgkin's disease. A, Nodular sclerosis type. There are bands of collagen forming nodules and characteristic lacunar RS cells (inbox in left figure). B, Mixed cellularity type. There is admixture of mature lymphocytes, plasma cells, neutrophils and eosinophils and classic RS cells in the centre of the field (inbox in right figure).

Table 12.10 Ann Arbor staging classification of Hodgkin's disease.

| | | |
|-----------------------|-------------------|--|
| Stage I (A or B) | I | Involvement of a single lymph node region. |
| | I _E | Involvement of a single extra-lymphatic organ or site. |
| Stage II (A or B) | II | Involvement of two or more lymph node regions on the same side of the diaphragm. |
| | II _E | (or) with localised contiguous involvement of an extranodal organ or site. |
| Stage III (A or B) | III | Involvement of lymph node regions on both sides of the diaphragm. |
| | III _E | (or) with localised contiguous involvement of an extranodal organ or site. |
| | III _S | (or) with involvement of spleen. |
| | III _{ES} | (or) both features of III _E and III _S . |
| Stage IV (A or B) | IV | Multiple or disseminated involvement of one or more extra-lymphatic organs or tissues with or without lymphatic involvement. |

(A = Asymptomatic; B = Presence of constitutional symptoms; E = Extranodal involvement; S = Splenomegaly).

4. *Routine blood counts* reveal moderate leukaemoid reaction. Cases with pruritus frequently show peripheral eosinophilia. Advanced disease is associated with absolute lymphopenia.

5. *Platelet count* is normal or increased.

6. *ESR* is invariably elevated.

Immunologic abnormalities

1. There is progressive fall in immunocompetent T-cells with *defective cellular immunity*. There is reversal of CD4: CD8 ratio and anergy to routine skin tests.

2. *Humoral antibody production* is normal in untreated patients until late in the disease.

STAGING

Following biopsy and histopathologic classification of HD, the extent of involvement of the disease (i.e. staging) is studied in order to select proper treatment and assess the prognosis. *Ann Arbor staging classification* takes into account both clinical and pathologic stage of the disease.

The suffix *A* or *B* are added to the above stages depending upon whether the three constitutional symptoms (fever, night sweats and unexplained weight loss exceeding 10% of normal) are absent (*A*) or present (*B*). The suffix *E* or *S* are used for extranodal involvement and splenomegaly respectively (**Table 12.10**).

For complete staging, a number of other *essential diagnostic studies* are recommended. These are as under:

1. Detailed physical examination including sites of nodal involvement and splenomegaly.
2. Chest radiograph to exclude mediastinal, pleural and lung parenchymal involvement.
3. CT scan of abdomen and pelvis.
4. Documentation of constitutional symptoms (*B* symptoms).
5. Laboratory evaluation of complete blood counts, liver and kidney function tests.
6. Bilateral bone marrow biopsy.
7. Finally, histopathologic documentation of the type of Hodgkin's disease.

More invasive investigations include *lymphangiography of lower extremities* and *staging laparotomy*. Staging laparotomy includes biopsy of selected lymph nodes in the retroperitoneum, splenectomy and wedge biopsy of the liver.

PROGNOSIS

With use of aggressive radiotherapy and chemotherapy, the outlook for Hodgkin's disease has improved significantly. Although several factors affect the prognosis, two important considerations in evaluating its outcome are the *extent of involvement by the disease (i.e. staging)* and the *histologic subtype*.

With appropriate treatment, the overall 5 years survival rate for *stage I and II A* is as high as about 100%, while the advanced stage of the disease may have upto 50% 5-year survival rate.

◆ Patients with *lymphocyte-predominance type* of HD tend to have localised form of the disease and have excellent prognosis.

◆ *Nodular sclerosis* variety too has very good prognosis but those patients with larger mediastinal mass respond poorly to both chemotherapy and radiotherapy.

◆ *Mixed cellularity type* occupies intermediate clinical position between the lymphocyte predominance and the lymphocyte-depletion type, but patients with disseminated disease and systemic manifestations do poorly.

◆ *Lymphocyte-depletion type* is usually disseminated at the time of diagnosis and is associated with constitutional symptoms. These patients usually have the most aggressive form of the disease.

The salient features to distinguish Hodgkin's disease and non-Hodgkin's lymphoma are summarised in **Table 12.11**.

GIST BOX 12.8

Hodgkin's Disease

- Hodgkin's disease (HD) primarily arises within the lymph nodes and involves the extranodal sites secondarily.
- Based on microscopy, HD is divided into classic and nodular lymphocyte predominant. Classic type has further 4 types: lymphocyte predominance, nodular sclerosis (most common), mixed cellularity, and lymphocyte depletion type (least common).
- Prognosis of lymphocyte predominance HD is excellent followed by nodular sclerosis and mixed cellularity. Lymphocyte-depletion HD has worst outcome.
- Clinically, patients of HD have lymphadenopathy, and may have splenomegaly, hepatomegaly and constitutional symptoms.
- Ann Arbor staging is followed for HD. Nodular sclerosis type has the best prognosis while lymphocyte depletion type has the worst prognosis.
- Various types of HD are diagnosed by biopsy and characteristic Reed-Sternberg cells.

NON-HODGKIN'S LYMPHOMAS-LEUKAEMIAS

Non-Hodgkin's lymphomas (NHLs) and lymphoid leukaemias comprise a large group of heterogeneous of neoplasms of lymphoid tissues and blood. As outlined in **Table 12.8**, NHLs have several types and are far more common (62%) than HD (8%). Some common and important examples are discussed in detail below while others are only briefly mentioned.

Table 12.11 Contrasting features of Hodgkin's disease and non-Hodgkin's lymphoma.

| FEATURE | HODGKIN'S | NON-HODGKIN'S |
|----------------------------|---|---------------------------|
| 1. Cell derivation | B-cell mostly | 90% B 10% T |
| 2. Nodal involvement | Localised, may spread to contiguous nodes | Disseminated nodal spread |
| 3. Extranodal spread | Uncommon | Common |
| 4. Bone marrow involvement | Uncommon | Common |
| 5. Constitutional symptoms | Common | Uncommon |
| 6. Chromosomal defects | Aneuploidy | Translocations, deletions |
| 7. Spill-over | Never | May spread to blood |
| 8. Prognosis | Better (75-85% cure) | Bad (30-40% cure) |

PRECURSOR (IMMATURE) B- AND T-CELL LEUKAEMIA/LYMPHOMA (SYNONYM: ACUTE LYMPHOBLASTIC LEUKAEMIA)

Lymphoid malignancy originating from precursor series of B or T cell (i.e. pre-B and pre-T) is the most common form of cancer of children under 4 years of age, together constituting 4% of all lymphoid malignancies. Pre-B cell ALL constitutes 90% cases while pre-T cell lymphoid malignancies comprise the remaining 10%. This group of lymphoid malignancies arises from more primitive stages of B or T cells but the stage of differentiation is not related to aggressiveness. Both these are presented together because of morphologic similarities.

CLINICAL FEATURES

PRECURSOR B-CELL LYMPHOBLASTIC LEUKAEMIA/LYMPHOMA Most often, it presents as ALL in children; rarely presentation may be in the form of lymphoma in children or adults and it rapidly transforms into leukaemia. In cases having leukaemic presentation, extranodal site involvement is early such as lymphadenopathy accompanied with hepatomegaly,

splenomegaly, CNS infiltration, testicular enlargement, and at times cutaneous infiltration. Infections due to cytopenia are present.

PRECURSOR T-CELL LYMPHOBLASTIC LEUKAEMIA/LYMPHOMA As the name implies, these cases may present as ALL or as lymphoma. Since the precursor T-cells differentiate in the thymus, this tumour often presents as mediastinal mass and pleural effusion and progresses rapidly to develop leukaemia in the blood and bone marrow. Clinically, features of bone marrow failure are present which include anaemia, neutropenia and thrombocytopenia. Lymphadenopathy, hepatosplenomegaly and CNS involvement are frequent.

Precursor T-cell lymphoma-leukaemia is, however, more aggressive than its B-cell counterpart.

MORPHOLOGIC FEATURES

Precursor B and T-cell ALL/lymphoma are indistinguishable on routine morphology. The diagnosis is made by following investigations:

1. Blood examination Peripheral blood generally shows anaemia and thrombocytopenia, and may show leucopenia-to-normal TLC to leucocytosis. DLC shows large number of circulating lymphoblasts (generally in excess of 20%) having round to convoluted nuclei, high nucleo-cytoplasmic ratio and absence of cytoplasmic granularity. It is important to distinguish AML from ALL; the morphologic features of myeloblasts and lymphoblasts are contrasted in Table 12.1. Typical characteristics of different forms of ALL (L1 to L3) are given in Table 12.6. It is usual to find some 'smear cells' in the peripheral blood which represent degenerated leucocytes (Fig. 12.19).

2. Bone marrow examination Marrow examination shows 20-95% malignant undifferentiated cells of precursor B or T cell origin as demonstrated by immunophenotyping. Megakaryocytes are usually reduced or absent.

3. Cytochemistry Cytochemical stains may be employed as an adjunct to Romanowsky staining for determining the type of leukaemia. Some of the commonly employed cytochemical stains in characterisation of leukaemic blasts in ALL are as under:

i) *Periodic acid-Schiff (PAS)*: Positive in immature lymphoid cells in ALL.

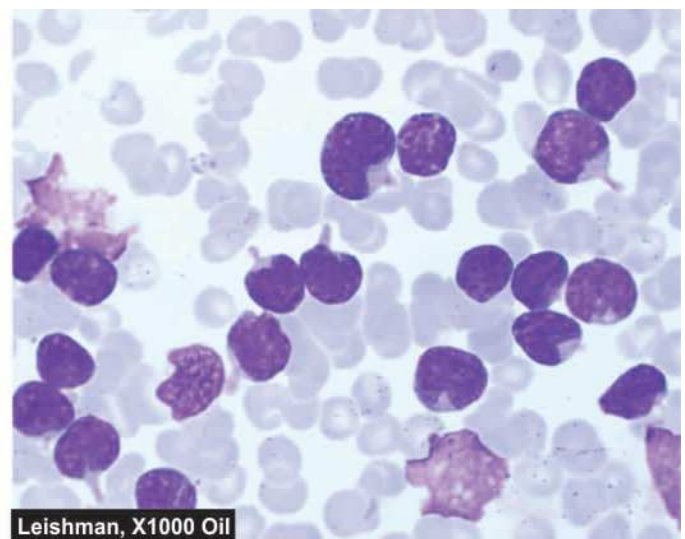

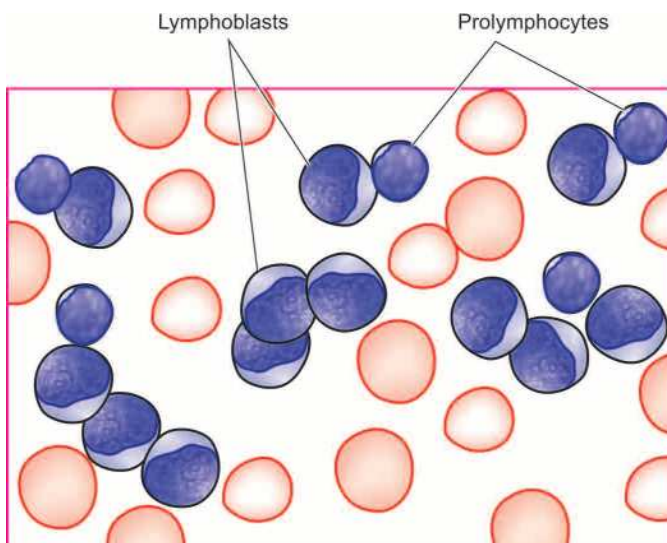

Figure 12.19 PBF findings in acute lymphoblastic leukaemia (ALL). The cells are large, with round to convoluted nuclei having high N/C ratio and no cytoplasmic granularity. A few degenerated cells (smear cells) are also seen.

ii) *Acid phosphatase*: Focal positivity in leukaemic blasts in ALL.

iii) *Myeloperoxidase*: Negative in immature cells in ALL.

iv) *Sudan Black*: Negative in immature cells in ALL.

v) *Non-specific esterase (NSE)*: Negative in ALL.

Immunophenotyping TdT (terminal deoxynucleotidyl transferase) is expressed by the nuclei of both pre-B and pre-T stages of differentiation of lymphoid cells. Specific diagnosis is established by following immunophenotyping:

Pre-B-cell type: Typically positive for pan-B cell markers CD19, CD10, CD9a.

Pre-T-cell type: Typically positive for CD1, CD2, CD3, CD5, CD7.

Cytogenetic analysis Leukaemic blasts in pre-B-cell ALL show characteristic cytogenetic abnormality of t(9;22) i.e. Philadelphia positive-ALL.

PRINCIPLES OF TREATMENT AND PROGNOSIS

Treatment plan for children with pre-B or pre-T cell ALL is intensive remission induction with combination therapy. Patients presenting with pre-B or pre-T cell lymphoma are treated as a case of ALL.

CHEMOTHERAPY The most useful drugs in the treatment of ALL are combination of vincristine, prednisolone,

anthracyclines (daunorubicin, adriamycin) and L-asparaginase. Other agents used are cytosine arabinoside and methotrexate. Though 90% of children with ALL show remission with this therapy, patients with T cell ALL and those with meningeal involvement carry a less favourable prognosis. CNS involvement is beyond the reach of most of the cytotoxic drugs used in the therapy of ALL. CNS prophylaxis in such cases is considered after the initial remission has been obtained and includes cranial irradiation and course of intrathecal methotrexate or cytosine arabinoside.

BONE MARROW TRANSPLANTATION Bone marrow (Stem cell) transplantation from suitable allogenic or autologous donor (HLA and mixed lymphocytes culture-matched) is used in preB and pre-T cell ALL in adults with relapses. Bone marrow transplantation has resulted in cure in about half the cases.

Prognosis and disease-free survival of children with both pre-B cell and pre-T cell ALL is better than in adults. Mean survival with treatment in children without CNS prophylaxis is 33 months, while with CNS prophylaxis is 60 months or more. Adult pre-T cell ALL, however, is as grave as AML and median survival is 12-18 months. Patients having limited disease confined to lymph nodes in both pre-B and pre-T cell type have a higher cure rate and better prognosis.

The salient differences between the two main forms of acute leukaemia (AML and ALL) are summarised in **Table 12.12**.

Table 12.12 Contrasting Features of AML and ALL.

| FEATURE | AML | ALL |
|-------------------------------|---|--|
| 1. <i>Common age</i> | Adults between 15-40 years; comprise 20% of childhood leukaemias | Children under 15 years; comprise 80% of childhood leukaemias |
| 2. <i>Physical findings</i> | Splenomegaly + Hepatomegaly + Lymphadenopathy + Bony tenderness + Gum hypertrophy + | Splenomegaly ++ Hepatomegaly ++ Lymphadenopathy ++ Bony tenderness + CNS involvement + |
| 3. <i>Laboratory findings</i> | Low-to-high TLC Predominance of myeloblasts and promyelocytes in blood and bone marrow Thrombocytopenia moderate to severe. | Low-to-high TLC Predominance of lymphoblasts in blood and bone marrow Thrombocytopenia moderate to severe. |
| 4. <i>Diagnostic criteria</i> | FAB types M0-M7 WHO criteria = >20% blasts | FAB types L1-L3, WHO types Pre B (90%) Pre T (10%) WHO criteria = >20% blasts |
| 5. <i>Cytochemical stains</i> | Myeloperoxidase +, Sudan black +, NSE + in M4 and M5, acid phosphatase (diffuse) + in M4 and M5 | PAS +, acid phosphatase (focal) + |
| 6. <i>Specific therapy</i> | Cytosine arabinoside, anthracyclines (daunorubicin, adriamycin) and 6-thioguanine | Vincristine, prednisolone, anthracyclines and L-asparaginase |
| 7. <i>Immunophenotyping</i> | CD13, 33, 41, 42 | Both B and T cell ALL TdT +ve Pre B: CD19, 20 Pre T: CD1, 2, 3, 5, 7 |
| 8. <i>Cytogenetics</i> | M3: t(15;17) M4: in(16) | Pre B: t(9;21) |
| 9. <i>Response to therapy</i> | Remission rate low, duration of remission shorter | Remission rate high, duration of remission prolonged |
| 10. <i>Median survival</i> | 12-18 months | Children without CNS prophylaxis 33 months, with CNS prophylaxis 60 months; adults 12-18 months |

GIST BOX 12.9

ALL (Precursor B- and T-Cell Leukaemia/Lymphoma)

- ▣ ALL is lymphoid malignancy of precursor series of B or T cells and is the most common cancer in children under 4 years of age; T cell type being more aggressive.
- ▣ It may have leukaemic presentation or as lymphoma with involvement of extranodal sites.
- ▣ As per FAB classification, ALL is further of 3 types: L1 (B/T cell childhood type), L2 (adult T cell type) and L3 (Burkitt type B cell) leukaemia.
- ▣ Blood examination shows leucocytosis, large number of undifferentiated lymphoblasts (20-95%) and thrombocytopenia.

PERIPHERAL(MATURE) B-CELL MALIGNANCIES

Peripheral or mature B-cell cancers are the most common lymphoid malignancies. These arise from the stage of lymphoid cells at which they become committed to B cell development, acquire surface characteristics and begin to secrete immunoglobulins. This group includes following common examples.

CHRONIC LYMPHOCYTIC LEUKAEMIA/ SMALL LYMPHOCYTIC LYMPHOMA (B-CELL CLL/SLL)

As the name implies, this subtype may present as leukaemia or lymphoma constituting 9% of all lymphoid neoplasms. As lymphoid leukaemia (CLL), this is the most common form while as SLL it constitutes 7% of all NHLs. B-cell CLL/SLL occurs more commonly in middle and older age groups (over 50 years of age) with a male preponderance (male-female ratio 2:1).

Clinical Features

The condition may remain asymptomatic, or may have an insidious onset and may present with nonspecific clinical features. Common presenting manifestations are as under:

1. Features of *anaemia* such as gradually increasing weakness, fatigue and dyspnoea.

2. Enlargement of superficial *lymph nodes* is a very common finding. The lymph nodes are usually symmetrically enlarged, discrete and non-tender.
3. *Splenomegaly* and *hepatomegaly* are usual.
4. *Haemorrhagic manifestations* are found in case of CLL with thrombocytopenia.
5. *Susceptibility to infections*, particularly of respiratory tract, is common in CLL.
6. *Less common findings* are: mediastinal pressure, tonsillar enlargement, disturbed vision, and bone and joint pains.

Morphologic Features

The diagnosis of CLL can usually be made on the basis of physical findings and blood smear examination (**Fig. 12.20**):

I. BLOOD PICTURE The findings of routine blood picture are as under:

1. Anaemia Anaemia is usually mild to moderate and normocytic normochromic in type. Mild reticulocytosis may be present. About 20% cases develop a Coombs'-positive autoimmune haemolytic anaemia.

2. White blood cells Typically, there is marked leucocytosis but less than that seen in CML (50,000-200,000/ μ l). Usually, more than 90% of leucocytes are mature small lymphocytes. Smudge or basket cells (degenerated forms) are present due to damaged nuclei of fragile malignant lymphocytes. The absolute neutrophil count is, however, generally within normal range. Granulocytopenia occurs when disease is fairly advanced.

3. Platelets The platelet count is normal or moderately reduced as an autoimmune phenomenon.

II. BONE MARROW EXAMINATION The typical findings are as under:

1. Increased lymphocyte count (25-95%).
2. Reduced myeloid precursors.
3. Reduced erythroid precursors.

III. LYMPH NODE BIOPSY Cases with lymphadenopathy at presentation show replacement of the lymph node

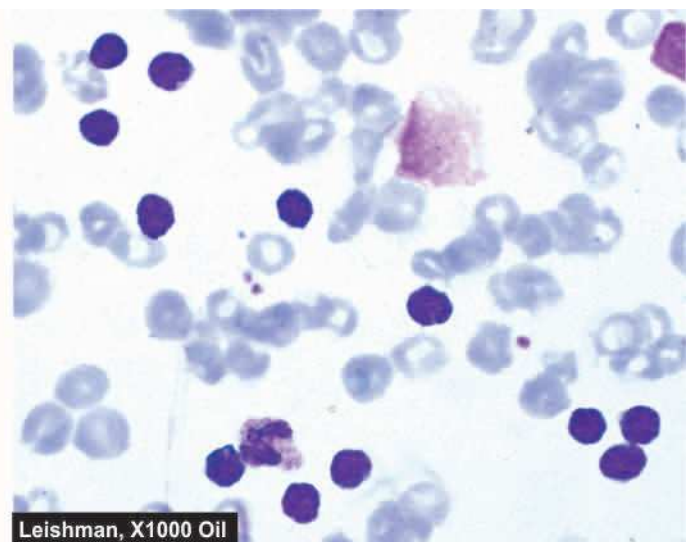

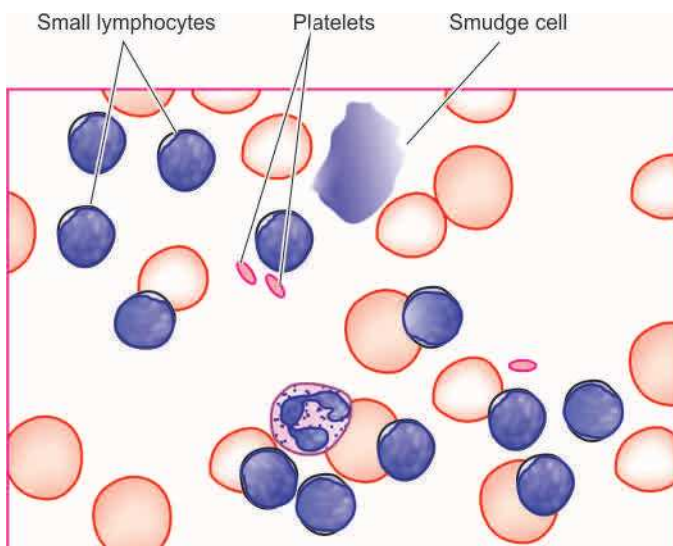

Figure 12.20 PBF in chronic lymphocytic leukaemia (CLL). There is large excess of mature and small differentiated lymphocytes and some degenerated forms appearing as bare smudged nuclei.

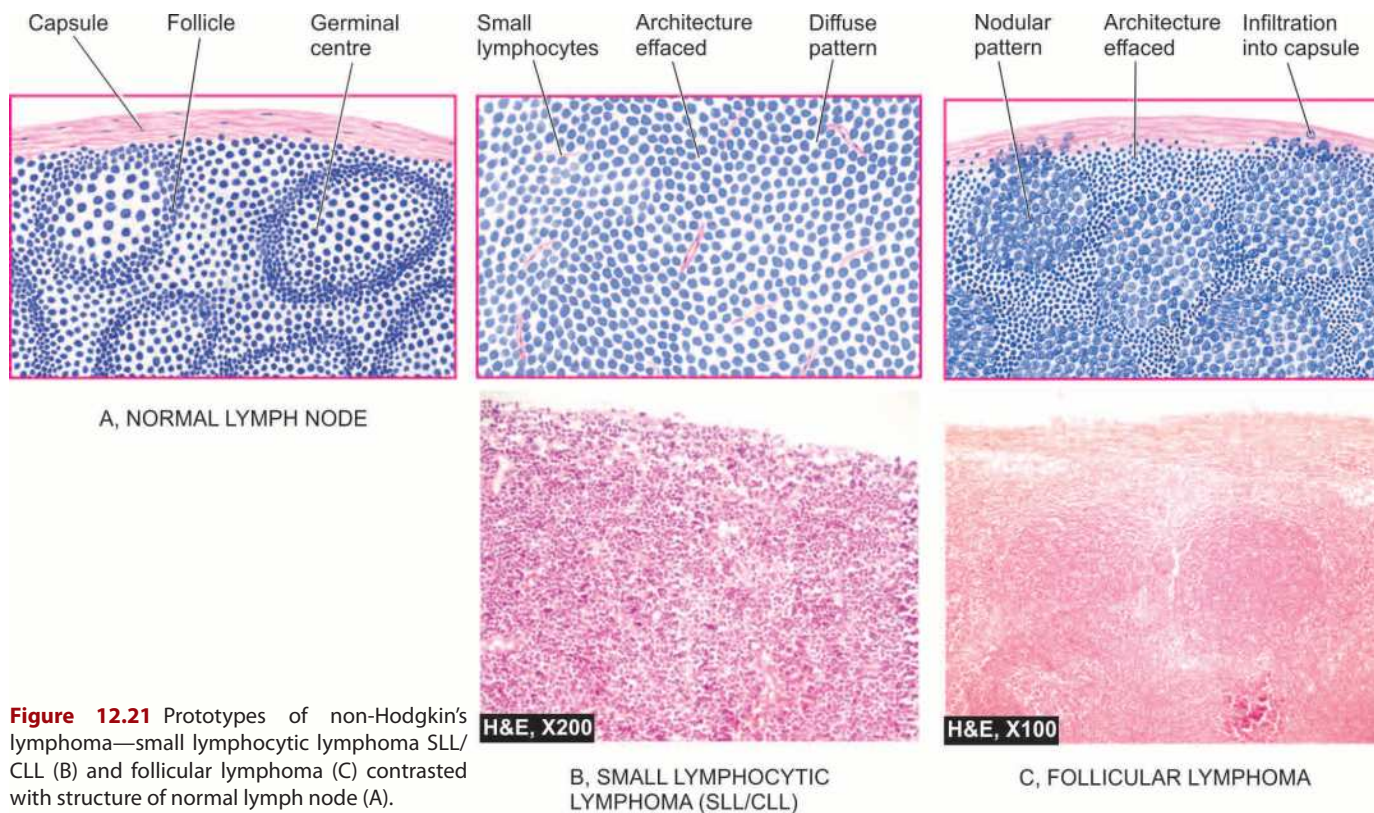

Figure 12.21 Prototypes of non-Hodgkin's lymphoma—small lymphocytic lymphoma SLL/CLL (B) and follicular lymphoma (C) contrasted with structure of normal lymph node (A).

by diffuse proliferation of well-differentiated, mature, small and uniform lymphocytes without any cytologic atypia or significant mitoses (**Fig. 12.21,B**). These cells are of monoclonal B-cell origin having immunologic features of mantle zone B-cells.

IV. OTHER INVESTIGATIONS These include the following:

1. *Erythrocyte rosette test* with mouse red cells is positive in more than 95% of cases indicating that CLL is a monoclonal B cell neoplasm.
2. *Positive for B-cell markers* e.g. typically CD5 positive; other pan-B cell markers are CD19, CD20, CD23, surface immunoglobulins of various classes, monoclonal light chains (λ or κ type).
3. *Serum immunoglobulin levels* are generally reduced.
4. *Coombs' test* is positive in 20% cases.
5. *Cytogenetic abnormalities*, most commonly trisomy 12 seen in about 25% cases.

Treatment Plan and Prognosis

Unlike other leukaemias, none of the available drugs and radiation therapy are capable of eradicating CLL and induce true complete remission. Treatment is, therefore, palliative and symptomatic, and with optimal management patient can usually lead a relatively normal life for several years. These approaches include: alkylating drugs (e.g. chlorambucil, cyclophosphamide), corticosteroids and radiotherapy. Splenectomy is indicated in cases of CLL with autoimmune haemolytic anaemia.

Prognosis of CLL/SLL is generally better than CML since *blastic transformation seldom occurs*. Prognosis correlates with the stage of disease as under:

Stage A: characterised by lymphocytosis alone, or with limited lymphadenopathy, has a good prognosis (median survival more than 10 years).

Stage B: having lymphocytosis with associated significant lymphadenopathy and hepatosplenomegaly has intermediate prognosis (median survival about 5 years).

Stage C: having lymphocytosis with associated anaemia and thrombocytopenia has a worse prognosis (median survival of less than 2 years).

Generally, the course is indolent. However, some cases of SLL may transform into more aggressive diffuse large B-cell lymphoma, or may be associated with occurrence of an IgM monoclonal gammopathy called Waldenström's macroglobulinaemia (page 364).

FOLLICULAR LYMPHOMA

In the earlier classification schemes, follicular lymphoma was known as nodular (poorly-differentiated) or follicular lymphoma (predominantly small/large cleaved cell type). Follicular lymphomas comprise approximately 22% of all NHLs. Follicular lymphomas occur in older individuals, most frequently presenting with painless peripheral lymphadenopathy which is usually waxing and waning type. In contrast to diffuse lymphomas, extranodal involvement is also infrequent.

MORPHOLOGIC FEATURES Following features are seen:

Lymph node biopsy As the name suggests, follicular lymphoma is characterised by follicular or nodular pattern of growth. The nuclei of tumour cells may vary from predominantly small cleaved (or indented) to predominantly large

cleaved variety (**Fig. 12.21,C**). The former is more common, has infrequent mitoses and the rate of growth slow (low grade), while the patients with large cell lymphoma have high proliferation and progress rapidly (high grade). In all follicular lymphomas, the tumour cells are positive for pan-B markers such as CD19 and CD20 along with expression of *BCL-2* protein (for distinction from normal germinal centre which is *BCL-2* negative). Cytogenetic studies show characteristic translocation t(14;18) in tumour cells.

Blood and bone marrow Peripheral blood involvement as occurs in SLL is uncommon in this variety. Infiltration in the bone marrow is typically paratrabecular.

About half the cases of low-grade follicular lymphomas, during their indolent biologic course, may evolve into diffuse large B-cell lymphoma. Median survival for patients with low grade follicular lymphoma is 7-9 years.

DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL)

Diffuse large B-cell lymphoma (DLBCL), earlier termed as diffuse poorly-differentiated lymphocytic lymphoma or follicular centre cell diffuse large, cleaved/non-cleaved lymphoma, is the most common comprising about 31% of all NHLs. It occurs in older patients with mean age of 60 years. It may present primarily as a lymph node disease or at extranodal sites. About half the cases have extranodal involvement at the time of presentation, particularly in the bone marrow and the alimentary tract. Primary diffuse large B-cell lymphoma of CNS may also occur.

A few subtypes of diffuse large B-cell lymphoma are described with distinct clinicopathologic settings:

- i) *Epstein-Barr virus (EBV)* infection has been etiologically implicated in diffuse large B-cell lymphoma in *immunosuppressed patients* of AIDS and organ transplant cases.
- ii) *Human herpes virus type 8 (HHV-8)* infection along with presence of immunosuppression is associated with a subtype of diffuse large B-cell lymphoma presenting with effusion, termed *primary effusion lymphoma*.
- iii) *Mediastinal large B-cell lymphoma* is diagnosed in patients with prominent involvement of mediastinum, occurs in young females and frequently spreads to CNS and abdominal viscera.

MORPHOLOGIC FEATURES DLBCL is the diffuse counterpart of follicular large cleaved cell lymphoma i.e. it is composed of large cleaved cells spread in a diffuse pattern. The cytoplasm in these tumour cells is pale and abundant while the nuclei have prominent 1-2 nucleoli. Immunophenotypic markers for pan-B cells (CD19, CD20) are positive, besides overexpression of surface immunoglobulins (IgM, IgG and light chains) and of *BCL-2* protein.

In general, DLBCL is aggressive tumour and disseminates widely.

BURKITT'S LYMPHOMA/LEUKAEMIA

Burkitt's lymphoma/leukaemia is an uncommon tumour in adults but comprises about 30% of childhood NHLs. Burkitt's leukaemia corresponds to L3 ALL of FAB grouping and is uncommon. Three subgroups of Burkitt's lymphoma are

recognised: *African endemic, sporadic and immunodeficiency-associated*:

- i) *African endemic Burkitt's lymphoma* was first described in African children, predominantly presenting as jaw tumour that spreads to extranodal sites such as the bone marrow and meninges. The relationship of this tumour with oncogenic virus, Epstein-Barr virus (EBV), has been discussed in Chapter 7.
- ii) *Sporadic Burkitt's lymphoma* is a related tumour in which the tumour cells are similar to those of Burkitt's lymphoma but are more pleomorphic and may sometimes be multinucleated. Sporadic variety has a propensity to infiltrate the CNS and is more aggressive than true Burkitt's lymphoma.
- iii) *Immunodeficiency-associated Burkitt's lymphoma* includes cases seen in association with HIV infection.

MORPHOLOGIC FEATURES *Histologically*, all three types of Burkitt's lymphoma are similar. Tumour cells are intermediate in size, non-cleaved, and homogeneous in size and shape. The nuclei are round to oval and contain 2-5 nucleoli. The cytoplasm is basophilic and contains lipid vacuolation. The tumour cells have a very high mitotic rate, and therefore high cell death. This feature accounts for presence of numerous macrophages in the background of this tumour containing phagocytosed tumour debris giving it a 'starry sky' appearance (**Fig. 12.22**).

Burkitt's leukaemia is identified by classical appearance of monomorphic medium-sized cells having round nuclei, frequent mitoses, multiple nucleoli, and basophilic cytoplasm with vacuoles.

Immunophenotypically, the tumour cells are positive for CD19 and CD10 and surface immunoglobulin IgM. Typical cytogenetic abnormalities in the tumour cells are t(8;14) and t(8;22) involving *MYC* gene on chromosome 8, with overexpression of *MYC* protein having transforming activity.

Burkitt's lymphoma is a high-grade tumour and is a very rapidly progressive human tumour.

EXTRANODAL MARGINAL ZONE B-CELL LYMPHOMA OF MALT TYPE (SYNONYM: MALTOMA)

MALT refers to mucosa-associated lymphoid tissue. This type comprises about 8% of all NHLs. In the earlier classification, maltoma was included under SLL, but in the WHO scheme it is categorised separately for 2 reasons:

- i) *Etiologic association with H. pylori infection*: Most frequent is gastric lymphoma of MALT type with its characteristic etiologic association with *H. pylori*.
- ii) *Occurrence at extranodal sites*: Besides stomach, other extranodal sites for this subtype of NHL are intestine, orbit, lung, thyroid, salivary glands and CNS.

About half the cases of gastric MALT lymphoma show genetic mutation t(11;18). Median age for this form of NHL is 60 years and often remains localised to the organ of origin but may infiltrate the regional lymph nodes.

MORPHOLOGIC FEATURES It is characterised by diffuse infiltration by monoclonal small B lymphocytes which are negative for CD5.

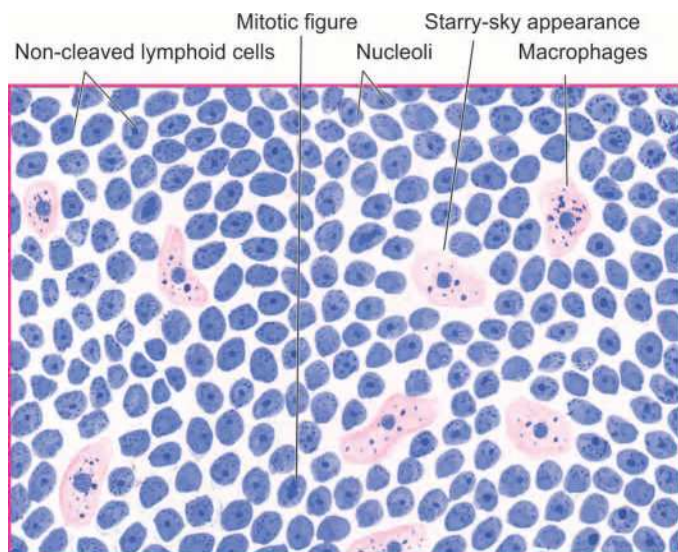

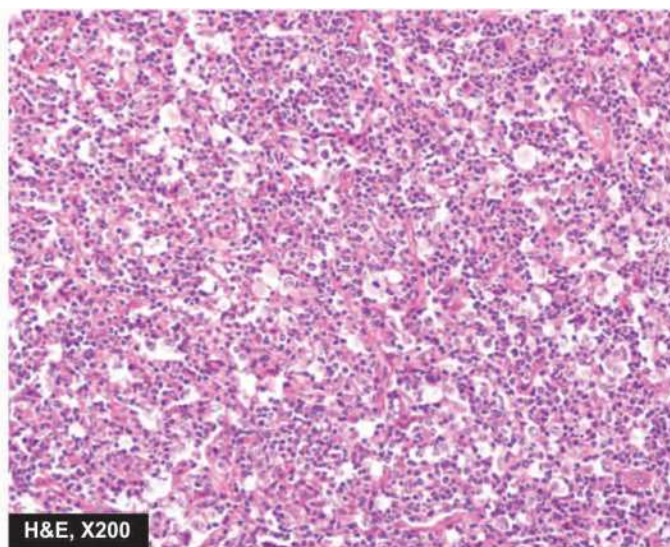

Figure 12.22 Burkitt's lymphoma. The tumour shows uniform cells having high mitotic rate. Scattered among the tumour cells are benign macrophages surrounded by a clear space giving 'starry sky' appearance.

MALT lymphoma has a good prognosis. Rarely, it may be more aggressive and may metastasise, or transform into diffuse large B-cell lymphoma.

MANTLE CELL LYMPHOMA

This subtype of NHL comprises about 8% of all NHLs. It was earlier included in SLL but has been identified as a separate subtype due to characteristic chromosomal translocation, t(11;14) and overexpression of *BCL-1* and surface immunoglobulins IgM and IgD protein. However, both SLL and mantle cell NHL are positive for CD5 antigen. Patients of mantle cell lymphoma are generally older males. The disease involves bone marrow, spleen, liver and bowel.

MORPHOLOGIC FEATURES Mantle cell lymphoma arises from B-cells of mantle zone of normal lymphoid follicle. The tumour cells show diffuse or nodular pattern of involvement in the lymph node and have somewhat indented nuclei.

It is more aggressive than other types of SLLs.

HAIRY CELL LEUKAEMIA (HCL)

Hairy cell leukaemia (HCL) is an unusual and uncommon form of B-cell malignancy characterised by presence of hairy cells in the blood and bone marrow and splenomegaly. It occurs in the older males. HCL is characterised clinically by the manifestations due to infiltration of reticuloendothelial organs (bone marrow, liver and spleen) and, hence, its previous name as *leukaemic reticuloendotheliosis*. Patients have susceptibility to infection with *M. avium intercellulare*.

MORPHOLOGIC FEATURES Laboratory diagnosis is made by the presence of pancytopenia due to marrow failure and splenic sequestration, and identification of characteristic hairy cells in the blood and bone marrow. Hairy cells are abnormal mononuclear cells with hairy cytoplasmic projections which are seen in the bone marrow,

peripheral blood and spleen. These cells are best recognised under phase contrast microscopy but may also be visible in routine blood smears (Fig. 12.23). These leukaemic 'hairy cells' have characteristically positive cytochemical staining for *tartrate-resistant acid phosphatase* (TRAP).

The controversy on the origin of hairy cells whether these cells represent neoplastic T cells, B cells or monocytes, is settled with the molecular analysis of these cells which assigns them *B cell origin* expressing CD19, CD20 and CD22 antigen. In addition to B cell markers, hairy cells are also positive for CD11, CD25 and CD103.

The disease often runs a chronic course requiring supportive care. The mean survival is 4-5 years. Patients respond to splenectomy, α -interferon therapy and 2-chlorodeoxyadenosine (2-CDA).

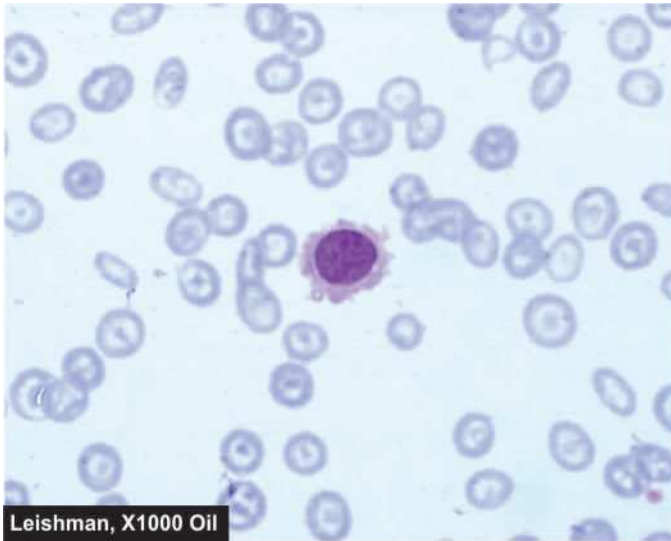

OTHER B-CELL MALIGNANCIES

Brief mention is made below on the other types of B-cell malignant tumours given in the WHO classification in Table 12.8:

i) **B-cell prolymphocytic leukaemia** is involvement of blood and bone marrow by large B lymphocytes having prominent nucleoli. These patients have leucocytosis with splenomegaly and lymphadenopathy.

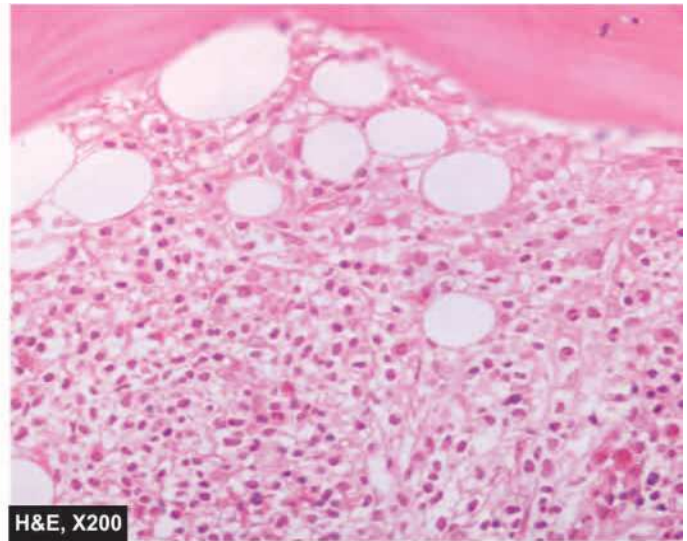

ii) **Splenic marginal zone lymphoma** is another uncommon B-cell neoplasm in which the splenic white pulp is infiltrated by small monoclonal B lymphocytes. The condition has a slow and indolent behaviour.

iii) **Lymphoplasmacytic lymphoma** is tissue manifestation of Waldenström's macroglobulinaemia, discussed later in this chapter. There is infiltration by IgM-secreting monoclonal lymphoplasmacytic cells into lymph nodes, spleen, bone marrow, and sometimes in the peripheral blood. It behaves like an indolent B-cell lymphoma. Etiologic association of this form of lymphoma with hepatitis C virus infection has also been proposed.

Leishman, X1000 Oil

A, PERIPHERAL BLOOD SMEAR

B, BONE MARROW TREPINE BIOPSY

Figure 12.23 Hairy cell leukaemia. A, Peripheral blood shows presence of a leukaemic cells with hairy cytoplasmic projections. B, Trephine biopsy shows replacement of marrow spaces with abnormal mononuclear cells.

iv) Nodal marginal zone lymphoma (monocytoid B-cell lymphoma) is another uncommon subtype of aggressive NHL. At presentation, the patients often have disseminated disease, involving bone marrow and leukaemic picture.

GIST BOX 12.10 Peripheral Mature B-Cell Malignancies

- ▣ B-cell CLL-SLL may appear as leukaemia or lymphoma, presenting with anaemia, lymphadenopathy and hepatosplenomegaly.
- ▣ Blood examination in CLL shows leucocytosis with marked lymphocytosis and basket or smear cells.
- ▣ Lymph node biopsy in CLL-SLL shows diffuse infiltration by well-differentiated nature uniform lymphocytes.
- ▣ Follicular lymphoma occurring in older patients is nodular replacement of nodal architecture.
- ▣ Burkitt's lymphoma/leukaemia is an uncommon B cell malignancy that occurs as African endemic, sporadic and immunodeficiency associated.
- ▣ Maltoma is a lymphoma arising in lymphoid tissues of the stomach, intestine and other mucosal sites and has *H. pylori* association.
- ▣ Hairy cell leukaemia is B cell malignancy characterised by hairy cells in the blood, bone marrow and spleen.

PERIPHERAL(MATURE) T-CELL MALIGNANCIES

Peripheral or mature T-cell lymphoid malignancies are relatively less common compared to mature B cell cancers. These arise at the stage when the lymphoid cells migrate to thymus and become committed to T-cell differentiation by acquiring T cell antigen receptor genes. A few common examples are discussed here.

MYCOSIS FUNGOIDES/SÉZARY SYNDROME

Mycosis fungoides is a slowly evolving cutaneous T-cell lymphoma occurring in middle-aged adult males.

MORPHOLOGICAL FEATURES The condition is often preceded by eczema or dermatitis for several years (*premycotic stage*). This is followed by infiltration by CD4+T-cells in the epidermis and dermis as a plaque (*plaque stage*) and eventually as *tumour stage* (page 781). The disease may spread to viscera and to peripheral blood as a leukaemia characterised by Sézary cells having cerebriform nuclei termed as Sézary syndrome.

Mycosis fungoides/Sézary syndrome is an indolent NHL and has a median survival of 8 to 9 years.

ADULT T-CELL LYMPHOMA/LEUKAEMIA (ATLL)

This is an uncommon T-cell malignancy but has gained much prominence due to association with retrovirus, human T-cell lymphotropic virus-I (HTLV-I) (Chapter 7). The infection is acquired by blood transfusion, breast milk, sexual route or transplacentally. ATLL is common in Japan, the Caribbean and parts of the US but is rare in rest of the world.

MORPHOLOGICAL FEATURES The involved lymph nodes have proliferation of CD4 positive large atypical T-cells with indented nuclei, called 'flower cells', most prominent in the paracortical zone. The blood also shows large pleomorphic T-cell leukaemia.

The patients have usually widespread lymphadenopathy with leukaemia, hepatosplenomegaly and involvement of skin and leptomeninges. This disease runs a fulminant course.

ANAPLASTIC LARGE T/NK CELL LYMPHOMA (ALCL)

ALCL is the T-cell counterpart of diffuse large B-cell lymphoma (DLBCL) and was previously included under malignant histiocytosis or diagnosed as anaplastic carcinoma. ALCL is defined by:

- i) documentation of t(2;5);
- ii) overexpression of ALK (anaplastic lymphoma kinase) protein.

Accordingly, depending upon presence or absence of rearrangement of ALK gene located on chromosome 2p23, it is categorised into ALK positive and ALK negative.

MORPHOLOGICAL FEATURES There is diffuse infiltration of lymph nodes by anaplastic lymphoid cells. These cells are immunophenotypically T-cells/null cells, positive for CD30 (Ki-1).

Clinically, ALCL occurs in young patients and is more common in males. Cutaneous involvement is frequent and produces an indolent cutaneous large T/null cell lymphoma. But bone marrow and other organ infiltration is rare.

OTHER PERIPHERAL T-CELL LYMPHOMAS

These group include a variety of aggressive T-cell lymphomas which are morphologically heterogeneous but have common immunotypic features of mature T-cells (CD4+, CD8+, or both). These are more common in young adults and often have bone marrow involvement at presentation. Examples of a few other peripheral T-cell lymphomas are as under:

i) Angioimmunoblastic T-cell lymphoma is relatively more common subtype, comprising about 20% of all T-cell NHLs. The patients have profound constitutional symptoms (fever, weight loss, skin rash), generalised lymphadenopathy and polyclonal hypergammaglobulinaemia.

ii) Extranodal T/NK cell lymphoma of nasal type is involvement of the upper airways by the monoclonal T-cells. The condition is quite aggressive and was earlier called as *lethal midline granuloma* or *angiocentric lymphoma* (page 498). The patients have haemophagocytic syndrome. During the course of the disease, blood and bone marrow may be involved producing leukaemic picture.

iii) Enteropathy type T-cell lymphoma is a rare aggressive lymphoma seen in association with untreated cases of gluten-sensitive enteropathy.

iv) Hepatosplenic T-cell lymphoma, unlike other lymphomas which occur as tumour masses, is characterised by sinusoidal infiltration of the liver, spleen and bone marrow by monoclonal T-cells. Systemic features are often present.

STAGING OF NHL

The Ann Arbor staging system developed for Hodgkin's disease (see Table 12.10, page 352) is used for staging NHL too. This staging system depends upon the number and location of nodal and extranodal sites involved, and presence or absence of constitutional (B) symptoms. But the concept of staging is much less helpful in NHL than in Hodgkin's disease because the prognosis is not correlated with the anatomic site of involvement of the disease.

LYMPH NODE METASTATIC TUMOURS

The regional lymph nodes draining the site of a primary malignant tumour are commonly enlarged. This enlargement may be due to benign *reactive hyperplasia* or *metastatic tumour deposits*.

1. Benign reactive hyperplasia, as already discussed (page 322), is due to immunologic reaction by the lymph node in

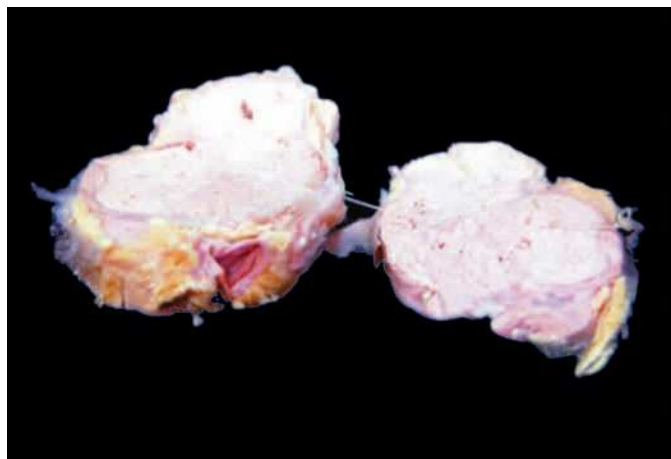

Figure 12.24 Metastatic carcinomatous deposits in the matted mass of lymph nodes. There are areas of necrosis in the circumscribed nodular areas.

response to tumour-associated antigens. It may be expressed as sinus histiocytosis, follicular hyperplasia, plasmacytosis and occasionally may show non-caseating granulomas.

2. Metastatic deposits in regional lymph nodes occur most commonly from carcinomas and malignant melanoma. Sarcomas often disseminate via haematogenous route but uncommonly may metastasise to the regional lymph nodes. Metastatic tumour cells from the primary malignant tumour are drained via lymphatics into the subcapsular sinuses initially but subsequently the lymph node stroma is also invaded. The pushing margins of advancing metastatic tumour in stroma of lymph node are characteristically well demarcated. Areas of necrosis are frequent in metastatic carcinomas (**Fig. 12.24**).

The morphologic features of primary malignant tumour are recapitulated in metastatic tumour in lymph nodes.

GIST BOX 12.11 Peripheral Mature T-Cell Malignancies

- ☐ Mycosis fungoides-Sezary's syndrome is a slow growing cutaneous T cell lymphoma-leukaemia.
- ☐ Adult T-cell lymphoma leukaemia is etiologically linked to human T-cell lymphotropic virus.
- ☐ Anaplastic large cell lymphoma (ALCL) of T/NK cells is a diffuse large cell lymphoma similar to its B-cell counterpart, DLBCL.
- ☐ Other peripheral T cell lymphomas are angioimmunoblastic type, extranodal nasal type, enteropathy type and hepatosplenic type.
- ☐ Regional lymph nodes draining the site of a primary malignant tumour may be enlarged due to benign reactive hyperplasia or metastatic tumour deposits.

PLASMA CELL DISORDERS

The plasma cell disorders are characterised by abnormal proliferation of immunoglobulin-producing cells and result in accumulation of monoclonal immunoglobulin in serum and urine. The group as a whole is known by various synonyms such as *plasma cell dyscrasias*, *paraproteinaemias*, *dysproteinaemias* and *monoclonal gammopathies*. The group comprises the following six disease entities:

1. Multiple myeloma
2. Localised plasmacytoma
3. Lymphoplasmacytic lymphoma (discussed above)
3. Waldenström's macroglobulinaemia
4. Heavy chain disease
5. Primary amyloidosis (Chapter 3)
6. Monoclonal gammopathy of undetermined significance (MGUS).

The feature common to all plasma cell disorders is the neoplastic proliferation of cells derived from B-lymphocyte lineage. These disorders constitute 16% of all B-cell malignancies. Normally B lymphocytes have surface immunoglobulin molecules of both M and G chains. Under normal circumstances, B-cells are stimulated by exposure to surface immunoglobulin-specific antigen and mature to form IgG-producing plasma cells. However, in plasma cell disorders, the control over this process is lost and results in abnormal production of immunoglobulin that appears in the blood and urine. These disorders differ from other B-cell lymphoid malignancies in having monoclonal synthesis of immunoglobulins and lack of prominent lymphadenopathy. In addition to the rise in complete immunoglobulins, plasma cell disorders synthesise excess of light chains (kappa or lambda), or heavy chains of a single class (alpha, gamma, or mu). Bence-Jones proteins are free light chains present in blood and excreted in urine of some plasma cell disorders.

After these brief general comments, we now turn to the discussion of the specific plasma cell disorders.

MULTIPLE MYELOMA

Multiple myeloma is a multifocal malignant proliferation of plasma cells derived from a single clone of cells (i.e. monoclonal). The terms multiple myeloma is used interchangeably with myeloma. The tumour, its products (M component), and the host response result in the most important and most common syndrome in the group of plasma cell disorders that produces osseous as well as extraosseous manifestations. Multiple myeloma primarily affects the elderly (peak incidence in 5th-6th decades) and increases in incidence with age. It is rare under the age of 40. Myeloma is more common in males than females.

Etiology and Pathogenesis

Myeloma is a monoclonal proliferation of B-cells. The etiology of myeloma remains unknown. However, following factors and abnormalities have been implicated:

1. **Radiation exposure** Large dose exposure to radiation with a long latent period has been seen in myeloma. For instance, survivors of nuclear attack in World War-II developed myeloma about 20 years later.
2. **Epidemiologic factors** Myeloma has higher incidence in blacks. Occupational exposure to petroleum products has been associated with higher incidence. Certain occupations such as farmers, wood workers and leather workers are more prone.
3. **Karyotypic abnormalities** Several chromosomal alterations have been observed in cases of myeloma, which include following translocations and deletions:
 - i) Translocations $t(11;14)(q13;q32)$ and $t(4;14)(p16;q32)$.
 - ii) Deletion of 13q.

4. Oncogenes-antioncogenes Overexpression and mutations in following genes have been noted in proliferation of tumour cells in myeloma:

- i) Overexpression of *MYC* and *RAS* growth promoting oncogenes in some cases.
- ii) Mutation in *p53* and *RB* growth-suppressing antioncogene in some cases.

Based on above, **molecular pathogenesis** of multiple myeloma and its major manifestations can be summed up as under and is schematically illustrated in **Fig. 12.25**:

1. Cell-surface *adhesion molecules* bind myeloma cells to bone marrow stromal cells and extracellular matrix proteins.
2. This binding triggers *adhesion-mediated signaling* and mediates *production of several cytokines* by fibroblasts and macrophages of the marrow. These include: IL-6, VEGF, TGF- β , TNF- α , IL-1, lymphotoxin, macrophage inhibitory factor-1 α (MIP-1 α) and receptor activator of nuclear factor- κ B (RANK) ligand.
3. Adhesion-mediated signaling affects the cell cycle via cyclin-D and p21 causing abnormal production of *myeloma (M) proteins*.
4. *IL-6 cytokine* plays a central role in cytokine-mediated signaling and causes proliferation as well as cell survival of tumour cells via its antiapoptotic effects on tumour cells.

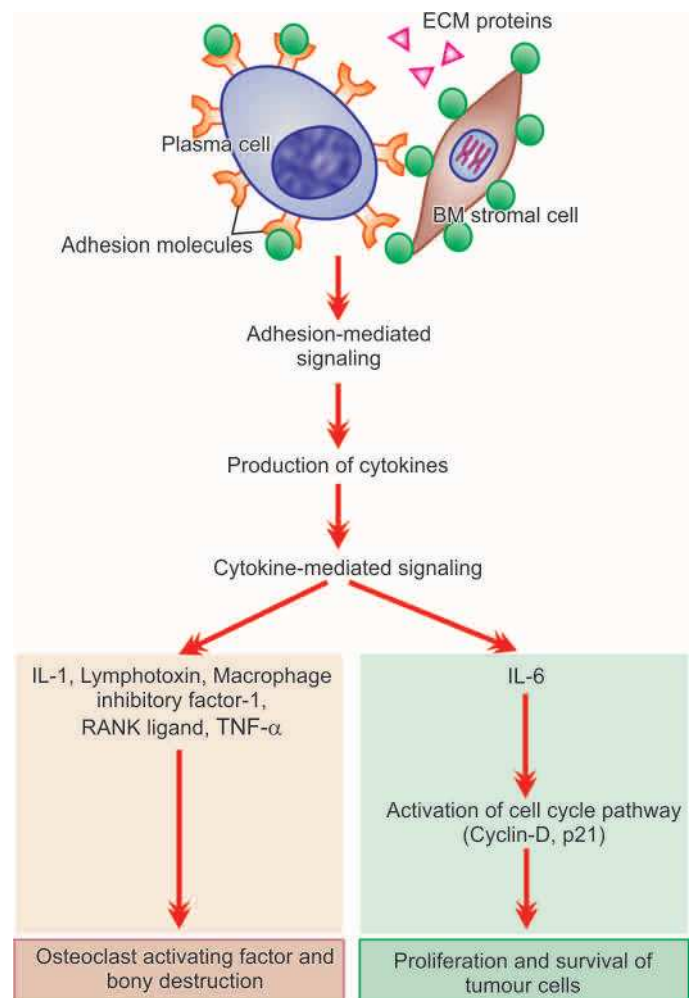

Figure 12.25 Schematic diagram showing molecular pathogenesis of multiple myeloma and its major manifestations.

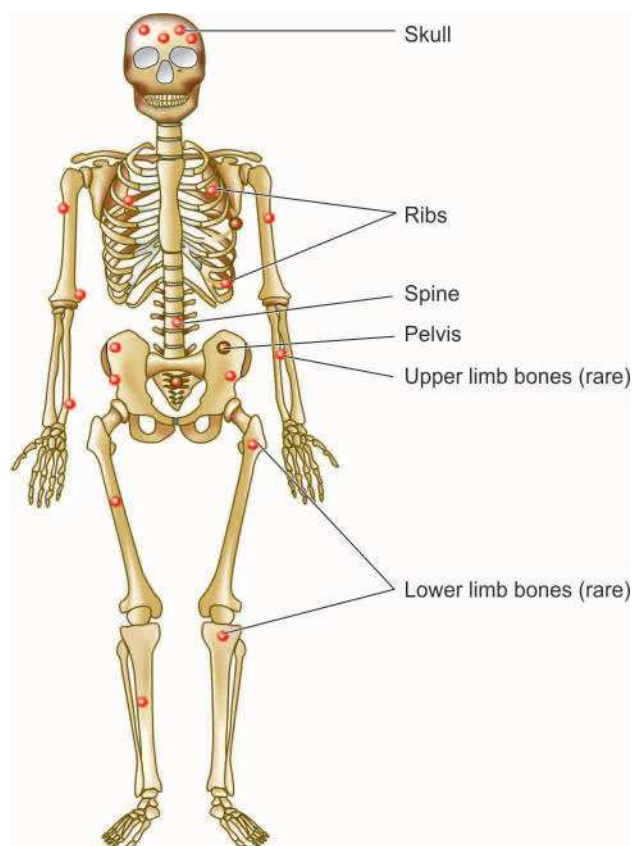

Figure 12.26 The major sites of lesions in multiple myeloma.

5. Certain cytokines produced by myeloma cells bring about bony destruction by acting as *osteoclast-activating factor (OAF)*. These are: IL-1, lymphotoxin, VEGF, macrophage inhibitory factor-1 α (MIP-1 α), receptor activator of NF- κ B ligand, and tumour necrosis factor (TNF).
6. Other effects of adhesion-mediated and cytokine-mediated signaling are development of *drug resistance and migration* of tumour cells in the bone marrow milieu.

Morphologic Features

Myeloma affects principally the bone marrow though during the course of the disease other organs are also involved. Therefore, the pathologic findings are described below under two headings—*osseous (bone marrow) lesions* and *extraosseous lesions*.

A. OSSEOUS (BONE MARROW) LESIONS In more than 95% of cases, multiple myeloma begins in the bone marrow. In majority of cases, the disease involves multiple bones. By the time the diagnosis is made, most of the bone marrow is involved. Most commonly affected bones are those with red marrow i.e. skull, spine, ribs and pelvis, but later long bones of the limbs are also involved (**Fig. 12.26**). The lesions begin in the medullary cavity, erode the cancellous bone and ultimately cause destruction of the bony cortex. Radiographically, these lesions appear as punched out, rounded, 1-2 cm sized defects in the affected bone.

Grossly, the normal bone marrow is replaced by soft, gelatinous, reddish-grey tumours. The affected bone usually shows focal or diffuse osteoporosis.

Microscopically, the diagnosis of multiple myeloma can be usually established by examining bone marrow aspiration from an area of bony rarefaction. However, if the bone marrow aspiration yields dry tap or negative results, biopsy of radiologically abnormal or tender site is usually diagnostic. The following features characterise a case of myeloma:

i) Cellularity There is usually hypercellularity of the bone marrow.

ii) Myeloma cells Myeloma cells constitute $\geq 10\%$ of the marrow cellularity. These cells may form clumps or sheets, or may be scattered among the normal haematopoietic cells. Myeloma cells may vary in size from small, differentiated cells resembling normal plasma cells to large, immature and undifferentiated cells. Binucleate and multinucleate cells are sometimes present. The nucleus of myeloma cell is commonly eccentric similar to plasma cells but usually lacks the cart-wheel chromatin pattern seen in classical plasma cells. Nucleoli are frequently present. The cytoplasm of these cells is abundant and basophilic with perinuclear halo, vacuolisation and contains Russell bodies consisting of hyaline globules composed of synthesised immunoglobulin (**Fig. 12.27**).

In addition to neoplastic proliferation of plasma cells in multiple myeloma, *reactive plasmacytosis* in the bone marrow can occur in some other disorders; these include: aplastic anaemia, rheumatoid arthritis, SLE, cirrhosis of liver, metastatic cancer and chronic inflammation and infections such as tuberculosis. However, in all these conditions the plasma cells are mature and they do not exceed 10% of the total marrow cells.

B. EXTRAOSSEOUS LESIONS Late in the course of disease, lesions at several extraosseous sites become evident. Some of the commonly involved sites are as under:

1. Blood Approximately 50% of patients with multiple myeloma have a few atypical plasma cells in the blood. Other changes in the blood in myeloma are the presence of anaemia (usually normocytic normochromic type), marked red cell rouleaux formation due to hyperviscosity of blood, and an elevated ESR.

2. Myeloma kidney Renal involvement in myeloma called myeloma nephrosis occurs in many cases (Chapter 20). The main mechanism of myeloma kidney is by filtration of light chain proteins (Bence Jones proteins) which are precipitated in the distal convoluted tubules in combination with Tamm-Horsfall proteins as tubular casts. The casts may be surrounded by some multinucleate giant-cells and a few inflammatory cells.

3. Myeloma neuropathy Infiltration of the nerve trunk roots by tumour cells produces nonspecific polyneuropathy. Pathologic fractures, particularly of the vertebrae, may occur causing neurologic complications.

4. Systemic amyloidosis Systemic primary generalised amyloidosis (AL amyloid) may occur in 10% cases of multiple myeloma and involve multiple organs and systems.

5. Liver, spleen involvement Involvement of the liver and spleen by myeloma cells sufficient to cause hepatomegaly, and splenomegaly occurs in a small percentage of cases.

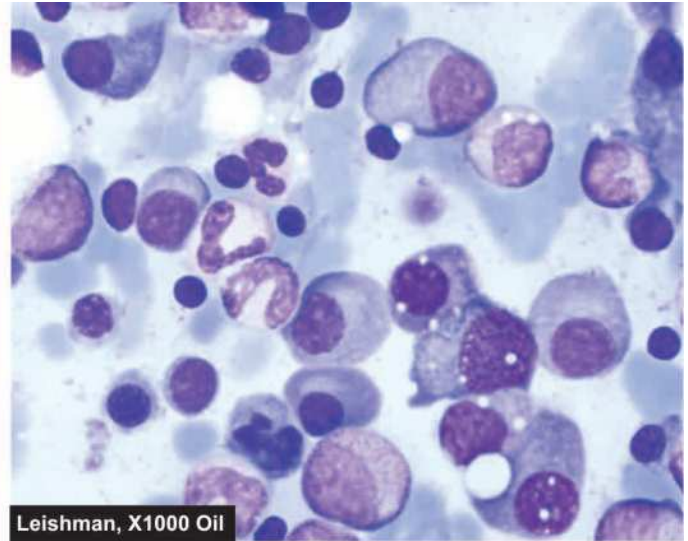

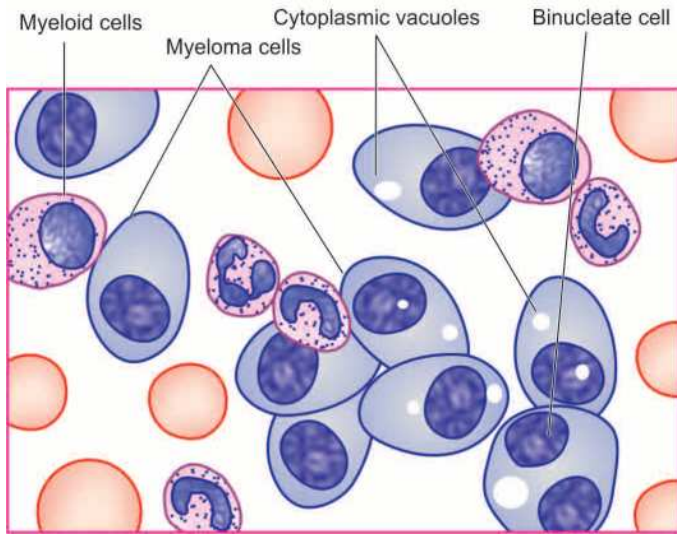

Figure 12.27 Bone marrow aspirate in myeloma showing numerous plasma cells, many with abnormal features.

Clinical Features

The clinical manifestations of myeloma result from the effects of infiltration of the bones and other organs by neoplastic plasma cells and from immunoglobulin synthesis. The principal clinical features are as under:

- Bone pain** is the most common symptom. The pain usually involves the back and ribs. Pathological fractures may occur causing persistent localised pain. Bone pain results from the proliferation of tumour cells in the marrow and activation of osteoclasts which destroy the bones.
- Susceptibility to infections** is the next most common clinical feature. Particularly common are bacterial infections such as pneumonias and pyelonephritis. Increased susceptibility to infection is related mainly to hypogammaglobulinaemia, and partly to granulocyte dysfunction and neutropenia.
- Renal failure** occurs in about 25% of patients, while renal pathology occurs in 50% of cases. Causes of renal failure in myeloma are hypercalcaemia, glomerular deposits of amyloid, hyperuricaemia and infiltration of the kidney by myeloma cells.
- Anaemia** occurs in about 80% of patients of myeloma and is related to marrow replacement by the tumour cells (myelophthisis) and inhibition of haematopoiesis.
- Bleeding tendencies** may appear in some patients due to thrombocytopenia, deranged platelet function and interaction of the M component with coagulation factors.
- Hyperviscosity syndrome** owing to hyperglobulinaemia may produce headache, fatigue, visual disturbances and haemorrhages.
- Neurologic symptoms** occur in a minority of patients and are explained by hyperviscosity, cryoglobulins and amyloid deposits.
- Biochemical abnormalities.** These include the following:
 - hypercalcaemia due to destruction of bone;
 - hyperuricaemia from necrosis of tumour mass and from uraemia related to renal failure; and
 - increased β -2 microglobulins and other globulins in urine and serum.

9. **POEMS syndrome** is seen in about 1% cases of myeloma and includes simultaneous manifestations of *poly*neuropathy, *organomegaly*, *endocrinopathy*, *multiple myeloma* and skin changes.

Diagnosis

The diagnosis of myeloma is made by classic *triad* of features:

- Marrow plasmacytosis** of more than 10%
- Radiologic evidence of **lytic bony lesions**
- Demonstration of serum and/or urine **M component**.

There is rise in the total serum protein concentration due to *paraproteinaemia* but normal serum immunoglobulins (IgG, IgA and IgM) and albumin are depressed. Paraproteins are abnormal immunoglobulins or their parts circulating in plasma and excreted in urine. About two-third cases of myeloma excrete Bence Jones (light chain) proteins in the urine, consisting of either kappa (κ) or lambda (λ) light chains, along with presence of Bence Jones paraproteins in the serum. On serum electrophoresis, the paraprotein usually appears as a single narrow homogeneous *M-band* component, most commonly in the region of γ -globulin (**Fig. 12.28**). Most frequent paraprotein is IgG seen in about 50% cases of myeloma, IgA in 25%, and IgD in 1%, while about 20% patients have only light chains in serum and urine (*light chain myeloma*). *Non-secretory myeloma* is absence of M-band on serum and/or electrophoresis but presence of other two features out of triad listed above. Though the commonest cause of paraproteinaemias is multiple myeloma, certain other conditions which may produce serum paraproteins need to be distinguished. These are as under:

- Monoclonal gammopathy of undetermined significance (MGUS)
- Waldenström's macroglobulinaemia
- Benign monoclonal gammopathy
- B-cell lymphomas
- CLL
- Light chain disease
- Heavy chain disease
- Cryoglobulinaemia.

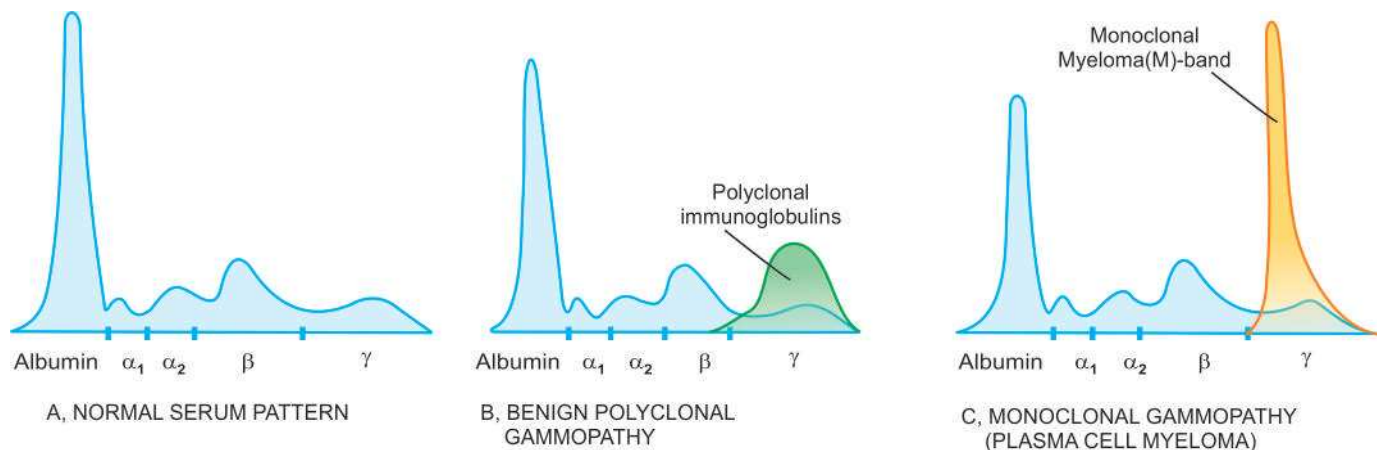

Figure 12.28 Serum electrophoresis showing normal serum pattern (A), as contrasted with that in benign polyclonal gammopathy (B) and in monoclonal gammopathy (C), typical of plasma cell myeloma.

Treatment Plan and Prognosis

Treatment of multiple myeloma consists of systemic chemotherapy in the form of alkylating agents and symptomatic supportive care. Autologous stem cell transplantation and interferon-therapy are the other modern treatment modalities offered. Poor prognostic predictors for lower survival are: secretion of λ -light chain than those secreting κ -light chain, larger number of cytogenetic abnormalities, and increased β -2 microglobulin level. The median survival is 2 years after the diagnosis is made. The terminal phase is marked by the development of pancytopenia, severe anaemia and sepsis.

LOCALISED PLASMACYTOMA

Two variants of myeloma which do not fulfil the criteria of classical triad are the localised form of *solitary bone plasmacytoma* and *extramedullary plasmacytoma*. Both these are associated with M component in about a third of cases and occur in young individuals. Solitary bone plasmacytoma is a lytic bony lesion without marrow plasmacytosis. Extramedullary plasmacytoma involves most commonly the submucosal lymphoid tissue of nasopharynx or paranasal sinuses. Both variants have better prognosis than the classic multiple myeloma. *Plasma cell granuloma*, on the other hand, is an inflammatory condition having admixture of other inflammatory cells with mature plasma cells, which can be easily distinguished by a discernible observer.

WALDENSTRÖM'S MACROGLOBULINAEMIA

Waldenström's macroglobulinaemia is an uncommon malignant proliferation of monoclonal B lymphocytes which secrete IgM paraproteins called macroglobulins as they have high molecular weight. The condition is more common in men over 50 years of age and behaves clinically like a slowly progressive lymphoma.

The exact etiology is not known but a possible relationship of IgM macroglobulin with myelin-associated glycoprotein which is lost in degenerating diseases has been suggested. The clinical evidence in favour is the appearance of peripheral neuropathy before the occurrence of macroglobulinaemia in some patients.

MORPHOLOGIC FEATURES Pathologically, the disease can be regarded as the hybrid between myeloma and small lymphocytic lymphoma.

◆ *Like myeloma*, the disease involves the bone marrow, but unlike myeloma it usually does not cause extensive bony lesions or hypercalcaemia. The bone marrow shows pleomorphic infiltration by lymphocytes, plasma cells, lymphocytoid plasma cells, mast cells and histiocytes. Like in myeloma, serum M component is present.

◆ *Unlike myeloma and more like small lymphocytic lymphoma*, enlargement of lymph nodes, spleen and liver due to infiltration by similar type of cells is present more frequently.

CLINICAL FEATURES The clinical features of the disease are due to both infiltration by the disease and paraproteins in the blood.

1. *Hyperviscosity syndrome* is the major clinical manifestation. It results in visual disturbances, weakness, fatigability, weight loss and nervous system symptoms. Raynaud's phenomenon may occur.
2. *Moderate organomegaly* in the form of lymphadenopathy, hepatomegaly and splenomegaly are frequently seen.
3. *Anaemia* due to bone marrow failure may be present.
4. *Bleeding tendencies* may occur due to interaction of macroglobulins with platelets and coagulation factors.

DIAGNOSIS Unlike myeloma, there are no characteristic radiologic findings. The diagnosis rests on laboratory data as under:

1. Pleomorphic bone marrow infiltration
2. Raised total serum protein concentration
3. Raised serum monoclonal M component which is due to IgM paraprotein
4. Elevated ESR
5. Normocytic normochromic anaemia.

The management of the patients is similar to that of myeloma. Patients respond to chemotherapy with a median survival of 3-5 years.

HEAVY CHAIN DISEASES

Heavy chain diseases are rare malignant proliferations of B-cells accompanied by monoclonal excess of one of the

heavy chains. Depending upon the type of excessive heavy chain, three types— γ , α and μ , of heavy chain diseases are distinguished:

GAMMA HEAVY CHAIN DISEASE Also called Franklin's disease, it is characterised by excess of mostly $\gamma 1$ -paraprotein, both in the serum and urine and is demonstrated as M component. Clinically, the condition may develop at any age and present with lymphadenopathy, splenomegaly, hepatomegaly, involvement of pharyngeal lymphoid tissue (Waldeyer's ring) and fever. Patients have rapidly downhill course due to severe and fatal infection.

ALPHA HEAVY CHAIN DISEASE This is the commonest of heavy chain diseases characterised by α -heavy chains in the plasma which are difficult to demonstrate in electrophoresis due to rapid polymerisation. The patients present with bowel symptoms such as chronic diarrhoea, malabsorption and weight loss and may have enlargement of abdominal lymph nodes. Chemotherapy may induce long-term remissions.

MU HEAVY CHAIN DISEASE This is the rarest heavy chain disease. The neoplastic B-cells produce m heavy chains which do not appear in the urine but κ light chains which are also produced appear in the urine. Another feature that distinguishes this type of heavy chain disease from the others is the presence of vacuoles in the malignant B lymphocytes. The course and prognosis are like those of leukaemia or lymphoma.

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE (MGUS)

Due to longevity, monoclonal gammopathy of undetermined significance (MGUS) is now increasingly diagnosed in asymptomatic healthy ageing population—1% at 50 years of age and in 10% individuals older than 75 years. This makes it the most common form of plasma cell dyscrasia. The defining criteria for MGUS are as under:

- i) M-protein in serum <3 gm/dl
- ii) Marrow plasmacytosis $<10\%$
- iii) No evidence of other B-cell proliferative disorder
- iv) Absence of myeloma-related end-organ tissue damage (i.e. absence of lytic bone lesions, high calcium level, anaemia).

The condition needs to be cautiously distinguished from myeloma and long term follow-up is required. In fact, MGUS has been considered as a forerunner of multiple myeloma in many studies because MGUS has been found to have the same chromosomal abnormalities as in myeloma.

GIST BOX 12.12 Plasma Cell Disorders

- Multiple myeloma is a multifocal malignant proliferation of plasma cells derived from a single clone of B cells (i.e. monoclonal).
- Prolonged radiation exposure and black race are some of the factors implicated in its etiology.
- The diagnosis of myeloma is made by osteolytic punched out osseous lesions, marrow plasmacytosis and demonstration of M band in serum or urine electrophoresis.
- Localised plasmacytoma may be solitary bone lesion or extramedullary. It is generally not associated with marrow plasmacytosis.
- Waldenstrom's macroglobulinaemia is an uncommon malignant proliferation of B cells.

- Heavy chain diseases due to malignant proliferation of B cells with monoclonal excess of one of heavy chains are rare.
- Monoclonal gammopathy of undetermined significance (MGUS) is common and is now increasingly diagnosed in asymptomatic healthy ageing population.

HISTIOCYTIC NEOPLASMS: LANGERHANS CELL HISTIOCYTOSIS

The term histiocytosis is used for a group of proliferations of dendritic cells, Langerhans cells or macrophages and includes both benign and malignant examples. While histiocytic sarcoma, Langerhans cell sarcoma and dendritic cell sarcoma are clearly malignant lymphomas and are uncommon, monoclonal proliferation of Langerhans cells are grouped under Langerhans cell histiocytosis (LCH) and are somewhat more common. LCH includes three clinicopathologically related conditions occurring in children: eosinophilic granuloma, Hand-Schüller-Christian disease and Letterer-Siwe syndrome. As a group, all the three conditions are associated with proliferation of 3 types of cells: histiocytes, lymphocytes and eosinophils.

Earlier, this group was referred to as histiocytosis-X but now following facts about this group are known:

◆ **Firstly**, histiocytosis-X are not proliferations of unknown origin (X-for unknown) but proliferating cells are actually Langerhans' cells of marrow origin. Langerhans' cells are normally present mainly in the epidermis of the skin but also in some other organs.

◆ **Secondly**, the three conditions included under histiocytosis-X are actually different expression of the same basic disorder. This concept has emerged from 2 features:

- i) Demonstration of common antigens on these cells by *immunohistochemical stains* for S-100 protein (**Fig. 12.29**), CD1a and HLA-DR.
- ii) Electron microscopic demonstration of *histiocytosis-X bodies or Birbeck granules* in the cytoplasm. These are rod-shaped structures having dilated tennis-racket like terminal end. Their function is not known but they arise from receptor-mediated endocytosis of langerin found in human epidermal cells, a protein involved in Birbeck granule biosynthesis.

The three disorders included in the group are briefly considered below.

EOSINOPHILIC GRANULOMA

Unifocal eosinophilic granuloma is more common (60%) than the multifocal variety which is often a component of Hand-Schüller-Christian disease (described below). Most of the patients are children and young adults, predominantly males. The condition commonly presents as a solitary osteolytic lesion in the femur, skull, vertebrae, ribs and pelvis. The diagnosis requires biopsy of the lytic bone lesion.

Microscopically, the lesion consists largely of closely-packed aggregates of macrophages admixed with variable number of eosinophils (**Fig. 12.29**). The macrophages contain droplets of fat or a few granules of brown pigment indicative of phagocytic activity. A few multinucleate macrophages may also be seen. The cytoplasm of these

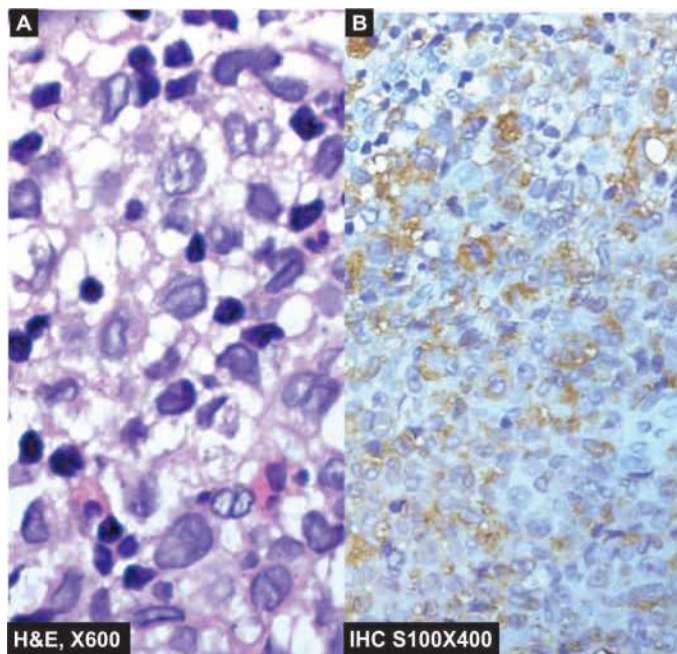

Figure 12.29 Langerhans cell histiocytosis—eosinophilic granuloma. A, Bone biopsy shows presence of infiltrate by collections of histiocytes having vesicular nuclei admixed with eosinophils. B, Immunohistochemical stain with S-100 shows cytoplasmic and nuclear positivity.

macrophages may contain rod-shaped inclusions called *histiocytosis-X bodies* or Birbeck granules, best seen by electron microscopy.

Clinically, unifocal eosinophilic granuloma is a benign disorder. The bony lesion remains asymptomatic until the erosion of the bone causes pain or fracture. Spontaneous fibrosis or healing may occur in some cases, while others may require curettage or radiotherapy.

HAND-SCHÜLLER-CHRISTIAN DISEASE

A triad of features consisting of *multifocal bony defects*, *diabetes insipidus* and *exophthalmos* is termed Hand-Schüller-Christian disease. The disease develops in children under 5 years of age. The multifocal lytic bony lesions may develop at any site. Orbital lesion causes exophthalmos, while involvement of the hypothalamus causes diabetes insipidus. Multiple spherical lesions in the lungs are frequently present. Half the patients have involvement of the liver, spleen and lymph nodes.

Microscopically, the lesions are indistinguishable from those of unifocal eosinophilic granuloma.

Clinically, the affected children frequently have fever, skin lesions, recurrent pneumonitis and other infections. Though the condition is benign, it is more disabling than the unifocal eosinophilic granuloma. The lesions may resolve spontaneously or may require chemotherapy or radiation.

LETTERER-SIWE DISEASE

Letterer-Siwe disease is an acute disseminated form of LCH occurring in infants and children under 2 years of age. The disease is characterised by hepatosplenomegaly, lymphadenopathy, thrombocytopenia, anaemia and leucopenia.

There is generalised hyperplasia of tissue macrophages in various organs.

Microscopically, the involved organs contain aggregates of macrophages which are pleomorphic and show nuclear atypia. The cytoplasm of these cells contains vacuoles and rod-shaped *histiocytosis-X bodies*.

Clinically, the child has acute symptoms of fever, skin rash, loss of weight, anaemia, bleeding disorders and enlargement of lymph nodes, liver and spleen. Cystic bony lesions may be apparent in the skull, pelvis and long bones. Intense chemotherapy helps to control Letterer-Siwe disease but intercurrent infections result in fatal outcome in many cases. The condition is currently regarded as an unusual form of malignant lymphoma.

GIST BOX 12.13 Langerhans Cell Histiocytosis

- ☐ Monoclonal proliferation of Langerhans cells are grouped under Langerhans cell histiocytosis (LCH) and includes three clinicopathologically related conditions occurring in children: eosinophilic granuloma, Hand-Schüller-Christian disease and Letterer-Siwe syndrome.
- ☐ As a group, all the three conditions are associated with proliferation of 3 types of cells: histiocytes, lymphocytes and eosinophils.
- ☐ Unifocal eosinophilic granuloma is a benign disorder.
- ☐ A triad of features consisting of *multifocal bony defects*, *diabetes insipidus* and *exophthalmos* is termed Hand-Schüller-Christian disease.
- ☐ Letterer-Siwe disease is an acute disseminated form of LCH and behaves like a lymphoma.

SPLEEN

NORMAL STRUCTURE

The spleen is the largest lymphoid organ of the body. Under normal conditions, the average weight of the spleen is about 150 gm in the adult. Normally, the organ lies well protected by the 9th, 10th and 11th ribs in the upper left quadrant. The surface of the spleen is covered by a layer of peritoneum underneath which the organ is ensheathed by a thin *capsule*. From the capsule extend connective tissue *trabeculae* into the pulp of the organ and serve as supportive network. Blood enters the spleen by the splenic artery which divides into branches that penetrate the spleen via trabeculae. From the trabeculae arise small branches called *central arterioles*. Blood in the central arterioles empties partly into splenic venules and from there into splenic vein, but largely into vascular sinuses of the red pulp and thence into the splenic venous system.

Grossly, the spleen consists of homogeneous, soft, dark red mass called the *red pulp* and long oval grey-white nodules called the *white pulp (malpighian bodies)*.

Microscopically, the red pulp consists of a network of thin-walled venous sinuses and adjacent blood spaces. The blood spaces contain blood cells, lymphocytes and macrophages and appear to be arranged in cords called

splenic cords or *cords of Billroth*. The white pulp is made up of lymphocytes surrounding an eccentrically placed arteriole. The periarteriolar lymphocytes are mainly T-cells, while at other places the lymphocytes have a germinal centre composed principally of B-cells surrounded by densely packed lymphocytes.

The spleen is a lymphoreticular organ that performs at least the following four *functions*:

1. Like other lymphoid tissues, it is an organ of the immune system where B and T lymphocytes multiply and help in *immune responses*.
2. The spleen plays an active role in *sequestering* and removing normal and abnormal blood cells.
3. The vasculature of the spleen plays a role in *regulating portal blood flow*.
4. Under pathologic conditions, the spleen may become the site of *extramedullary haematopoiesis*.

The spleen is rarely the primary site of disease. Being the largest lymphoreticular organ, it is involved secondarily in a wide variety of systemic disorders which manifest most commonly as splenic enlargement (splenomegaly) described below. A few other systemic involvements such as splenic infarcts and chronic venous congestion (CVC) of spleen have already been considered in Chapter 4 of General Pathology.

SPLENIC ENLARGEMENT AND EFFECTS ON FUNCTION

SPLENOMEGALY

Enlargement of the spleen termed splenomegaly, occurs in a wide variety of disorders which increase the cellularity and vascularity of the organ. Many of the causes are exaggerated forms of normal splenic function. Splenic enlargement may occur as a result of one of the following pathophysiologic mechanisms:

- I. Infections
- II. Disordered immunoregulation
- III. Altered splenic blood flow
- IV. Lymphohaematogenous malignancies
- V. Diseases with abnormal erythrocytes
- VI. Storage diseases
- VII. Miscellaneous causes.

Based on these mechanisms, an abbreviated list of causes of splenomegaly is given in **Table 12.13**. Most of these conditions have been discussed elsewhere.

The **degree of splenomegaly** varies with the disease entity:

- ◆ **Mild enlargement (upto 5 cm)** occurs in CVC of spleen in CHF, acute malaria, typhoid fever, bacterial endocarditis, SLE, rheumatoid arthritis and thalassaemia minor.
- ◆ **Moderate enlargement (upto umbilicus)** occurs in hepatitis, cirrhosis, lymphomas, infectious mononucleosis, haemolytic anaemia, splenic abscesses and amyloidosis.
- ◆ **Massive enlargement (below umbilicus)** occurs in CML, myeloid metaplasia with myelofibrosis, storage diseases, thalassaemia major, chronic malaria, leishmaniasis and portal vein obstruction.

Mild to moderate splenomegaly is usually symptomless, while a massively enlarged spleen may cause dragging sensation in the left hypochondrium. Spleen becomes palpable only when it is enlarged.

| | 2. Niemann-Pick's disease |
| VII. | MISCELLANEOUS |
| | 1. Amyloidosis |
| | 2. Primary and metastatic splenic tumours |
| | 3. Idiopathic splenomegaly |

Grossly, an enlarged spleen is heavy and firm. The capsule is tense and thickened. The sectioned surface of the organ is firm with prominent trabeculae (**Fig. 12.30**).

Microscopically, there is dilatation of sinusoids with prominence of splenic cords. The white pulp is atrophic while the trabeculae are thickened. Long-standing congestion may produce haemorrhages and *Gamna-Gandy bodies* resulting in *fibrocongestive splenomegaly*, also called *Banti's spleen*.

HYPERSPLENISM

The term hypersplenism is used for conditions which cause excessive removal of erythrocytes, granulocytes or platelets from the circulation. The mechanism for excessive removal

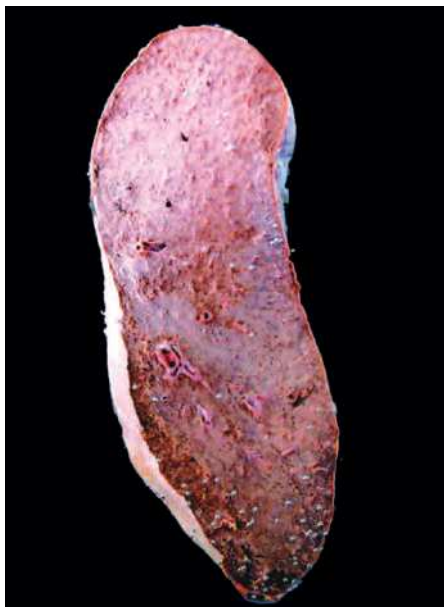

Figure 12.30 CVC spleen (Congestive splenomegaly). Sectioned surface shows that the spleen is heavy and enlarged in size. The colour of sectioned surface is grey-tan.

could be due to increased sequestration of cells in the spleen by altered splenic blood flow or by production of antibodies against respective blood cells. The criteria for hypersplenism are as under:

1. Splenomegaly.
2. Splenic destruction of one or more of the cell types in the peripheral blood causing anaemia, leucopenia, thrombocytopenia, or pancytopenia.
3. Bone marrow cellularity is normal or hyperplastic.
4. Splenectomy is followed by improvement in the severity of blood cytopenia.

EFFECTS OF SPLENECTOMY

In view of the prominent role of normal spleen in sequestration of blood cells, splenectomy in a normal individual is followed by significant haematologic alterations. Induction of similar haematologic effects is made use in the treatment of certain pathologic conditions. For example, in autoimmune haemolytic anaemia or thrombocytopenia, the respective blood cell counts are increased following splenectomy. The blood changes following splenectomy are as under:

1. **Red cells** There is appearance of target cells in the blood film. Howell-Jolly bodies are present in the red cells as they are no longer cleared by the spleen. Osmotic fragility test shows increased resistance to haemolysis. There may be appearance of normoblasts.
2. **White cells** There is leucocytosis reaching its peak in 1-2 days after splenectomy. There is shift-to-left of the myeloid cells with appearance of some myelocytes.
3. **Platelets** Within hours after splenectomy, there is rise in platelet count upto 3-4 times normal.

SPLENIC RUPTURE

The most common cause of splenic rupture or laceration is blunt trauma. The trauma may be direct or indirect. Non-traumatic or spontaneous rupture occurs in an enlarged spleen but almost

never in a normal spleen. In acute infections, the spleen can enlarge rapidly to 2 to 3 times its normal size causing acute splenic enlargement termed *acute splenic tumour* e.g. in pneumonias, septicaemia, acute endocarditis etc. Some of the other common causes of spontaneous splenic rupture are splenomegaly due to chronic malaria, infectious mononucleosis, typhoid fever, splenic abscess, thalassaemia and leukaemias.

Rupture of spleen is an acute surgical emergency due to rapid blood loss and haemoperitoneum. Sometimes fragments of splenic tissue are autotransplanted within the peritoneal cavity and grow into tiny spleens there (*splenosis*).

TUMOURS

◆ **Primary tumours** of the spleen are extremely rare. The only notable benign tumours are haemangiomas and lymphangioma, while examples of primary malignant neoplasms of haematopoietic system i.e. Hodgkin's disease and non-Hodgkin's lymphomas. Non-haematopoietic tumours of the spleen such as angiosarcoma are rare.

◆ **Secondary tumours** occur late in the course of disease and represent haematogenous dissemination of the malignant tumour. Splenic metastases appear as multiple nodules. The most frequent primary sites include: lung, breast, prostate, colon and stomach. Rarely, direct extension from an adjacent malignant neoplasm may occur.

GIST BOX 12.14

Splenic Enlargement and Effects on Function

- Enlargement of the spleen, splenomegaly, may result from a variety of causes and may produce mild, moderate and marked enlargement.
- Hypersplenism is a condition which causes excessive removal of red cells, granulocytes and platelets. Thus, there is pancytopenia.
- Removal of spleen may cause appearance of target cells, leucocytosis, and thrombocytosis.
- Splenic replete may occur from blunt trauma, especially if it is enlarged.
- Spleen may be the site of primary (e.g. haemangioma, lymphoma) and metastatic tumours.

THYMUS

NORMAL STRUCTURE

The thymus gland is a complex lymphoreticular organ lying buried within the mediastinum. At birth, the gland weighs 10-35 gm and grows in size upto puberty, following which there is progressive involution in the elderly. In the adult, thymus weighs 5-10 gm.

The gland consists of right and left encapsulated lobes, joined together by fibrous connective tissue. Connective tissue septa pass inwards from the capsule and subdivide the lobe into large number of lobules. The histologic structure of the lobule shows *outer cortex* and *inner medulla*. Both cortex and medulla contain two types of cells: epithelial cells and lymphocytes (thymocytes).

◆ **Epithelial cells** are similar throughout the thymus gland. These cells have elongated cytoplasmic processes forming network in which thymocytes and macrophages are found. *Hassall's corpuscles* are distinctive structures within the

medulla composed of onion skin-like concentrically arranged epithelial cells having central area of keratinisation.

◆ **Thymocytes** are predominantly present in the cortex. These cells include immature T lymphocytes in the cortex and mature T lymphocytes in the medulla. Well-developed B-cell lymphoid follicles with germinal centres are rare in thymus gland.

The main **function** of the thymus is in the cell-mediated immunity by T-cells and by secretion of thymic hormones such as *thymopoietin* and *thymosin- α 1*.

Thymic lesions are associated with diverse conditions which may be immunologic, haematologic or neoplastic. These can be broadly categorised into thymic hypoplasia and agenesis, thymic hyperplasia and thymoma, while thymic involvement in myasthenia gravis is discussed in Chapter 26.

STRUCTURAL AND FUNCTIONAL CHANGES IN THYMUS

THYMIC HYPOPLASIA AND AGENESIS

Thymic hypoplasia and agenesis are acquired and congenital disorders respectively in which the gland is either unusually small or absent. These conditions are various types of hereditary (primary) immunodeficiency diseases such as DiGeorge's syndrome, severe combined immunodeficiency and reticular dysgenesis. Acquired hypoplasia occurs as an ageing phenomenon or may occur in the young due to severe stress, malnutrition, irradiation, therapy with cytotoxic drugs and glucocorticoids.

THYMIC HYPERPLASIA

Enlargement of the thymus or failure to involute produces thymic hyperplasia. Hyperplasia is usually associated with appearance of lymphoid follicles in the medulla of the thymus and is called *thymic follicular hyperplasia*. Most common cause of follicular hyperplasia of the thymus is myasthenia gravis. Less common causes are: Addison's disease, Graves' disease, rheumatoid arthritis, SLE, scleroderma and cirrhosis of liver.

THYMOMA

Most common primary tumour present in the anterosuperior mediastinum is thymoma. Although thymus is a lympho-epithelial organ, the term thymoma is used for the tumour of epithelial origin. Most of the patients are adults. In about half the cases, thymoma remains asymptomatic and is accidentally discovered in X-rays. Other patients have associated conditions like myasthenia gravis or local symptoms such as cough, dyspnoea and chest pain.

MORPHOLOGIC FEATURES *Grossly*, the tumour is spherical, measuring 5-10 cm in diameter with an average weight of 150 gm. Sectioned surface is soft, yellowish, lobulated and may be either homogeneous or contain cysts due to the presence of haemorrhage and necrosis.

Microscopically, the tumour has a thick fibrous capsule from which extend collagenous septa into the tumour dividing it into lobules. The histology of lobule shows various patterns. The tumour consists of neoplastic epithelial cells and variable number of non-neoplastic lymphocytes. Thymoma may be of following types:

Benign thymoma is more common. It consists of epithelial cells which are similar to the epithelial cells in the medulla of thymus and hence also called as medullary thymoma.

Malignant thymoma is less common and is further of 2 types:

Type 1 is cytologically benign looking but aggressive and invades the mediastinal structures locally.

Type 2 is also called thymic carcinoma and has cytologic features of cancer. Further subtypes of epithelial malignancy may be squamous cell type (most common) and lymphoepithelial type.

Thymomas are known for their association with paraneoplastic syndrome. These include: myasthenia gravis (most common), hypogammaglobulinaemia, erythroid hypoplasia (pure red cell aplasia), peripheral T cell leukaemia/lymphoma, multiple myeloma, other autoimmune disease associations and other systemic malignancies.

GIST BOX 12.15

Structural and Functional Changes in Thymus

- ☐ Thymic hypoplasia may occur due to immunodeficiency diseases.
- ☐ Thymic hyperplasia is most often due to myasthenia gravis.
- ☐ Thymoma is an epithelial tumour and may be benign or malignant. Thymoma may produce paraneoplastic syndrome of myasthenia gravis and other autoimmune disease association.

CLINICAL CASE 7

A 4 years old male child is brought by the mother to the paediatrician with low-grade fever, headache and bleeding from nose.

On examination, the child is found to have mild hepatosplenomegaly but no lymphadenopathy. A routine complete blood count (CBC) reveals haemoglobin 6 g/dl, white blood cell count 80,000/ μ l and platelet count 40,000/ μ l.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 908 (Appendix II)

CLINICAL CASE 8

A 70 years old man complains of pain lower back, fatigue and increasing pallor for one month.

On examination, he has tenderness over the lower vertebral region. An X-ray shows multiple lytic lesions in the pelvis and sacrum.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

Answers on page 908 (Appendix II)

Section III SYSTEMIC PATHOLOGY

13

The Blood Vessels and Lymphatics

The blood vessels are closed circuits for the transport of blood from the left heart to the metabolising cells, and then back to the right heart. The blood containing oxygen, nutrients and metabolites is routed through arteries, arterioles, capillaries, venules and veins. These blood vessels differ from each other in their structure and function.

NORMAL STRUCTURE

ARTERIES

Depending upon the calibre and certain histologic features, arteries are divided into 3 types: large (elastic) arteries, medium-sized (muscular) arteries and the smallest arterioles.

Histologically, all major arteries of the body have 3 layers in their walls: the tunica intima, the tunica media and the tunica adventitia. These layers progressively decrease with diminution in the size of the vessels.

1. Tunica intima This is the inner coat of the artery. It is composed of the lining endothelium, subendothelial connective tissue and bounded externally by internal elastic lamina.

◆ **Endothelium** is a layer of flattened cells adjacent to the flowing blood. Narrow junctions exist between the adjoining endothelial cells through which certain materials pass. The integrity of the endothelial layer is of paramount importance in maintenance of vascular functions since damage to it is the most important event in the initiation of thrombus formation at the site.

◆ **Subendothelial tissue** consists of loose meshwork of connective tissue that includes myointimal cells, collagen, proteoglycans, elastin and matrix glycoproteins.

◆ **Internal elastic lamina** is a layer of elastic fibres having minute fenestrations.

2. Tunica media Tunica media is the middle coat of the arterial wall, bounded internally by internal elastic lamina and externally by external elastic lamina. This layer is the thickest and consists mainly of smooth muscle cells and elastic fibres. The *external elastic lamina* consisting of condensed elastic tissue is less well defined than the *internal elastic lamina*.

3. Tunica adventitia The outer coat of arteries is the tunica adventitia. It consists of loose mesh of connective

tissue and some elastic fibres that merge with the adjacent tissues. This layer is rich in lymphatics and autonomic nerve fibres.

The layers of arterial wall receive nutrition and oxygen from 2 sources:

1. Tunica intima and inner third of the media are nourished by *direct diffusion* from the blood present in the lumen.
2. Outer two-thirds of the media and the adventitia are supplied by *vasa vasora* (i.e. *vessels of vessels*), the nutrient vessels arising from the parent artery.

As the calibre of the artery decreases, the three layers progressively diminish. Thus, there are structural variations in three types of arteries:

◆ **Large, elastic arteries** such as the aorta, innominate, common carotid, major pulmonary, and common iliac arteries have very high content of elastic tissue in the media and thick elastic laminae and hence the name.

◆ **Medium-sized, muscular arteries** are the branches of elastic arteries. All the three layers of arterial wall are thinner than in the elastic arteries. The internal elastic lamina appears as a single wavy line while the external elastic lamina is less prominent. The media primarily consists of smooth muscle cells and some elastic fibres (**Fig. 13.1**).

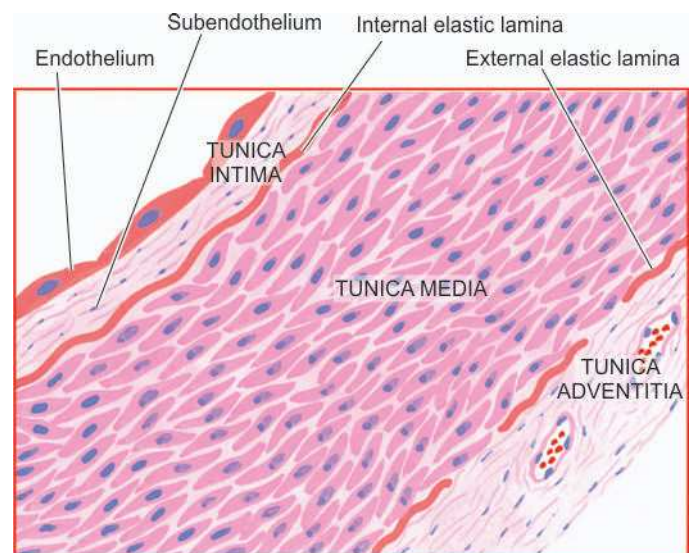

Figure 13.1 The structure of a medium-sized muscular artery.

◆ *Arterioles* are the smallest branches with internal diameter 20-100 μm . Structurally, they consist of three layers as in muscular arteries but are much thinner and cannot be distinguished. The arterioles consist of a layer of endothelial cells in the intima, one or two smooth muscle cells in the media and small amount of collagen and elastic tissue comprising the adventitia. The elastic laminae are virtually lost.

VEINS

The structure of normal veins is basically similar to that of arteries. The walls of the veins are thinner, the three tunicae (intima, media and adventitia) are less clearly demarcated, elastic tissue is scanty and not clearly organised into internal and external elastic laminae. The media contains very small amount of smooth muscle cells with abundant collagen. All veins, except vena cavae and common iliac veins, have valves best developed in veins of the lower limbs. The valves are delicate folds of intima, located every 1-6 cm, often next to the point of entry of a tributary vein. They prevent any significant retrograde venous blood flow.

CAPILLARIES

Capillaries are about the size of an RBC (7-8 μm) and have 1-2 endothelial cells but no media. Blood from capillaries returns to the heart via *post-capillary venules* and from there into venules and then drained into veins.

LYMPHATICS

Lymphatic capillaries, lymphatic vessels and lymph nodes comprise the lymphatic system. Lymphatic capillaries resemble blood capillaries, and larger lymphatics are identical to veins. However, lymphatics lined by a single layer of endothelium have thin muscle in their walls than in veins of the same size and the valves are more numerous. Lymphatic capillaries and lymphatics form plexuses around tissues and organs. The walls of lymphatic capillaries are permeable to tissue fluid, proteins and particulate matter.

GIST BOX 13.1

Normal Structure of Blood Vessels and Lymphatics

- ▣ Arteries are of 3 types: large (elastic) arteries, medium-sized (muscular) arteries and the smallest arterioles.
- ▣ Major arteries of the body have 3 layers in their walls: the tunica intima, the tunica media and the tunica adventitia. Internal and external elastic laminae bounding the media are well developed in arteries.
- ▣ The walls of the veins are thinner, three tunicae (intima, media and adventitia) are less clearly demarcated, elastic tissue is scanty and not clearly organised into internal and external elastic laminae.
- ▣ Capillaries are tiny of the size of a red cell and have 1-2 endothelial cells only in their wall.
- ▣ Lymphatic channels are similar to veins and form plexus around tissues and organs.

ARTERIOSCLEROSIS

Arteriosclerosis is a general term used to include all conditions with thickening and hardening of the arterial walls.

The following morphologic entities are included under arteriosclerosis:

- I. Senile arteriosclerosis (affects arteries)
- II. Hypertensive arteriolosclerosis (affects arterioles)
- III. Mönckeberg's arteriosclerosis (Medial calcific sclerosis) (affects arteries)
- IV. Atherosclerosis (affects arteries)

The last-named, atherosclerosis, is the most common and most important form of arteriosclerosis; if not specified, the two terms are used interchangeably with each other.

SENILE ARTERIOSCLEROSIS

Senile arteriosclerosis is the thickening of media and intima of the arteries seen due to ageing. The changes are non-selective and affect most of the arteries. These are possibly induced by stress and strain on vessel wall during life.

MORPHOLOGIC FEATURES The changes are as under:

1. *Fibroelastosis*: The intima and media are thickened due to increase in elastic and collagen tissue.
2. *Elastic reduplication*: The internal elastic lamina is split or reduplicated so that two wavy layers are seen.

Eventually, the fibrotic changes result in age-related elevation of systolic blood pressure.

HYPERTENSIVE ARTERIOLOSCLEROSIS

Hypertension is the term used to describe an elevation in blood pressure. Pathology of 3 forms of hypertension—systemic, pulmonary and portal, is discussed in detail with diseases of the kidneys (Chapter 20), lungs (Chapter 15) and liver (Chapter 19) respectively.

Arteriolosclerosis is the term used to describe 3 morphologic forms of vascular disease affecting arterioles and small muscular arteries. These are: hyaline arteriolosclerosis, hyperplastic arteriolosclerosis and necrotising arteriolitis. All the three types are common in hypertension but may occur due to other causes as well.

HYALINE ARTERIOLOSCLEROSIS

Hyaline sclerosis is a common arteriolar lesion that may be seen *physiologically* due to ageing, or may occur *pathologically* in benign nephrosclerosis in hypertensives and as a part of microangiopathy in diabetics; the subject is discussed again in Chapter 20.

MORPHOLOGIC CHANGES The visceral arterioles are particularly involved. The vascular walls are thickened and the lumina narrowed or even obliterated.

Microscopically, the thickened vessel wall shows structureless, eosinophilic, hyaline material in the intima and media (**Fig. 13.2,A**).

PATHOGENESIS The exact pathogenesis is not known. However, the following hypotheses have been proposed:

- i) The lesions result most probably from *leakage of components of plasma* across the vascular endothelium. This is substantiated by the demonstration of immunoglobulins, complement, fibrin and lipids in the lesions. The permeability

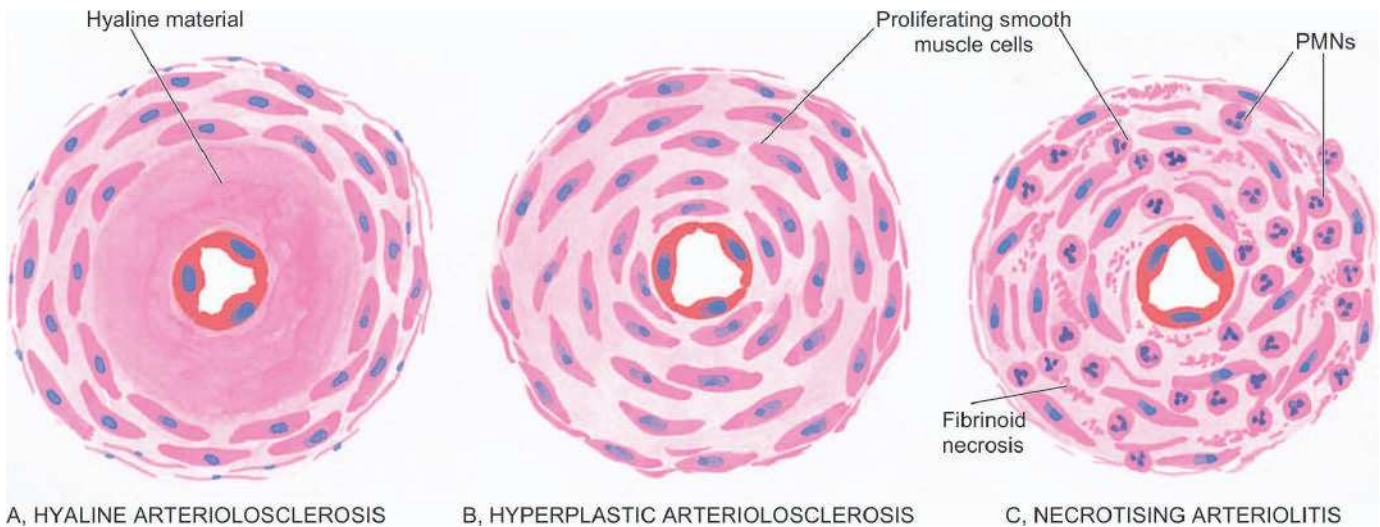

Figure 13.2 Diagrammatic representation of three forms of arteriosclerosis, commonly seen in hypertension.

of the vessel wall is increased, due to haemodynamic stress in hypertension and metabolic stress in diabetes, so that these plasma components leak out and get deposited in the vessel wall.

- ii) An alternate possibility is that the lesions may be due to *immunologic reaction*.
- iii) Some have considered it to be *normal aging process* that is exaggerated in hypertension and diabetes mellitus.

HYPERPLASTIC ARTERIOSCLEROSIS

The hyperplastic or proliferative type of arteriosclerosis is a characteristic lesion of malignant hypertension; other causes include haemolytic-uraemic syndrome, scleroderma and toxæmia of pregnancy.

MORPHOLOGIC FEATURES The morphologic changes affect mainly the intima, especially of the interlobular arteries in the kidneys. Three types of intimal thickening may occur.

- i) *Onion-skin lesion* consists of loosely-placed concentric layers of hyperplastic intimal smooth muscle cells like the bulb of an onion. The basement membrane is also thickened and reduplicated (**Fig. 13.2, B**).
- ii) *Mucinous intimal thickening* is the deposition of amorphous ground substance, probably proteoglycans, with scanty cells.
- iii) *Fibrous intimal thickening* is less common and consists of bundles of collagen, elastic fibres and hyaline deposits in the intima.

Severe intimal sclerosis results in narrowed or obliterated lumen. With time, the lesions become more and more fibrotic.

PATHOGENESIS The pathogenesis of hyperplastic intimal thickening is unclear. Probably, the changes result following endothelial injury from systemic hypertension, hypoxia or immunologic damage leading to increased permeability. A healing reaction occurs in the form of proliferation of smooth muscle cells with fibrosis.

NECROTISING ARTERIOLITIS

In cases of severe hypertension and malignant hypertension, parts of small arteries and arterioles show changes of hyaline sclerosis and parts of these show necrosis, or necrosis may be superimposed on hyaline sclerosis. However, hyaline sclerosis may not be always present in the vessel wall.

MORPHOLOGIC FEATURES Besides the changes of hyaline sclerosis, the changes of necrotising arteriolitis include fibrinoid necrosis of vessel wall, acute inflammatory infiltrate of neutrophils in the adventitia. Oedema and haemorrhages often surround the affected vessels (**Fig. 13.2, C**).

PATHOGENESIS Since necrotising arteriolitis occurs in vessels in which there is sudden and great elevation of pressure, the changes are said to result from direct physical injury to the vessel wall.

MÖNCKEBERG'S ARTERIOSCLEROSIS (MEDIAL CALCIFIC SCLEROSIS)

Mönckeberg's arteriosclerosis is calcification of the media of large and medium-sized muscular arteries, especially of the extremities and of the genital tract, in persons past the age of 50. The condition occurs as an age-related degenerative process, and therefore, an example of dystrophic calcification, and has little or no clinical significance. However, medial calcification also occurs in some pathological states like pseudoxanthoma elasticum and in idiopathic arterial calcification of infancy.

MORPHOLOGIC FEATURES Medial calcification is often an incidental finding in X-rays of the affected sites having muscular arteries. The deposition of calcium salts in the media produces pipestem-like rigid tubes without causing narrowing of the lumen.

Microscopically, Mönckeberg's arteriosclerosis is characterised by deposits of calcium salts in the media without associated inflammatory reaction while the intima and the adventitia are spared (**Fig. 13.3**). Often, coexistent

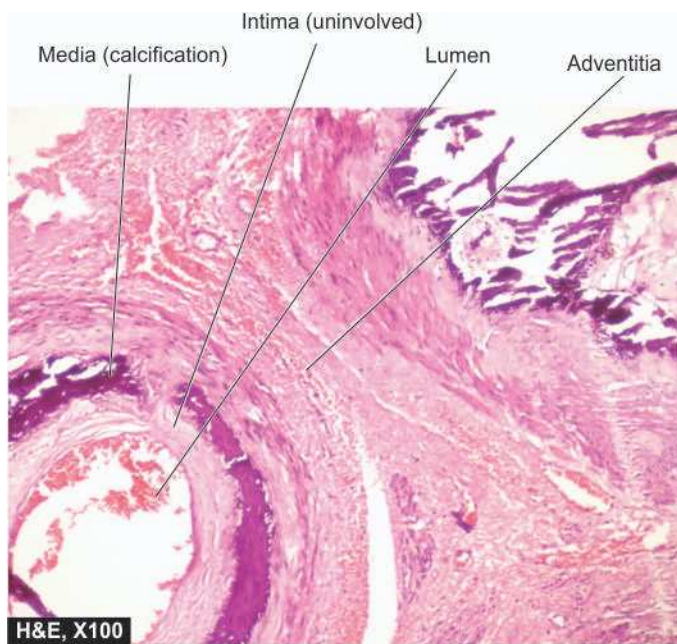

Figure 13.3 Mönckeberg's arteriosclerosis (medial calcific sclerosis). There is calcification exclusively in the tunica media unassociated with any significant inflammation.

changes of atherosclerosis are present altering the histologic appearance.

PATHOGENESIS Pathogenesis of this condition is not known but it is considered as an age-related physiologic change due to prolonged effect of vasoconstriction.

GIST BOX 13.2 Arteriosclerosis

- ▣ Arteriosclerosis is the term used for thickening and hardening of arterial wall.
- ▣ Senile arteriosclerosis is age-related thickening of the intima and media.
- ▣ Hypertensive arteriolosclerosis affects arterioles and includes hyaline thickening, or hyperplastic or proliferative change or necrotising lesion.
- ▣ Mönckeberg's medial calcific sclerosis affects the media of large and medium-sized muscular arteries.

ATHEROSCLEROSIS

DEFINITION

Atherosclerosis is an thickening and hardening of large and medium-sized muscular arteries, primarily due to involvement of tunica intima and is characterised by fibrofatty plaques or atheromas.

The term atherosclerosis is derived from *athero-* (meaning porridge) referring to the soft lipid-rich material in the centre of atheroma, and *sclerosis* (scarring) referring to connective tissue in the plaques.

Atherosclerosis is the commonest and the most important of the arterial diseases. Though any large and medium-sized artery may be involved in atherosclerosis, the most commonly

affected are the aorta, the coronaries and the cerebral arterial systems. Therefore, the major clinical syndromes resulting from ischaemia due to atherosclerosis are as under:

1. Heart (angina and myocardial infarcts or *heart attacks*)
2. Brain (transient cerebral ischaemia and cerebral infarcts or *strokes*)
3. Other sequelae are: peripheral vascular disease, aneurysmal dilatation due to weakened arterial wall, chronic ischaemic heart disease, ischaemic encephalopathy and mesenteric arterial occlusion.

ETIOLOGY

Atherosclerosis is widely prevalent in industrialised countries. However, majority of the data on etiology are based on the animal experimental work and epidemiological studies. The incidence for atherosclerosis quoted in the literature is based on the major clinical syndromes produced by it, the most important interpretation being that death from myocardial infarction is related to underlying atherosclerosis. Cardiovascular disease, mostly related to atherosclerotic coronary heart disease or ischaemic heart disease (IHD) is the most common cause of premature death in the developed countries of the world. It is estimated that by the year 2020, cardiovascular disease, mainly atherosclerosis, will become the leading cause of total global disease burden.

Systematic large-scale studies of investigations on living populations have revealed a number of *risk factors* which are associated with increased risk of developing clinical atherosclerosis. Often, they are acting in combination rather than singly. These risk factors are divided into two groups (**Table 13.1**):

I. Major risk factors These are further considered under 2 headings:

- A) *Major risk factors modifiable by life style and/or therapy:* This includes major risk factors which can be controlled by modifying life style and/or by pharmacotherapy and includes: dyslipidaemias, hypertension, diabetes mellitus and smoking.
- B) *Constitutional risk factors:* These are non-modifiable major risk factors that include: increasing age, male sex, genetic abnormalities, and familial and racial predisposition.

Table 13.1 Risk factors in atherosclerosis.

| I. MAJOR RISK FACTORS | II. EMERGING RISK FACTORS |
|--------------------------------|--|
| A) <i>Modifiable</i> | 1. Environmental influences |
| 1. Dyslipidaemia | 2. Obesity |
| 2. Hypertension | 3. Hormones: oestrogen deficiency, oral contraceptives |
| 3. Diabetes mellitus | 4. Physical inactivity |
| 4. Smoking | 5. Stressful life |
| B) <i>Constitutional</i> | 6. Homocystinuria |
| 1. Age | 7. Role of alcohol |
| 2. Sex | 8. Prothrombotic factors |
| 3. Genetic factors | 9. Infections (<i>C. pneumoniae</i> , Herpesvirus, CMV) |
| 4. Familial and racial factors | 10. High CRP |

II. Non-traditional emerging risk factors This group includes a host of factors whose role in atherosclerosis is minimal, and in some cases, even uncertain.

Apparently, a combination of etiologic risk factors have additive effect in producing the lesions of atherosclerosis.

Major Risk Factors Modifiable By Life Style and/or Therapy

There are four major risk factors in atherogenesis—lipid disorders, hypertension, cigarette smoking and diabetes mellitus.

1. DYSLIPIDAEMIAS Virchow in 19th century first identified cholesterol crystals in the atherosclerotic lesions. Since then, extensive information on lipoproteins and their role in atherosclerotic lesions has been gathered. Abnormalities in plasma lipoproteins have been firmly established as the most important major risk factor for atherosclerosis. It has been firmly established that hypercholesterolaemia has directly proportionate relationship with atherosclerosis and IHD. The following evidences are cited in support of this:

- i) The atherosclerotic plaques contain cholesterol and cholesterol esters, largely derived from the lipoproteins in the blood.
- ii) The lesions of atherosclerosis can be induced in experimental animals by feeding them with diet rich in cholesterol.
- iii) Individuals with hypercholesterolaemia due to various causes such as in diabetes mellitus, myxoedema, nephrotic syndrome, von Gierke's disease, xanthomatosis and familial hypercholesterolaemia have increased risk of developing atherosclerosis and IHD.
- iv) Populations having hypercholesterolaemia have higher mortality from IHD. Dietary regulation and administration of cholesterol-lowering drugs have beneficial effect on reducing the risk of IHD.

The concentration of total cholesterol in the serum reflects the concentrations of different lipoproteins in the serum. The lipoproteins are divided into classes according to the density of solvent in which they remain suspended on centrifugation at high speed. The major classes of lipoprotein particles are *chylomicrons*, *very-low density lipoproteins (VLDL)*, *low-density lipoproteins (LDL)*, and *high-density lipoproteins (HDL)*. Lipids are insoluble in blood and therefore are carried in circulation and across the cell membrane by carrier proteins called *apoproteins*. Different apoproteins are named by letter A, B, C, D etc while their subfractions are numbered serially.

The major fractions of lipoproteins tested in blood lipid profile and their varying effects on atherosclerosis and IHD are as under (**Table 13.2**):

i) Total cholesterol Desirable normal serum level is 140-200 mg/dl, while levels of borderline high are considered between 200-240 mg/dl. An elevation of total serum cholesterol levels above 260 mg/dl in men and women between 30 and 50 years of age has three times higher risk of developing IHD as compared with people with total serum cholesterol levels within normal limits.

ii) Triglycerides Normal serum level is below 150 mg/dl.

iii) Low-density lipoproteins (LDL) cholesterol Optimal serum level of LDL is <100 mg/dl. LDL is richest in cholesterol and has the *maximum association* with atherosclerosis.

iv) Very-low-density lipoprotein (VLDL) VLDL carries much of the triglycerides and its blood levels therefore parallel with that of triglycerides; VLDL has *less marked* effect than LDL.

v) High-density lipoproteins (HDL) cholesterol Normal desirable serum level is <50 mg/dl. HDL is *protective* ('good cholesterol') against atherosclerosis.

Many studies have demonstrated the harmful effect of diet containing larger quantities of saturated fats (e.g. in eggs, meat, milk, butter etc) and trans fats (i.e. unsaturated fats produced by artificial hydrogenation of polyunsaturated fats) which raise the plasma cholesterol level. This type of diet is consumed more often by the affluent societies who are at greater risk of developing atherosclerosis. On the contrary, a diet low in saturated fats and high in poly-unsaturated fats and having omega-3 fatty acids (e.g. in fish, fish oils etc) lowers the plasma cholesterol levels. Aside from lipid-rich diet, high intake of the total number of calories from carbohydrates, proteins, alcohol and sweets has adverse effects.

Besides above, *familial hypercholesterolaemia*, an autosomal codominant disorder, is characterised by elevated LDL cholesterol and normal triglycerides and occurrence of xanthomas and premature coronary artery disease. It occurs due to mutations in LDL receptor gene.

Currently, management of dyslipidaemia is directed at *lowering LDL* in particular, and total cholesterol in general, by use of statins, and for *raising HDL* by weight loss, exercise and use of nicotinic acid. Thus currently, preferred term for hyperlipidaemia is dyslipidaemia because one risky plasma lipoprotein (i.e. LDL) is elevated and needs to be brought down, while the other good plasma lipoprotein (i.e. HDL) when low requires to be raised.

How hypercholesterolaemia and various classes of lipoproteins produce atherosclerosis is described under 'pathogenesis'.

2. HYPERTENSION Hypertension is a risk factor for all clinical manifestations of atherosclerosis. Hypertension

Table 13.2 Fractions of lipoproteins in serum.

| CLASSES | SITES OF SYNTHESIS | NORMAL SERUM LEVELS* | ROLE IN ATHEROSCLEROSIS |
|-----------------------|------------------------------|----------------------|-------------------------|
| 1. HDL cholesterol | Liver, intestine | > 50 mg/dl | Protective |
| 2. LDL cholesterol | Liver | < 100 mg/dl | Maximum |
| 3. VLDL triglycerides | Intestine, liver | < 150 mg/dl | Less marked |
| 4. Total cholesterol | Liver, intestine | < 200 mg/dl | Maximum |
| 5. Chylomicrons | Liver, intestine, macrophage | — | Indirect |

*Easy way to remember optimum desirable cut off levels of serum lipids in mg/dl is a multiple of 50: <200 for cholesterol, <150 for LDL, <100 for triglycerides (or VLDL), and >50 for HDL.

Lipids can also be measured in plasma (EDTA blood); plasma values are 3% lower than in serum.

doubles the risk of all forms of cardiovascular disease. It acts probably by mechanical injury to the arterial wall due to increased blood pressure. Elevation of systolic pressure of over 160 mmHg or a diastolic pressure of over 95 mmHg is associated with five times higher risk of developing IHD than in people with blood pressure within normal range (140/90 mmHg or less).

3. SMOKING The extent and severity of atherosclerosis are much greater in smokers than in non-smokers. Cigarette smoking is associated with higher risk of atherosclerotic IHD and sudden cardiac death. Men who smoke a pack of cigarettes a day are 3-5 times more likely to die of IHD than non-smokers. The increased risk and severity of atherosclerosis in smokers is due to reduced level of HDL, deranged coagulation system and accumulation of carbon monoxide in the blood that produces carboxyhaemoglobin and eventually hypoxia in the arterial wall favouring atherosclerosis.

4. DIABETES MELLITUS Clinical manifestations of atherosclerosis are far more common and develop at an early age in people with both type 1 and type 2 diabetes mellitus. In particular, association of type 2 diabetes mellitus characterised by metabolic (insulin resistance) syndrome and abnormal lipid profile termed 'diabetic dyslipidaemia' is common and heightens the risk of cardiovascular disease (page 809). The risk of developing IHD is doubled, tendency to develop cerebrovascular disease is high, and frequency to develop gangrene of foot is about 100 times increased. The causes of increased severity of atherosclerosis are complex and numerous which include endothelial dysfunction, increased aggregation of platelets, increased LDL and decreased HDL.

Constitutional Risk Factors

Age, sex and genetic influences, race and family do affect the appearance of lesions of atherosclerosis.

1. AGE Atherosclerosis is an age-related disease. Though early lesions of atherosclerosis may be present in childhood, clinically significant lesions are found with increasing age. Fully-developed atheromatous plaques usually appear in the 4th decade and beyond. Evidence in support comes from the high death rate from IHD in this age group.

2. SEX The incidence and severity of atherosclerosis are more in men than in women and the changes appear a decade earlier in men (≥ 45 years) than in women (≥ 55 years). The prevalence of atherosclerotic IHD is about three times higher in men in 4th decade than in women and the difference slowly declines with age but remains higher at all ages in men. The lower incidence of IHD in women, especially in premenopausal age, is probably due to high levels of oestrogen and high-density lipoproteins, both of which have anti-atherogenic influence.

3. GENETIC FACTORS Genetic factors play a significant role in atherogenesis. Hereditary derangements of lipoprotein metabolism predispose the individual to high blood lipid level and familial hypercholesterolaemia.

4. FAMILIAL AND RACIAL FACTORS The familial predisposition to atherosclerosis may be related to other risk factors like diabetes, hypertension and hyperlipoproteinaemia. Racial differences too exist; Blacks have generally less severe atherosclerosis than Whites.

Emerging Risk Factors

There are a number of nontraditional newly emerging risk factors for which the role in the etiology of atherosclerosis is yet not fully supported. These factors are as under:

1. Higher incidence of atherosclerosis in developed countries and low prevalence in underdeveloped countries, suggesting the role of *environmental influences*.
2. *Metabolic syndrome* characterised by abdominal obesity along with glucose intolerance, insulin resistance and dyslipidaemia and hypertension, is associated with increased risk.
3. Use of *exogenous hormones* (e.g. oral contraceptives) by women or *endogenous oestrogen deficiency* (e.g. in post-menopausal women) has been shown to have an increased risk of developing myocardial infarction or stroke.
4. *Physical inactivity* and lack of exercise are associated with the risk of developing atherosclerosis and its complications.
5. *Stressful life style*, termed as 'type A' behaviour pattern, characterised by aggressiveness, competitive drive, ambitiousness and a sense of urgency, is associated with enhanced risk of IHD compared with 'type B' behaviour of relaxed and happy-go-lucky type.
6. *Hypercystinaemia* due to elevated serum homocysteine level from low folate and vitamin B₁₂ have a relationship with coronary artery disease and its consequences.
7. Patients with *homocystinuria*, an uncommon inborn error of metabolism, having hypercystinaemia have also been reported to have early atherosclerosis and coronary artery disease.
8. *Prothrombotic factors* and elevated fibrinogen levels favour formation of thrombi which is the gravest complication of atherosclerosis.
9. Role of *infections*, particularly of *Chlamydia pneumoniae* and viruses such as herpesvirus and cytomegalovirus, has been found in coronary atherosclerotic lesions by causing inflammation. Possibly, infections may be acting in combination with some other factors.
10. Markers of inflammation such as *elevated C reactive protein*, an acute phase reactant, correlate with risk of developing atherosclerosis.

However, there are some reports in the literature which suggest that moderate consumption of *alcohol* has slightly beneficial effect by raising the level of HDL cholesterol.

PATHOGENESIS

As stated above, atherosclerosis is not caused by a single etiologic factor but is a multifactorial process whose exact pathogenesis is still not known. Since the times of Virchow, a number of theories have been proposed.

◆ **Insudation hypothesis** The concept hypothesised by *Virchow in 1856* that atherosclerosis is a form of cellular proliferation of the intimal cells resulting from increased imbibing of lipids from the blood came to be called the '*lipid theory*'. Modified form of this theory is currently known as '*response to injury hypothesis*' and is now-a-days the most widely accepted theory.

◆ **Encrustation hypothesis** The proposal put forth by *Rokitansky in 1852* that atheroma represented a form of encrustation on the arterial wall from the components in the blood forming thrombi composed of platelets, fibrin

and leucocytes, was named as 'encrustation theory' or 'thrombogenic theory'. Since currently it is believed that encrustation or thrombosis is not the sole factor in atherogenesis but the components of thrombus (platelets, fibrin and leucocytes) have a role in atheromatous lesions, this theory has now been incorporated into the response-to-injury hypothesis mentioned above.

Though, there is no consensus regarding the origin and progression of lesion of atherosclerosis, the role of four key factors—arterial smooth muscle cells, endothelial cells, blood monocytes and dyslipidaemia, is accepted by all. However, the areas of disagreement exist in the mechanism and sequence of events involving these factors in initiation, progression and complications of disease. Currently, pathogenesis of atherosclerosis is explained on the basis of the following two theories:

1. *Reaction-to-injury hypothesis*, first described in 1973, and modified in 1986 and 1993 by Ross.
2. *Monoclonal theory*, based on neoplastic proliferation of smooth muscle cells, postulated by Benditt and Benditt in 1973.

1. Reaction-to-Injury Hypothesis

This theory is most widely accepted and incorporates aspects of two older historical theories of atherosclerosis—the lipid theory of Virchow and thrombogenic (encrustation) theory of Rokitansky.

◆ The *original response to injury theory* was first described in 1973 according to which the initial event in atherogenesis was considered to be endothelial injury followed by smooth muscle cell proliferation so that the early lesions, according to this theory, consist of smooth muscle cells mainly.

◆ The *modified response-to-injury hypothesis* described subsequently in 1993 implicates lipoprotein entry into the intima as the initial event followed by lipid accumulation in the macrophages (foam cells now) which according to modified theory, are believed to be the dominant cells in early lesions.

Both these theories—original and modified, have attracted support and criticism. However, following is the generally accepted role of key components involved in atherogenesis, diagrammatically illustrated in Fig. 13.4.

i) Endothelial injury It has been known for many years that endothelial injury is the initial triggering event in the development of lesions of atherosclerosis. Actual endothelial denudation is not an essential requirement, but endothelial dysfunction may initiate the sequence of events. Numerous causes ascribed to endothelial injury in experimental animals are: mechanical trauma, haemodynamic forces, immunological and chemical mechanisms, metabolic agent as chronic dyslipidaemia, homocysteine, circulating toxins from systemic infections, viruses, hypoxia, radiation, carbon monoxide and tobacco products.

In humans, two of the major risk factors which act together to produce endothelial injury are: *haemodynamic stress from hypertension and chronic dyslipidaemia*. The role of haemodynamic forces in causing endothelial injury is further supported by the distribution of atheromatous plaques at points of bifurcation or branching of blood vessels which are under greatest shear stress.

ii) Intimal smooth muscle cell proliferation Endothelial injury causes adherence, aggregation and platelet release reaction at the site of exposed subendothelial connective

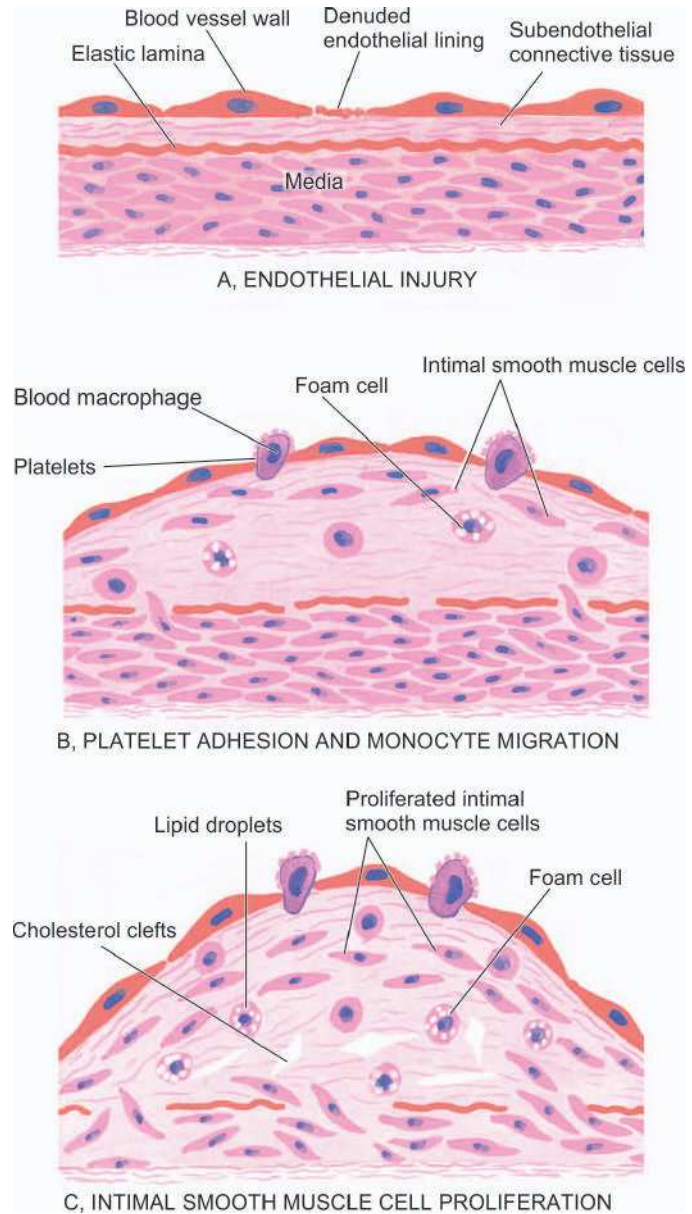

Figure 13.4 Diagrammatic representation of pathogenesis of atherosclerosis as explained by 'reaction-to-injury' hypothesis. A, Endothelial injury. B, Adhesion of platelets and migration of blood monocytes from blood stream. C, Smooth muscle cell proliferation into the intima and ingrowth of new blood vessels.

tissue and infiltration by inflammatory cells. Proliferation of intimal smooth muscle cells and production of extracellular matrix are stimulated by various cytokines such as IL-1 and TNF- α released from invading monocyte-macrophages and by activated platelets at the site of endothelial injury. These cytokines lead to local synthesis of following growth factors having distinct roles in plaque evolution:

Platelet-derived growth factor (*PDGF*) and fibroblast growth factor (*FGF*) stimulate proliferation and migration of smooth muscle cells from their usual location in the media into the intima.

Transforming growth factor- β (*TGF- β*) and interferon (*IFN*)- γ derived from activated T lymphocytes within lesions regulate the synthesis of collagen by smooth muscle cells.

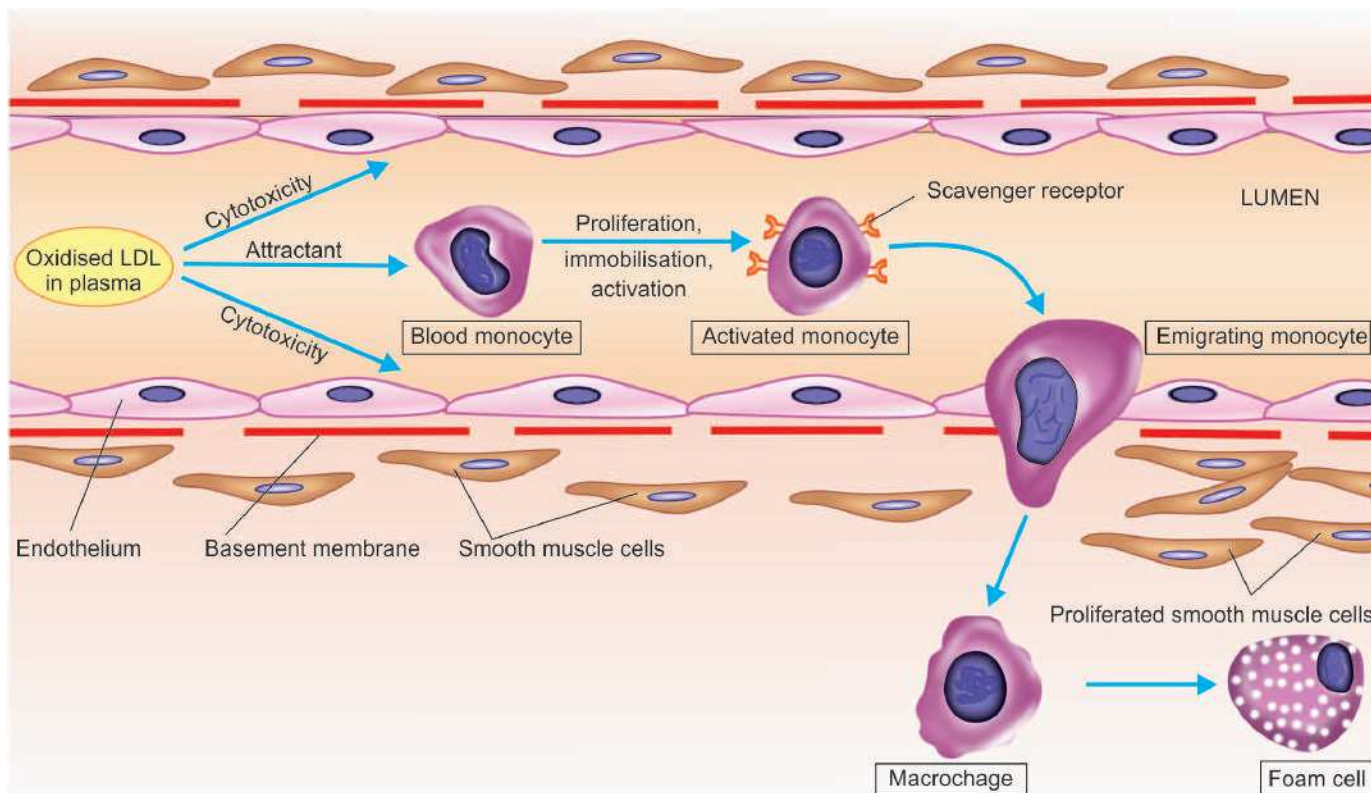

Figure 13.5 Mechanism of foam cell formation.

Smooth muscle cell proliferation is also facilitated by biomolecules such as nitric oxide and *endothelin* released from endothelial cells. Intimal proliferation of smooth muscle cells is accompanied by synthesis of matrix proteins—collagen, elastic fibre proteins and proteoglycans.

iii) Role of blood monocytes Though blood monocytes do not possess receptors for normal LDL, LDL does appear in the monocyte cytoplasm to form foam cell by mechanism illustrated in **Fig. 13.5**. Plasma LDL on entry into the intima undergoes oxidation. The 'oxidised LDL' formed in the intima performs the following all-important functions on monocytes and endothelium:

a) For monocytes: Oxidised LDL acts to attract, proliferate, immobilise and activate them as well as is readily taken up by scavenger receptor on the monocyte to transform it to a lipid-laden foam cell.

b) For endothelium: Oxidised LDL is cytotoxic.

Death of foam cell by apoptosis releases lipid to form lipid core of plaque.

iv) Role of dyslipidaemia As stated already, chronic dyslipidaemia in itself may initiate endothelial injury and dysfunction by causing increased permeability. In particular, hypercholesterolaemia with increased serum concentration of LDL promotes formation of foam cells, while high serum concentration of HDL has anti-atherogenic effect.

v) Thrombosis As apparent from the foregoing, endothelial injury exposes subendothelial connective tissue resulting in formation of small platelet aggregates at the site and causing proliferation of smooth muscle cells. This causes mild inflammatory reaction which together with foam cells is incorporated into the atheromatous plaque. The lesions

enlarge by attaching fibrin and cells from the blood so that thrombus becomes a part of atheromatous plaque.

2. Monoclonal Hypothesis

This hypothesis is based on the postulate that proliferation of smooth muscle cells is the primary event and that this proliferation is monoclonal in origin similar to cellular proliferation in neoplasms (e.g. in uterine leiomyoma, page 201). The evidence cited in support of monoclonal hypothesis is the observation on proliferated smooth muscle cells in atheromatous plaques which have only one of the two forms of glucose-6-phosphate dehydrogenase (G6PD) isoenzymes, suggesting monoclonality in origin. The monoclonal proliferation of smooth muscle cells in atherosclerosis may be initiated by mutation caused by exogenous chemicals (e.g. cigarette smoke), endogenous metabolites (e.g. lipoproteins) and some viruses (e.g. Marek's disease virus in chickens, herpesvirus).

MORPHOLOGIC FEATURES

Early lesions in the form of diffuse intimal thickening, fatty streaks and gelatinous lesions are often the forerunners in the evolution of atherosclerotic lesions. However, the clinical disease states due to luminal narrowing in atherosclerosis are caused by fully developed atheromatous plaques and complicated plaques (**Fig. 13.6**).

1. FATTY STREAKS AND DOTS Fatty streaks and dots on the intima by themselves are harmless but may be the precursor lesions of atheromatous plaques. They are seen in all races of the world and begin to appear in the first year of life. However, they are uncommon in older persons and

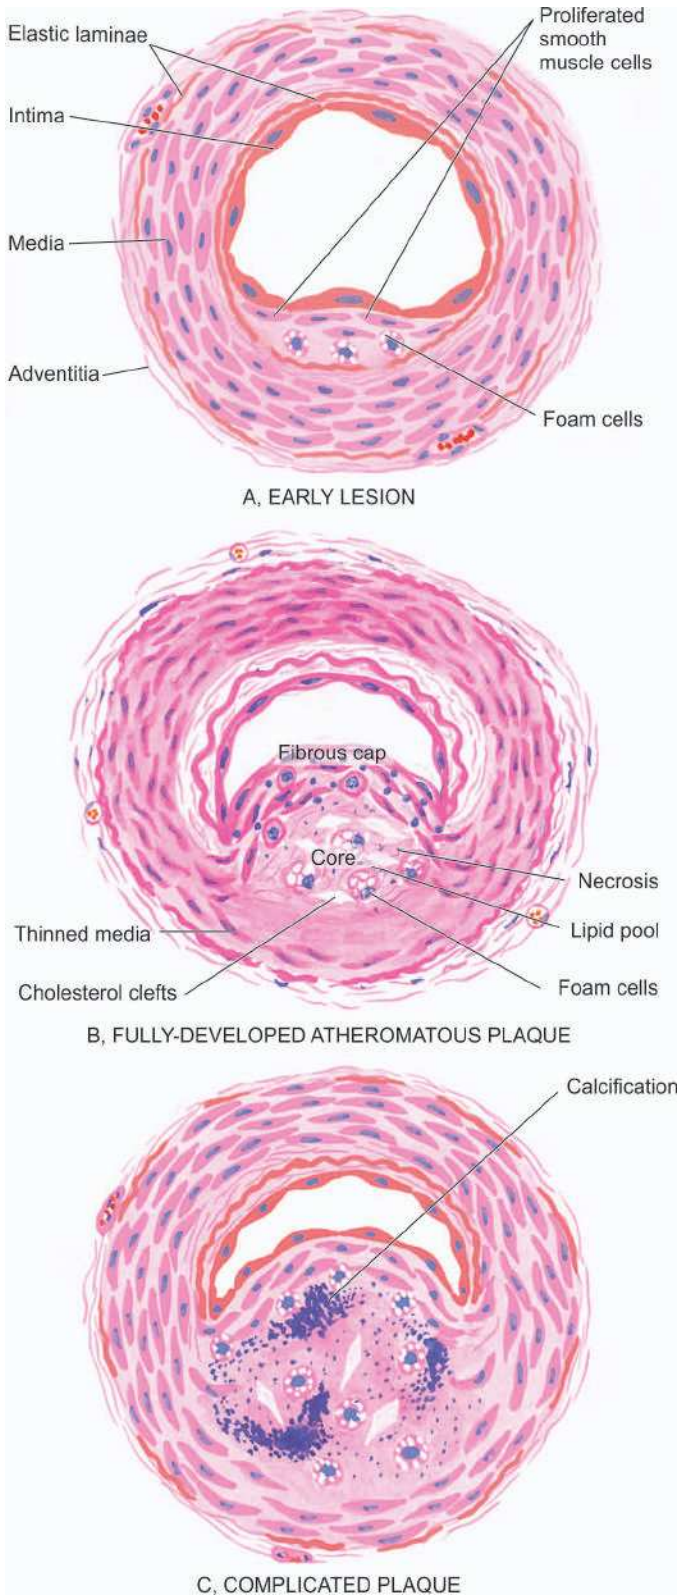

Figure 13.6 Schematic evolution of lesions in atherosclerosis.

are probably absorbed. They are especially prominent in the aorta and other major arteries, more often on the posterior wall than the anterior wall.

Grossly, the lesions may appear as flat or slightly elevated and yellow. They may be either in the form of small, multiple dots, about 1 mm in size, or in the form of elongated, beaded streaks.

Microscopically, fatty streaks lying under the endothelium are composed of closely-packed foam cells, lipid-containing elongated smooth muscle cells and a few lymphoid cells. Small amount of extracellular lipid, collagen and proteoglycans are also present.

2. GELATINOUS LESIONS Gelatinous lesions develop in the intima of the aorta and other major arteries in the first few months of life. Like fatty streaks, they may also be precursors of plaques. They are round or oval, circumscribed grey elevations, about 1 cm in diameter.

Microscopically, gelatinous lesions are foci of increased ground substance in the intima with thinned overlying endothelium.

3. ATHEROMATOUS PLAQUES A fully developed atherosclerotic lesion is called atheromatous plaque, also called *fibrous plaque*, *fibrofatty plaque* or *atheroma*. Unlike fatty streaks, atheromatous plaques are selective in different geographic locations and races and are seen in advanced age. These lesions may develop from progression of early lesions of the atherosclerosis just described. *Most often and most severely affected is the abdominal aorta*, though smaller lesions may be seen in descending thoracic aorta and aortic arch. The major branches of the aorta around the ostia are often severely involved, especially the iliac, femoral, carotid, coronary, and cerebral arteries.

Grossly, atheromatous plaques are white to yellowish-white lesions, varying in diameter from 1-2 cm and raised on the surface by a few millimetres to a centimetre in thickness (**Fig. 13.7**). Cut section of the plaque reveals the luminal surface as a firm, white *fibrous cap* and a *central core* composed of yellow to yellow-white, soft, porridge-like material and hence the name atheroma.

Microscopically, the appearance of plaque varies depending upon the age of the lesion. However, the following features are invariably present (**Fig. 13.8**):

- i) Superficial luminal part of the *fibrous cap* is covered by endothelium, and is composed of smooth muscle cells, dense connective tissue and extracellular matrix containing proteoglycans and collagen.
- ii) *Cellular area* under the fibrous cap is comprised by a mixture of macrophages, foam cells, lymphocytes and a few smooth muscle cells which may contain lipid.
- iii) Deeper *central soft core* consists of extracellular lipid material, cholesterol clefts, fibrin, necrotic debris and lipid-laden foam cells.
- iv) In older and *more advanced lesions*, the collagen in the fibrous cap may be dense and hyalinised, smooth muscle cells may be atrophic and foam cells are fewer.

4. COMPLICATED PLAQUES Various pathologic changes that occur in fully-developed atheromatous plaques are called the complicated lesions. These account for the most serious harmful effects of atherosclerosis and even death. These changes include calcification, ulceration, thrombosis, haemorrhage and aneurysmal dilatation. It is not uncommon to see more than one form of complication in a plaque.

i) Calcification Calcification occurs more commonly in advanced atheromatous plaques, especially in the aorta and coronaries. The diseased intima cracks like an egg-shell when the vessel is incised and opened.

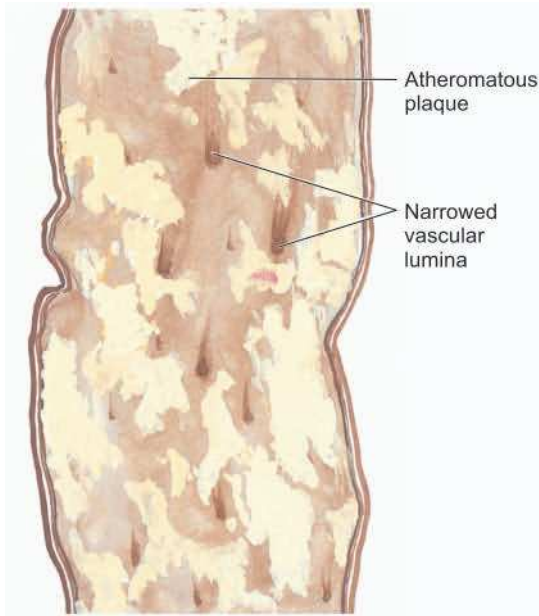

Figure 13.7 Structure of a fully-developed atheroma. The opened up inner surface of the abdominal aorta shows a variety of atheromatous lesions. While some are raised yellowish-white lesions raised above the surface, a few have ulcerated surface. Orifices of some of the branches coming out of the wall are narrowed by the atherosclerotic process.

Microscopically, the calcium salts are deposited in the vicinity of necrotic area and in the soft lipid pool deep in the thickened intima (**Fig. 13.9**). This form of atherosclerotic *intimal* calcification differs from Mönckeberg's *medial* calcific arteriosclerosis that affects only the tunica media (page 372).

ii) Ulceration The layers covering the soft pul-taceous material of an atheroma may ulcerate as a result of haemodynamic forces or mechanical trauma. This results in discharge of emboli composed of lipid material and debris into the blood stream, leaving a shallow, ragged

ulcer with yellow lipid debris in the base of the ulcer. Occasionally, atheromatous plaque in a coronary artery may suddenly rupture into the arterial lumen forcibly and cause thromboembolic occlusion.

iii) Thrombosis The ulcerated plaque and the areas of endothelial damage are vulnerable sites for formation of superimposed thrombi. These thrombi may get dislodged to become emboli and lodge elsewhere in the circulation, or may get organised and incorporated into the arterial wall as mural thrombi. Mural thrombi may become occlusive thrombi which may subsequently recanalise.

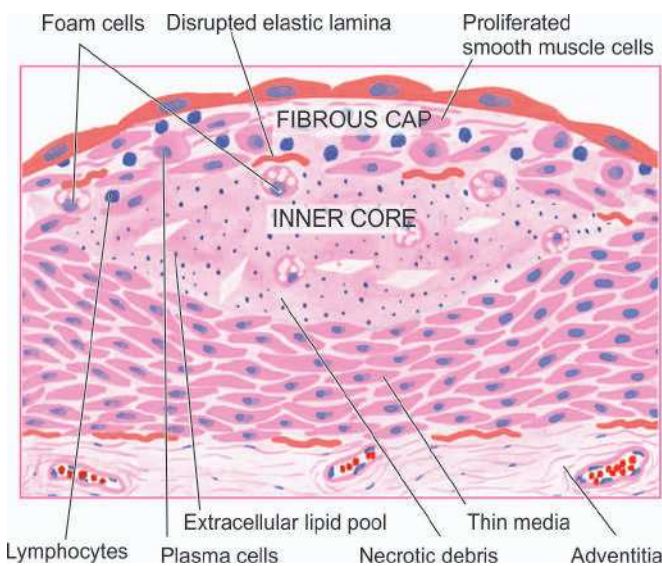

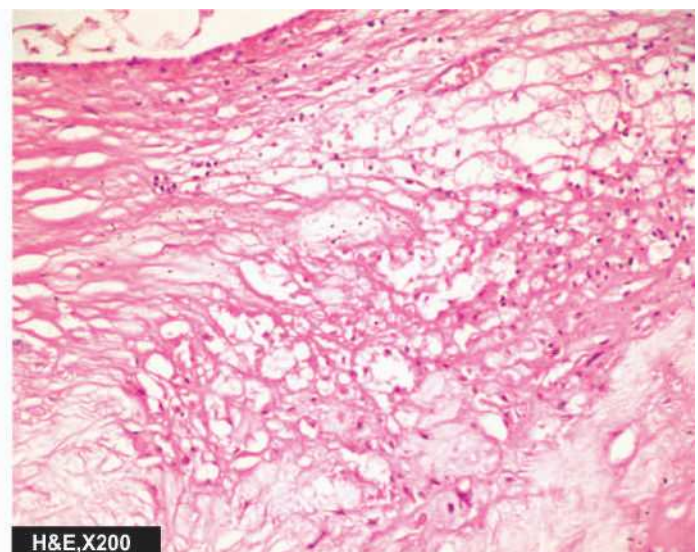

Figure 13.8 Histologic appearance of a fully-developed atheroma.

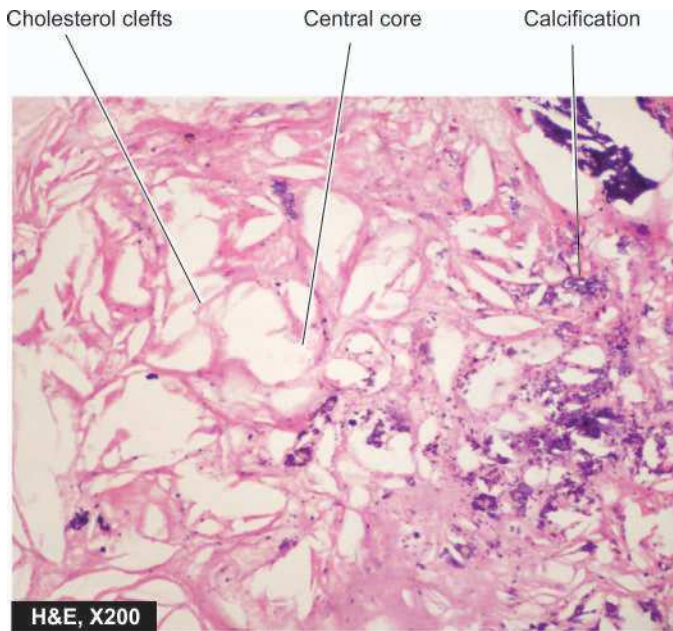

Figure 13.9 Complicated atheromatous plaque lesion. There is narrowing of the lumen of coronary due to fully developed atheromatous plaque which has dystrophic calcification in its core.

iv) Haemorrhage Intimal haemorrhage may occur in an atheromatous plaque either from the blood in the vascular lumen through an ulcerated plaque, or from rupture of thin-walled capillaries that vascularise the atheroma from adventitial vasa vasorum. Haemorrhage is particularly a common complication in coronary arteries. The haematoma formed at the site contains numerous haemosiderin-laden macrophages.

v) Aneurysm formation Though atherosclerosis is primarily an intimal disease, advanced lesions are associated with secondary changes in the media and adventitia. The changes in media include atrophy and thinning of the media and fragmentation of internal elastic lamina. The adventitia undergoes fibrosis and some inflammatory changes. These changes cause weakening in the arterial wall resulting in aneurysmal dilatation.

CLINICAL EFFECTS

The clinical effects of atherosclerosis depend upon the size and type of arteries affected. In general, the clinical effects result from the following:

1. Slow luminal narrowing causing ischaemia and atrophy.
2. Sudden luminal occlusion causing infarction necrosis.
3. Propagation of plaque by formation of thrombi and emboli.
4. Formation of aneurysmal dilatation and eventual rupture.

Large arteries affected most often are the aorta, renal, mesenteric and carotids, whereas the medium- and small-sized arteries frequently involved are the coronaries, cerebrals and arteries of the lower limbs. Accordingly, the symptomatic atherosclerotic disease involves most often the heart, brain, kidneys, small intestine and lower extremities (**Fig. 13.10**). The effects pertaining to these organs are described in relevant chapters later while the major effects are listed below (**Fig. 13.11**):

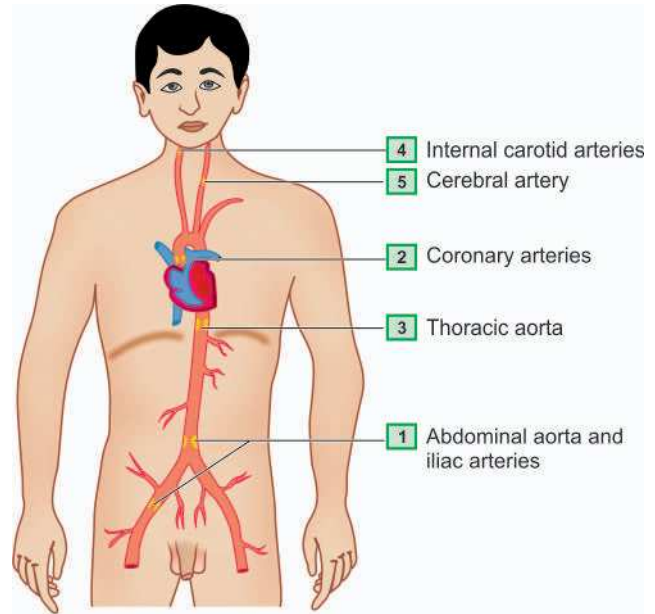

Figure 13.10 Major sites of atherosclerosis (serially numbered) in descending order of frequency.

- i) *Heart*—Myocardial infarction, ischaemic heart disease.
- ii) *Brain*—Chronic ischaemic brain damage, cerebral infarction and stroke.
- iii) *Aorta*—Aneurysm formation, thrombosis and embolisation to other organs.
- iv) *Small intestine*—Ischaemic bowel disease, infarction.
- v) *Lower extremities*—Intermittent claudication, gangrene.

GIST BOX 13.3 Atherosclerosis

- ☐ Atherosclerosis is thickening and hardening of large and medium-sized muscular arteries, primarily due to involvement of tunica intima and is characterised by fibrofatty plaques or atheromas.
- ☐ Major risk factors are modifiable by life style and/or therapy and include: dyslipidaemias, hypertension, diabetes mellitus and smoking.
- ☐ Constitutional risk factors are advancing age, male sex, and genetic influences, familial predisposition and white race.
- ☐ Atherogenesis is explained commonly by reaction to injury hypothesis that involves: endothelial injury, intimal smooth muscle cell proliferation, circulating monocytes, dyslipidaemia and thrombosis.
- ☐ The lesions of atherosclerosis begin with fatty streaks and gelatinous lesions.
- ☐ Full blown atheromatous lesions or fibrofatty plaques have a superficial cap and cellular or soft centre.
- ☐ Complicated atheromas may have dystrophic calcification, ulceration, thrombosis, haemorrhage and aneurysm formation.
- ☐ Major clinical effects of atherosclerosis are on the heart (coronary artery disease), brain (stroke), aorta (aneurysmal dilatation), intestine (ischaemia) and lower extremities (gangrene).

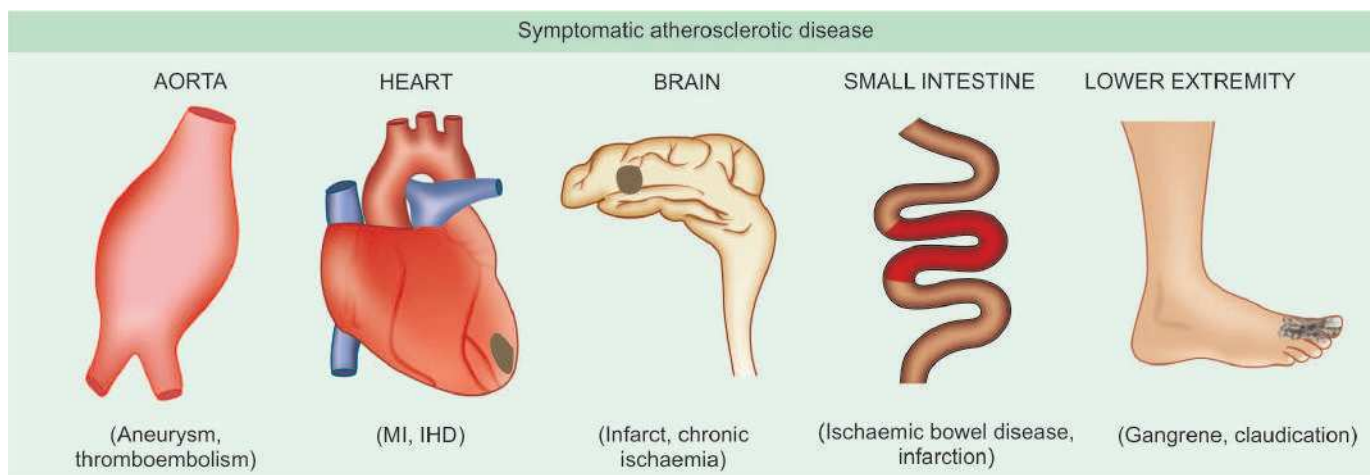

Figure 13.11 Major forms of symptomatic atherosclerotic disease.

VASCULITIS

Arteritis, angiitis and vasculitis are the common terms used for inflammatory involvement of an artery, arterioles, venules and capillaries. It may occur following invasion of the vessel by infectious agents, or may be induced by non-infectious injuries such as chemical, mechanical, immunologic and radiation injury. The non-infectious group is more important than the infectious type. A classification of arteritis based on this is given in **Table 13.3**.

I. INFECTIOUS ARTERITIS

Direct invasion of the artery by infectious agents, especially bacteria and fungi, causes infectious arteritis. It may be found in the vicinity of an infected focus like in tuberculosis, pneumonia, abscesses, etc. or less frequently may arise from haematogenous spread of infection such as in infective endocarditis, septicaemia, etc. Some common types are described here.

Table 13.3 Classification of vasculitis.

- | |
|---|
| I. INFECTIOUS ARTERITIS |
| 1. Endarteritis obliterans |
| 2. Syphilitic arteritis |
| 3. Non-specific infective arteritis |
| II. NON-INFECTIOUS ARTERITIS |
| 1. Polyarteritis nodosa (PAN) |
| 2. Hypersensitivity (allergic, leucocytoclastic) vasculitis |
| 3. Wegener's granulomatosis |
| 4. Temporal (giant cell) arteritis |
| 5. Takayasu's arteritis (pulseless disease) |
| 6. Kawasaki's disease |
| 7. Buerger's disease (thromboangiitis obliterans) |
| 8. Miscellaneous vasculitis |

ENDARTERITIS OBLITERANS

Endarteritis obliterans is not a disease entity but a pathologic designation used for non-specific inflammatory response of arteries and arterioles to a variety of irritants. It is commonly seen close to the lesions of peptic ulcers of the stomach and duodenum, tuberculous and chronic abscesses in the lungs, chronic cutaneous ulcers, chronic meningitis, and in post-partum and post-menopausal uterine arteries.

Grossly, the affected vessels may appear unaltered externally but on cross-section show obliteration of their lumina.

Microscopically, the obliteration of the lumen is due to concentric and symmetric proliferation of cellular fibrous tissue in the intima. Though the condition has suffix—*itis* attached to it, there is minimal or no inflammatory cell infiltrate.

SYPHILITIC ARTERITIS

Syphilitic or luetic vascular involvement occurs in all stages of syphilis but is more prominent in the tertiary stage. The changes that are found in the syphilitic arteritis are seen within the arterial tissue (*syphilitic endarteritis*) and in the periarterial tissues (*syphilitic periarteritis*). Manifestations of the disease are particularly prominent at two sites—the aorta and the cerebral arteries.

SYPHILITIC AORTITIS Syphilitic involvement of the ascending aorta and the aortic arch is the commonest manifestation of cardiovascular syphilis. It occurs in about 80% cases of tertiary syphilis. Preferential involvement of the arch of aorta may be due to involvement of mediastinal lymph nodes in secondary syphilis through which the treponemes spread to the lymphatics around the aortic arch. The lesions diminish in severity in descending thoracic aorta and disappear completely at the level of the diaphragm.

Grossly, the affected part of the aorta may be dilated, and its wall somewhat thickened and adherent to the neighbouring mediastinal structures. Longitudinally opened vessels show intimal surface studded with pearly-white thickenings, varying from a few millimeters to a centimeter in diameter.

These lesions are separated by wrinkled normal intima, giving it characteristic *tree-bark appearance*. Cut section of the lesion shows more firm and fibrous appearance than the atheromatous plaques. However, superimposed atherosclerotic lesions may be present.

Microscopically, the conspicuous features are as under (Fig. 13.12):

- i) Endarteritis and periarteritis of the vasa vasorum located in the media and adventitia.
- ii) Perivascular accumulation of plasma cells, lymphocytes and macrophages that may form miliary gummas which undergo necrosis and are replaced by scar tissue.
- iii) Intimal thickenings consist of dense avascular collagen that may undergo hyalinisation and calcification.

The effects of syphilitic aortitis may vary from trivial to catastrophic. These are as follows:

- a) *Aortic aneurysm* may result from damage to the aortic wall (page 387).
- b) *Aortic valvular incompetence* used to be considered an important sequela of syphilis but now-a-days rheumatic disease is considered its more important cause. The aortic incompetence results from spread of the syphilitic process to the aortic valve ring.
- c) *Stenosis of coronary ostia* is seen in about 20% cases of syphilitic aortitis and may lead to progressive myocardial fibrosis, angina pectoris and sudden death.

The features distinguishing syphilitic aortitis from aortic atheroma are given in Table 13.4.

CEREBRAL SYPHILITIC ARTERITIS (HEUBNER'S ARTERITIS) Syphilitic involvement of small and medium-sized cerebral arteries occurs during the tertiary syphilis. The changes may accompany syphilitic meningitis.

Grossly, the cerebral vessels are white, rigid and thick-walled.

Microscopically, changes of endarteritis and periarteritis similar to those seen in syphilitic aortitis are found. There is atrophy of muscle in the media and replacement by fibrosis. This results in ischaemic atrophy of the brain.

NON-SPECIFIC INFECTIVE ARTERITIS

Various forms of invasions of the artery by bacteria, fungi, parasites or viruses, either directly or by haematogenous route, cause non-syphilitic infective arteritis.

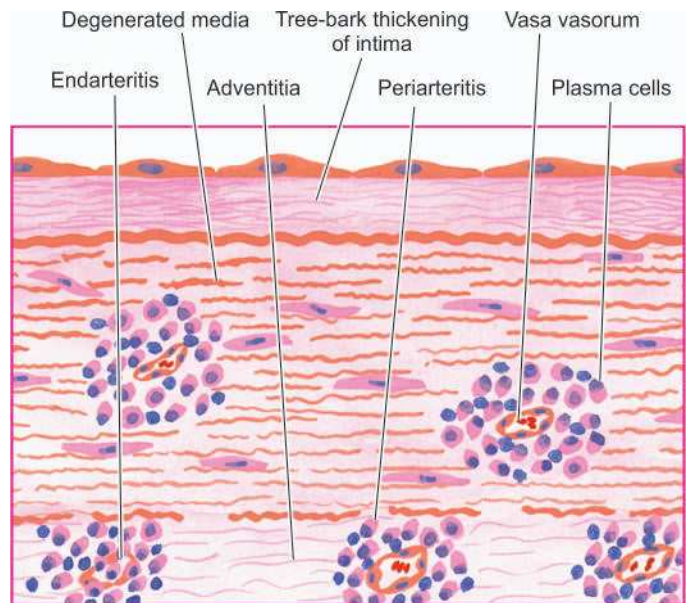

Figure 13.12 Syphilitic aortitis. There is endarteritis and periarteritis of the vasa vasorum in the media and adventitia. There is perivascular infiltrate of plasma cells, lymphocytes and macrophages.

Microscopically, the inflammatory infiltrate is present in the vessel wall. The vascular lumen may get occluded by thrombi and result in ischaemic necrosis of the affected tissue.

II. NON-INFECTIOUS ARTERITIS

This group consists of most of the important forms of vasculitis, more often affecting arterioles, venules and capillaries, and hence also termed as *small vessel vasculitis*. Their exact etiology is not known but available evidence suggests that many of them have immunologic origin. Serum from many of patients with vasculitis of immunologic origin show the presence of following immunologic features:

1. Anti-neutrophil cytoplasmic antibodies (ANCA)

Patients with immunologic vasculitis have autoantibodies in their serum against the cytoplasmic antigens of the neutrophils, macrophages and endothelial cells; these are called ANCA. Neutrophil immunofluorescence is used to demonstrate their presence, of which two distinct patterns of ANCA are seen:

Table 13.4 Contrasting features of syphilitic aortitis and aortic atheroma.

| FEATURE | SYPHILITIC AORTITIS | AORTIC ATHEROMA |
|---------------|---|--|
| 1. Sites | Ascending aorta, aortic arch; absent below diaphragm | Progressive increase from the arch to abdominal aorta, more often at the bifurcation |
| 2. Macroscopy | Pearly-white intimal lesions resembling tree-bark without fat in the core; ulceration and calcification often not found | Yellowish-white intimal plaques with fat in the core; ulceration and calcification in plaques common |
| 3. Microscopy | Endarteritis and periarteritis of vasa vasorum, perivascular infiltrate of plasma cells and lymphocytes | Fibrous cap with deeper core containing foam cells, cholesterol clefts and soft lipid |
| 4. Effects | Thoracic aortic aneurysm, incompetence of the aortic valve, stenosis of coronary ostia | Abdominal aortic aneurysm, aortic valve stenosis, stenosis of abdominal branches |

i) *Cytoplasmic ANCA (c-ANCA) pattern* is specific for proteinase-3 (PR-3), a constituent of neutrophilic granules; this is seen in cases with active Wegener's granulomatosis.

ii) *Perinuclear ANCA (p-ANCA) pattern* is specific for myeloperoxidase enzyme; this is noted in patients with microscopic polyarteritis nodosa and primary glomerular disease.

2. Anti-endothelial cell antibodies (AECAs) These antibodies are demonstrable in cases of SLE, Kawasaki disease and Buerger's disease.

3. Pauci-immune vasculitis While most cases of immunologic vasculitis have immune complex deposits in the vessel wall, there are some cases which do not have such immune deposits and are termed as cases of pauci-immune vasculitis (similar to pauci-immune glomerulonephritis, Chapter 20). Pathogenesis of lesions in these cases is explained by other mechanisms.

POLYARTERITIS NODOSA

Polyarteritis nodosa (PAN) is a necrotising vasculitis involving small and medium-sized muscular arteries of multiple organs and tissues. 'Polyarteritis' is the preferred nomenclature over 'periarteritis' because inflammatory involvement occurs in all the layers of the vessel wall.

The disease occurs more commonly in adult males than females. Most commonly affected organs, in descending order of frequency of involvement, are the kidneys, heart, liver, gastrointestinal tract, muscle, pancreas, testes, nervous system and skin. The syndrome of PAN presents with varied symptoms pertaining to different organs. However, some usual clinical features are fever, malaise, weakness, weight loss, renal manifestations (albuminuria, haematuria and renal failure), vascular lesions in the alimentary tract (abdominal pain and melaena), peripheral neuritis and hypertension. The condition is believed to result from deposition of immune complexes and tumour-related antigens.

Grossly, the lesions of PAN involve segments of vessels, especially at the bifurcations and branchings, as tiny beaded nodules.

Microscopically, there are 3 sequential stages in the evolution of lesions in PAN:

- i) *Acute stage*—There is fibrinoid necrosis in the centre of the nodule located in the media. An acute inflammatory response develops around the focus of fibrinoid necrosis. The inflammatory infiltrate is present in the entire circumference of the affected vessel (periarteritis) and consists chiefly of neutrophils and eosinophils, and some mononuclear cells. The lumen may show thrombi and the weakened wall may be the site of aneurysm formation.
- ii) *Healing stage*—This is characterised by marked fibroblastic proliferation producing firm nodularity. The inflammatory infiltrate now consists mainly of lymphocytes, plasma cells and macrophages.
- iii) *Healed stage*—In this stage, the affected arterial wall is markedly thickened due to dense fibrosis. The internal elastic lamina is fragmented or lost. Healed stage may contain haemosiderin-laden macrophages and organised thrombus.

However, it may be mentioned here that various stages of the disease may be seen in different vessels and even within the same vessel.

HYPERSENSITIVITY VASCULITIS

Hypersensitivity vasculitis, also called as allergic or leucocytoclastic vasculitis or microscopic polyarteritis, is a group of clinical syndromes differing from PAN in having inflammatory involvement of venules, capillaries and arterioles. The tissues and organs most commonly involved are the skin, mucous membranes, lungs, brain, heart, gastrointestinal tract, kidneys and muscle. The condition results from immunologic response to an identifiable antigen that may be bacteria (e.g. streptococci, staphylococci, mycobacteria), viruses (e.g. hepatitis B virus, influenza virus, CMV), malarial parasite, certain drugs and chemicals. Hypersensitivity vasculitis includes clinicopathologic entities such as serum sickness, Henoch-Schönlein purpura, mixed cryoglobulinaemia, vasculitis associated with malignancy, and vasculitis associated with connective tissue diseases like rheumatoid arthritis and SLE.

Microscopically, the lesions characteristically involve smallest vessels, sparing medium-sized and larger arteries. Two histologic forms are described:

- i) *Leucocytoclastic vasculitis*, characterised by fibrinoid necrosis with neutrophilic infiltrate in the vessel wall. Many of the neutrophils are fragmented (**Fig. 13.13**). This form is found in vasculitis caused by deposits of immune complexes.
- ii) *Lymphocytic vasculitis*, in which the involved vessel shows predominant infiltration by lymphocytes. This type is seen in vascular injury due to delayed hypersensitivity or cellular immune reactions.

WEGENER'S GRANULOMATOSIS

Wegener's granulomatosis is another form of necrotising vasculitis characterised by a *clinicopathologic triad* consisting of the following:

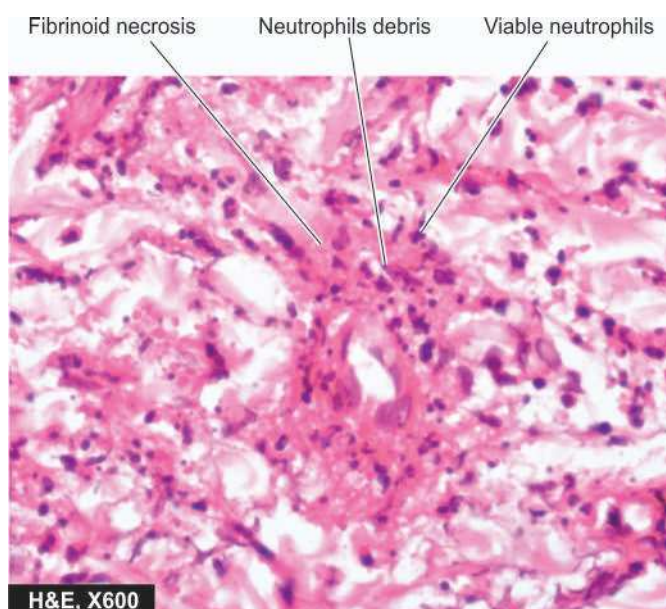

Figure 13.13 Leucocytoclastic vasculitis. The vessel wall shows fibrinoid necrosis surrounded by viable as well as fragmented neutrophils.

- i) Acute necrotising granulomas of the upper and lower respiratory tracts involving nose, sinuses and lungs;
- ii) focal necrotising vasculitis, particularly of the lungs and upper airways; and
- iii) focal or diffuse necrotising glomerulonephritis.

A *limited form* of Wegener's granulomatosis is the same condition without renal involvement. As with PAN, the condition is more common in adult males and involves multiple organs and tissues. Most commonly involved organs are the lungs, paranasal sinuses, nasopharynx and kidneys. Other involved organs are joints, skin, eyes, ears, heart and nervous system. Accordingly, clinical features are variable. Typical features include pneumonitis with bilateral infiltrates in the lungs (page 476), chronic sinusitis, nasopharyngeal ulcerations (page 498) and renal disease (page 655). The etiology is not known but possibly the lesions occur due to the presence of circulating immune complexes. This is supported by the observation of subepithelial immunoglobulin deposits on the glomerular basement membrane and induction of remission by immunosuppressive therapy. The serum of these patients shows c-ANCA positivity. Disseminated form of Wegener's granulomatosis differs from a related entity, *idiopathic lethal midline granuloma*, in the sense that the latter condition is highly destructive and progressively necrotic disease of the upper airways.

Histologically, the characteristic feature of Wegener's granulomatosis is the presence of necrotising granulomatous inflammation of the tissues and necrotising vasculitis with or without granulomas:

- i) The granulomas consist of fibrinoid necrosis with extensive infiltration by neutrophils, mononuclear cells, epithelioid cells, multinucleate giant cells and fibroblastic proliferation.
- ii) The necrotising vasculitis may be segmental or circumferential.
- iii) The renal lesions are those of focal or diffuse necrotising glomerulonephritis.

TEMPORAL (GIANT CELL) ARTERITIS

This is a form of granulomatous inflammation of medium-sized and large arteries. Preferential sites of involvement are the cranial arteries, especially the temporal, and hence the name. However, the aorta and other major arteries like common carotid, axillary, brachial, femoral and mesenteric arteries are also involved, and therefore, it is preferable to call the entity as '*giant cell arteritis*'. The patients are generally over the age of 70 years with slight female preponderance. The usual clinical manifestations are headache and blindness if ophthalmic artery is involved. An association with polymyalgia rheumatica has been observed. The cause of the condition remains unknown though there is suggestion of T cell mediated immunologic reaction to some component of the arterial wall, especially against the damaged internal elastic lamina. Biopsy of the affected artery is not only of diagnostic value but also relieves the patient of painful symptoms.

Grossly, the affected artery is thickened, cord-like and the lumen is usually reduced to a narrow slit.

Histologically, the features include the following:

- i) There is chronic granulomatous reaction, usually around the internal elastic lamina and typically involves the entire circumference of the vessel.

- ii) Giant cells of foreign body or Langhans' type are found in two-third of cases.
- iii) The internal elastic lamina is often fragmented.
- iv) There is eccentric or concentric intimal cellular proliferation causing marked narrowing of the lumen. The narrowed lumen may contain thrombus.
- v) Occasionally, only nonspecific inflammatory cell infiltrate consisting of neutrophils, lymphocytes and eosinophils is found throughout the arterial wall.

TAKAYASU'S ARTERITIS (PULSELESS DISEASE)

This is a form of granulomatous vasculitis affecting chiefly the aorta and its major branches and hence is also referred to as *aortic arch syndrome*. The disease affects chiefly young women and is typically characterised by absence of pulse in both arms and presence of ocular manifestations. Other features referable to ischaemic effects from thrombotic occlusion of vessels include myocardial infarction, congestive heart failure and neurologic deficits. The etiology of Takayasu's arteritis is not known but the autoimmune reaction to aortic tissue has been suggested as the possible cause.

Grossly, the aortic wall is irregularly thickened and intima wrinkled. The branches of major arteries coming off the aortic arch have obliterated lumina.

Histologically, the features are as under:

- i) There is severe mononuclear inflammatory infiltrate involving the full thickness of the affected vessel wall.
- ii) The inflammatory changes are more severe in the adventitia and media and there is perivascular infiltration of the vasa vasorum.
- iii) Granulomatous changes in the media with central necrosis and Langhans' giant cells are found in many cases.
- iv) Advanced lesions show extensive fibrosis of the media and adventitia causing thickening in the vessel wall.

KAWASAKI'S DISEASE

Also known by more descriptive name of '*mucocutaneous lymph node syndrome*', it is an acute and subacute illness affecting mainly young children and infants. Kawasaki's disease is a febrile illness with mucocutaneous symptoms like erosions of oral mucosa and conjunctiva, skin rash and lymphadenopathy. The etiology is unknown; possible causes considered are infectious, genetic, toxic and immunological. The most characteristic finding is the presence of multiple aneurysms of the coronaries detected by angiography during life or observed at autopsy. Other vessels that may be involved are renal, mesenteric, hepatic and pancreatic arteries.

Histologically, the picture is of panarteritis resembling PAN, characterised by necrosis and inflammation of the entire thickness of the vessel wall. Therefore, some consider Kawasaki's disease as an infantile form of PAN.

BUERGER'S DISEASE (THROMBOANGIITIS OBLITERANS)

Buerger's disease is a specific disease entity affecting chiefly small and medium-sized arteries and veins of the extremities and characterised by acute and chronic occlusive inflammatory involvement. The disease affects chiefly men under the age of 35 years who are heavy cigarette smokers. The symptom-

complex consists of intermittent claudication due to ischaemia manifested by intense pain affecting the limbs, more commonly the legs. Eventually, gangrene of the affected extremities occurs requiring amputation.

ETIOPATHOGENESIS Following possible mechanisms have been suggested:

- i) There is consistent association with heavy cigarette smoking. This has led to the hypothesis that *tobacco products* cause either direct endothelial damage leading to hypercoagulability and thrombosis, or it is a result in hypersensitivity to tobacco products. In support is the demonstration of anti-endothelial cell antibodies (AECAs).
- ii) *Genetic factors* play a role as the disease has familial occurrence and has HLA association. An increased prevalence is seen in individuals with HLA-A9 and HLA-B5 antigens. It is seen more commonly in persons from Israel, Japan and in India.

Grossly, the lesions are typically segmental affecting small and medium-sized arteries, especially of the lower extremities. Involvement of the arteries is often accompanied with involvement of adjacent veins and nerves. Fibrous tissue cuff generally surrounds these three structures. Mural thrombi are frequently present in the vessels.

Microscopically, the following changes are seen in different stages of the disease:

- i) In *early stage*, there is infiltration by polymorphs in all the layers of vessels and there is invariable presence of mural or occlusive thrombosis of the lumen (**Fig. 13.14**). The appearance differs from atherosclerosis in having microabscesses in the thrombi, proliferation of endothelial cells, lack of lipid aggregates and presence of intact internal elastic lamina.
- ii) In *advanced stage*, the cellular infiltrate is predominantly mononuclear and may contain an occasional epithelioid cell granuloma with Langhans' giant cells. The thrombi undergo organisation and recanalisation. In more chronic cases, marked fibrosis of the media is present.

MISCELLANEOUS HYPERSENSITIVITY VASCULITIS

Various connective tissue diseases (e.g. rheumatoid arthritis, ankylosing spondylitis and SLE), rheumatic fever, certain malignancies and Henoch-Schönlein purpura are associated with vasculitis. The type of vasculitis is generally of hypersensitivity or allergic angiitis as already explained but sometimes may resemble PAN.

◆ *Rheumatoid vasculitis* affects chiefly the small and medium-sized arteries of multiple visceral organs in patients who have rheumatoid nodules of long duration. Vasculitis in SLE affects mainly the small arteries of the skin.

◆ *Rheumatic vasculitis* involves the aorta, carotid and coronary arteries and the visceral vessels. Usually, fibrinoid change and perivascular inflammation are seen rather than typical Aschoff nodules (page 423).

RAYNAUD'S DISEASE AND RAYNAUD'S PHENOMENON

Raynaud's disease is not a vasculitis but is a functional vaso-spastic disorder affecting chiefly small arteries and arterioles of the extremities, occurring in otherwise young healthy females. The disease affects most commonly the fingers and hands. The ischaemic effect is provoked primarily by cold but other stimuli such as emotions, trauma, hormones and drugs also play a role. Clinically, the affected digits show *pallor*, followed by *cyanosis*, and then *redness*, corresponding to *arterial ischaemia*, *venostasis* and *hyperaemia* respectively. Long-standing cases may develop ulceration and necrosis of digits but occurrence of true gangrene is rare. The cause of the disease is unknown but probably occurs due to vasoconstriction mediated by autonomic stimulation of the affected vessels. Though usually no pathologic changes are observed in the affected vessels, long-standing cases may show endothelial proliferation and intimal thickening.

Raynaud's phenomenon differs from Raynaud's disease in having an underlying cause e.g. secondary to arteriosclerosis, connective tissue diseases like scleroderma and SLE, Buerger's disease, multiple myeloma, pulmonary hypertension and ingestion of ergot group of drugs. Raynaud's phenomenon like

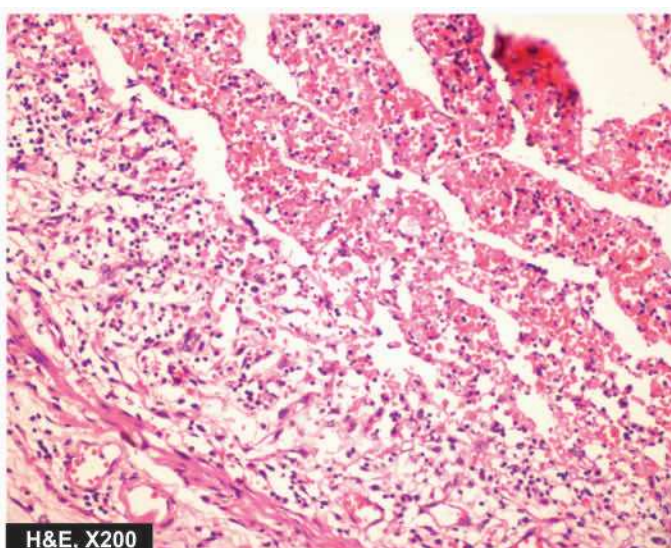

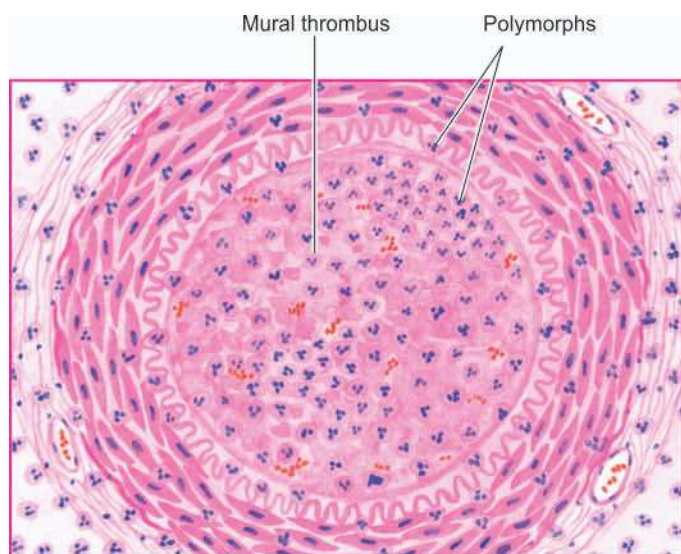

Figure 13.14 Buerger's disease (Thromboangiitis obliterans). There is acute panarteritis. The lumen is occluded by a thrombus containing microabscesses.

Raynaud's disease, also shows cold sensitivity but differs from the latter in having structural abnormalities in the affected vessels. These changes include segmental inflammation and fibrinoid change in the walls of capillaries.

GIST BOX 13.4 Vasculitis

- ▣ Arteritis, angiitis and vasculitis are the terms used for inflammatory involvement of the vessel wall, often arteries, arterioles, venules or capillaries.
- ▣ It may be caused by infectious agents or induced by non-infectious injuries; the latter is more important.
- ▣ Infectious vasculitis may be nonspecific or syphilitic.
- ▣ Non-infectious vasculitis are often of immunologic origin and may be positive for serum antibodies: ANCA (c-ANCA or p-ANCA) or AECA.
- ▣ Common examples of non-infectious vasculitis are polyarteritis nodosa, hypersensitivity vasculitis, Wegener's granulomatosis, temporal arteritis, Takayasu's arteritis, Kawasaki's disease and Buerger's disease.
- ▣ Raynaud's disease is a vasospastic disorder in young women and not a vasculitis.

ANEURYSMS

DEFINITION AND CLASSIFICATION

An aneurysm is defined as a permanent abnormal dilatation of a blood vessel occurring due to congenital or acquired weakening or destruction of the vessel wall. Most commonly, aneurysms involve large elastic arteries, especially the aorta and its major branches. Aneurysms can cause various ill-effects such as thrombosis and thromboembolism, alteration in the flow of blood, rupture of the vessel and compression of neighbouring structures.

Aneurysms can be classified on the basis of various features:

A. Depending upon the composition of the wall

1. *True aneurysm* composed of all the layers of a normal vessel wall.
2. *False aneurysm* having fibrous wall and occurring often from trauma to the vessel.

B. Depending upon the shape

These are as under (Fig. 13.15):

1. *Saccular* having large spherical outpouching.
2. *Fusiform* having slow spindle-shaped dilatation.
3. *Cylindrical* with a continuous parallel dilatation.
4. *Serpentine or varicose* which has tortuous dilatation of the vessel.

5. *Racemose or circoid* having mass of intercommunicating small arteries and veins.

C. Based on pathogenetic mechanisms This classification is followed most often (Fig. 13.16):

1. *Atherosclerotic (arteriosclerotic) aneurysms* are the most common type.
2. *Syphilitic (luetica) aneurysms* found in the tertiary stage of the syphilis.
3. *Dissecting aneurysms (Dissecting haematoma)* in which the blood enters the separated or dissected wall of the vessel.
4. *Mycotic aneurysms* which result from weakening of the arterial wall by microbial infection.
5. *Berry aneurysms* which are small dilatations especially affecting the circle of Willis in the base of the brain (Chapter 28).

The three common types of aortic aneurysms—atherosclerotic, syphilitic and dissecting, are described below:

ATHEROSCLEROTIC ANEURYSMS

Atherosclerotic aneurysms are the most common form of aortic aneurysms. They are seen more commonly in males and the frequency increases after the age of 50 years when the incidence of complicated lesions of advanced atherosclerosis is higher. They are most common in the abdominal aorta, so much so that all forms of aneurysms of abdominal aorta (fusiform, cylindrical and saccular) should be considered atherosclerotic until proved otherwise. Other locations include thoracic aorta (essentially the ascending part and arch of aorta), iliac arteries and other large systemic arteries.

PATHOGENESIS Obviously, severe atherosclerotic lesions are the basic problem which cause thinning and destruction of the medial elastic tissue resulting in atrophy and weakening of the wall. Since atherosclerotic lesions are most common and severe in the abdominal aorta, atherosclerotic aneurysms occur most frequently here. In the thoracic aorta, besides atherosclerotic lesions, medial degeneration is another additional factor implicated in pathogenesis.

MORPHOLOGIC FEATURES Atherosclerotic aneurysms of the abdominal aorta are most frequently infra-renal, above the bifurcation of the aorta but may extend into common iliac arteries. They may be of variable size but are often larger than 5-6 cm in diameter. Atherosclerotic aneurysm is most frequently fusiform in shape and the lumen of aneurysm often contains mural thrombus.

Histologically, the wall of atherosclerotic aneurysm loses its normal arterial structure. Instead, there is predominance of fibrous tissue in the media and adventitia with mild chronic inflammatory reaction. The intima and inner part of the media show remnants of atheromatous plaques and mural thrombus.

Figure 13.15 Common shapes of aneurysms of various types.

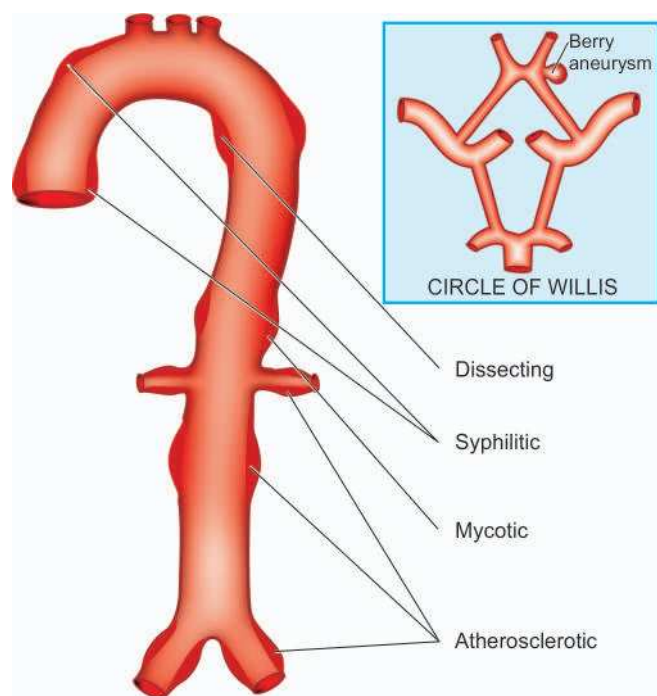

Figure 13.16 Sites of major forms of aneurysms.

EFFECTS The clinical effects of atherosclerotic aneurysms are due to complications. These are as under:

1. Rupture Rupture of the atherosclerotic aneurysm is the most serious and fatal complication. The risk of rupture depends upon the size and duration of the aneurysm and the blood pressure. Rupture of abdominal aneurysm may occur either into the peritoneum or into the retroperitoneum resulting in sudden and massive bleeding. Occasionally, there may be slow progressive leak from the aneurysm. A ruptured aneurysm is more likely to get infected.

2. Compression The atherosclerotic aneurysm may press upon some adjacent structures such as compression of ureter and erosion on the vertebral bodies.

3. Arterial occlusion Atherosclerotic aneurysms of the abdominal aorta may occlude the inferior mesenteric artery, or there may be development of occlusive thrombosis. However, collateral circulation develops slowly and is nearly always sufficient so as not to produce effects of ischaemia. Thromboembolism is rather common in abdominal aneurysms.

SYPHILITIC (LUETIC) ANEURYSMS

Cardiovascular syphilis occurs in about 10% cases of syphilis. It causes arteritis—syphilitic aortitis and cerebral arteritis, both of which are already described in this chapter. One of the major complications of syphilitic aortitis is syphilitic or luetic aneurysm that develops in the tertiary stage of syphilis. It usually manifests after the age of 50 years and is more common in men. The predominant site of involvement is the thoracic aorta, especially in the ascending part and arch of aorta. It may extend proximally into the aortic valve causing aortic incompetence and may lead to syphilitic heart disease. Less often, it may extend distally to involve abdominal aorta.

PATHOGENESIS About 40% cases of syphilitic aortitis develop syphilitic aneurysms. The process begins from

inflammatory infiltrate around the vasa vasorum of the adventitia, followed by endarteritis obliterans. This results in ischaemic injury to the media causing destruction of the smooth muscle and elastic tissue of the media and scarring. Since syphilitic aortitis involves the proximal aorta maximally, aortic aneurysm is found most frequently in the ascending aorta and in the aortic arch.

MORPHOLOGIC FEATURES Syphilitic aneurysms occurring most often in the ascending part and the arch of aorta are saccular in shape and usually 3-5 cm in diameter. Less often, they are fusiform or cylindrical. The intimal surface is wrinkled and shows *tree-bark appearance*. When the aortic valve is involved, there is stretching and rolling of the valve-leaflets producing valvular incompetence and left ventricular hypertrophy due to volume overload. This results in massively enlarged heart called ‘cor bovinum.’

Histologically, the features of healed syphilitic aortitis are seen (page 381). The adventitia shows fibrous thickening with endarteritis obliterans of vasa vasorum. The fibrous scar tissue may extend into the media and the intima. Rarely, spirochaetes may be demonstrable in syphilitic aneurysm. Often, mural thrombus is found in the aneurysm.

EFFECTS The clinical manifestations are found much more frequently in syphilitic aneurysms than in atherosclerotic aneurysms. The effects include the following:

1. Rupture Syphilitic aneurysm is likely to rupture causing massive and fatal haemorrhage into the pleural cavity, pericardial sac, trachea and oesophagus.

2. Compression The aneurysm may press on the adjacent tissues and cause symptoms such as on trachea causing dyspnoea, on oesophagus causing dysphagia, on recurrent laryngeal nerve leading to hoarseness; and erosion of vertebrae, sternum and ribs due to persistent pressure.

3. Cardiac dysfunction When the aortic root and valve are involved, syphilitic aneurysm produces aortic incompetence and cardiac failure. Narrowing of the coronary ostia may further aggravate cardiac disease.

DISSECTING ANEURYSMS AND CYSTIC MEDIAL NECROSIS

The term dissecting aneurysm is applied for a dissecting haematoma in which the blood enters the separated (dissected) wall of the vessel and spreads for varying distance longitudinally. The most common site is the aorta and is an acute catastrophic aortic disease. The condition occurs most commonly in men in the age range of 50 to 70 years. In women, dissecting aneurysms may occur during pregnancy.

PATHOGENESIS The pathogenesis of dissecting aneurysm is explained on the basis of weakened aortic media. Various conditions causing weakening in the aortic wall resulting in dissection are as under:

i) Hypertensive state About 90% cases of dissecting aneurysm have hypertension which predisposes such patients to degeneration of the media in some questionable way.

ii) Non-hypertensive cases These are cases in whom there is some local or systemic connective tissue disorder e.g.

a) Marfan's syndrome, an autosomal dominant disease with genetic defect in fibrillin which is a connective tissue protein required for elastic tissue formation.

- b) Development of *cystic medial necrosis of Erdheim*, especially in old age.
 c) *Iatrogenic trauma* during cardiac catheterisation or coronary bypass surgery.
 d) *Pregnancy*, for some unknown reasons.

Once medial necrosis has occurred, haemodynamic factors, chiefly hypertension, cause tear in the intima and initiate the dissecting aneurysms. The media is split at its weakest point by the inflowing blood. An alternative suggestion is that the medial haemorrhage from the vasa vasorum occurs first and the intimal tear follows it. Further extension of aneurysm occurs due to entry of blood into the media through the intimal tear.

MORPHOLOGIC FEATURES Dissecting aneurysm differs from atherosclerotic and syphilitic aneurysms in having no significant dilatation. Therefore, it is currently referred to as '*dissecting haematoma*.' Dissecting aneurysm classically begins in the arch of aorta. In 95% of cases, there is a sharply-incised, transverse or oblique intimal tear, 3-4 cm long, most often located in the ascending part of the aorta. The dissection is seen most characteristically between the outer and middle third of the aortic media so that the column of blood in the dissection separates the *intima and inner two-third of the media* on one side from the *outer one-third of the media and the adventitia* on the other. The dissection extends proximally into the aortic valve ring as well as distally into the abdominal aorta (Fig. 13.17).

Occasionally, the dissection may extend into the branches of aorta e.g. into the arteries of the neck, coronaries, renal, mesenteric and iliac arteries. The dissection may affect the entire circumference of the aortic media or a segment of it. In about 10% of dissecting aneurysms, a second intimal tear is seen in the distal part of the dissection so that the blood enters the false lumen through the proximal tear and re-enters the true lumen through the distal tear. If the patient survives, the false lumen may develop endothelial lining and '*double-barrel aorta*' is formed.

Two **classification schemes** for dissections of thoracic aorta and intramural haematoma have been described (Fig. 13.18):

I. DeBakey classification. Depending upon the extent of aortic dissection, three types are described:

Type I: Comprises 75% of cases; the intimal tear begins in the ascending aorta but dissection extends distally for some distance.

Type II: Comprises 5% of cases and dissection is limited to the ascending aorta.

Type III: Constitutes the remaining 20% cases. In these cases, intimal tear begins in the descending thoracic aorta near the origin of subclavian artery and dissection extends distally.

II. Stanford classification. Depending upon clinical management, these are divided into 2 types:

Type A (Proximal dissection): Involves the ascending aorta and includes type I and II of the above scheme because

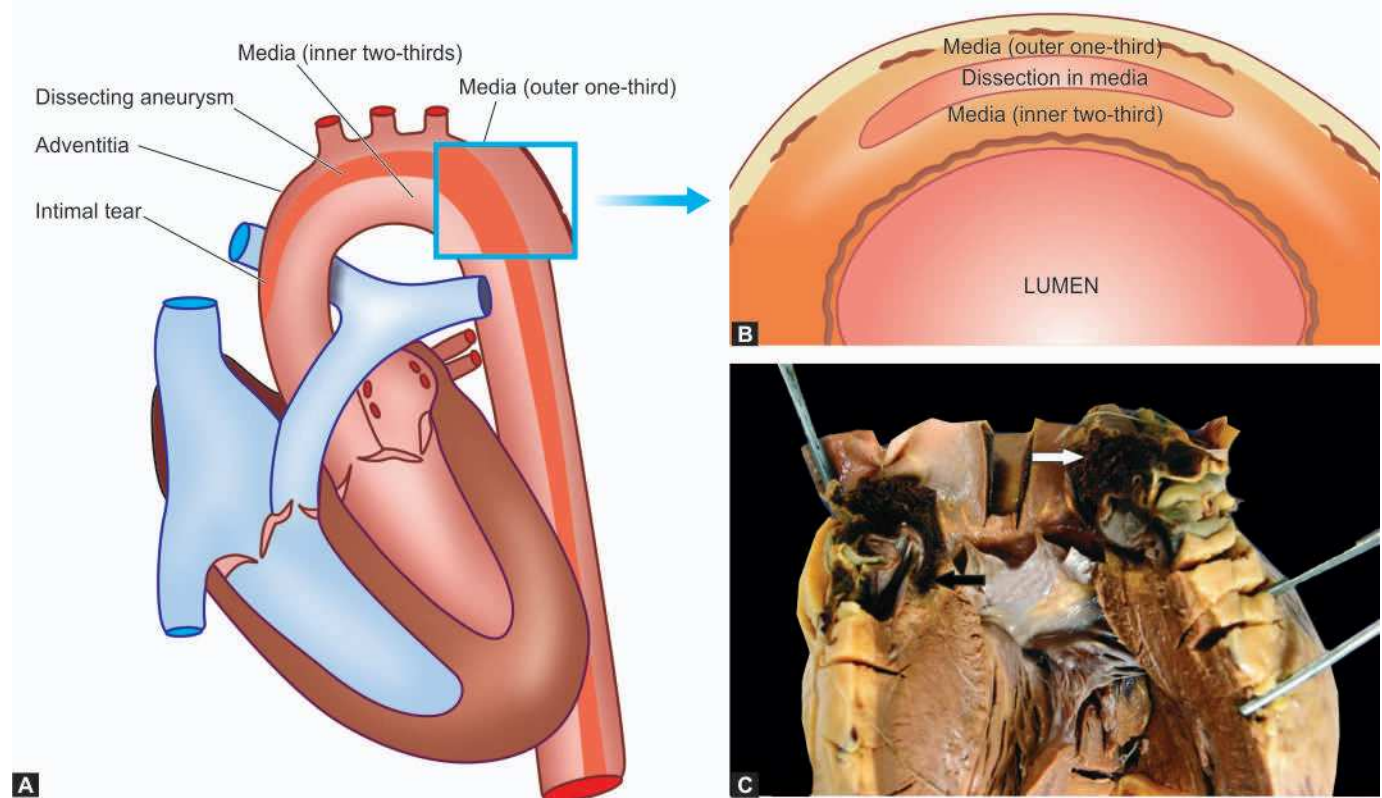

Figure 13.17 A, Dissecting aneurysm, (Type 1) beginning in the aortic arch and extending distally into the descending thoracic aorta as well as proximally into the ascending aorta. An intimal tear is seen in the arch. B, The cross section shows dissection typically separating the intima and inner two-thirds of the media on *luminal* side, from the *outer* one-third of the media and the adventitia. C, The ascending aorta is seen with the heart. There is an intimal tear in the aortic wall (black arrow) extending proximally upto aortic valve dissecting the media which contains clotted blood (white arrow)

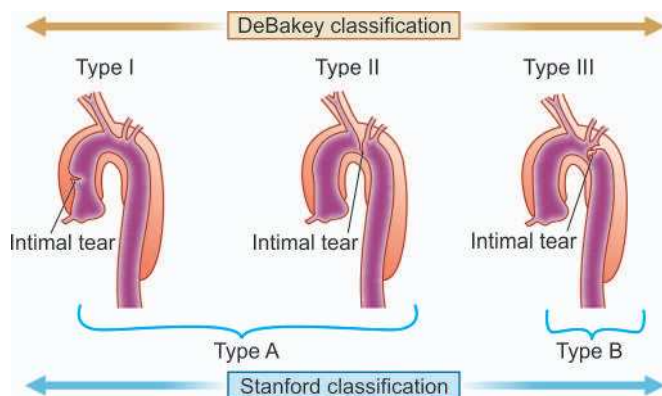

Figure 13.18 Two classification schemes of thoracic aortic dissection: Stanford and DeBakey. Stanford type A involving ascending aorta only includes DeBakey's type I (involving ascending aorta and extending into descending aorta as well) and II (limited to ascending aorta only), while Stanford type B is limited to descending aorta corresponds to DeBakey type III.

clinical management of DeBakey type I and II is not different.

Type B (Distal dissection): Limited to descending aorta and sparing the ascending aorta; it corresponds to DeBakey type III.

Histologically, the characteristic features of cystic medial necrosis are found. These are as under:

- i) Focal separation of the fibromuscular and elastic tissue of the media.
- ii) Numerous cystic spaces in the media containing basophilic ground substance.
- iii) Fragmentation of the elastic tissue.
- iv) Increased fibrosis of the media.

EFFECTS The classical clinical manifestation of a dissecting aneurysm is excruciating tearing pain in the chest moving downwards. The complications arising from dissecting aneurysms are as under:

- 1. Rupture** Haemorrhage from rupture of a dissecting aneurysm in the ascending aorta results in mortality in 90% of cases. Most often, haemorrhage occurs into the pericardium; less frequently it may rupture into thoracic cavity, abdominal cavity or retroperitoneum.
- 2. Cardiac disease** Involvement of the aortic valve results in aortic incompetence. Obstruction of coronaries results in ischaemia causing fatal myocardial infarction. Rarely, dissecting aneurysm may extend into the cardiac chamber.
- 3. Ischaemia** Obstruction of the branches of aorta by dissection results in ischaemia of the tissue supplied. Thus, there may be renal infarction, cerebral ischaemia and infarction of the spinal cord.

FIBROMUSCULAR DYSPLASIA

Fibromuscular dysplasia first described in 1976, is a non-atherosclerotic and non-inflammatory disease affecting arterial wall, most often renal artery. Though the process may involve intima, media or adventitia, medial fibroplasia is the most common.

MORPHOLOGIC FEATURES **Grossly**, the involvement is characteristically segmental—affecting vessel in a bead-like pattern with intervening uninvolved areas.

Microscopically, the beaded areas show collections of smooth muscle cells and connective tissue. There is often rupture and retraction of internal elastic lamina.

The main **effects** of renal fibromuscular dysplasia, depending upon the region of involvement, are renovascular hypertension and changes of renal atrophy.

GIST BOX 13.5 Aneurysms

- ☐ An aneurysm is a permanent abnormal dilatation of a blood vessel due to congenital or acquired weakening or destruction of the vessel wall.
- ☐ Based on pathogenetic mechanisms, aneurysms are atherosclerotic, syphilitic (luetetic), dissecting, mycotic and berry aneurysms; the last ones are seen in the circle of Willis in the base of the brain.
- ☐ Atherosclerotic aneurysms are the most common and affect abdominal aorta more often. They may rupture or cause compression on adjacent tissues.
- ☐ Syphilitic aneurysm occurs due to syphilitic aortitis and affects ascending and arch of aorta.
- ☐ Dissecting haematoma is often preceded by hypertension and affects the arch and ascending aorta most often.

COMMON DISEASES OF VEINS

VARICOSITIES

Varicosities are abnormally dilated and tortuous veins. The veins of lower extremities are involved most frequently, called *varicose veins*. The veins of other parts of the body which are affected are the lower oesophagus (*oesophageal varices*, Chapter 19), the anal region (*haemorrhoids*, Chapter 20) and the spermatic cord (*varicocele*, Chapter 21).

Varicose Veins

Varicose veins are permanently dilated and tortuous superficial veins of the lower extremities, especially the long saphenous vein and its tributaries. About 10-12% of the general population develops varicose veins of lower legs, with the peak incidence in 4th and 5th decades of life. Adult females are affected more commonly than the males, especially during pregnancy. This is attributed to venous stasis in the lower legs because of compression on the iliac veins by pregnant uterus.

ETIOPATHOGENESIS A number of etiologic and pathogenetic factors are involved in causing varicose veins. These are as follows:

- i) Familial weakness of vein walls and valves is the most common cause.
- ii) Increased intraluminal pressure due to prolonged upright posture e.g. in nurses, policemen, surgeons etc.
- iii) Compression of iliac veins e.g. during pregnancy, intra-vascular thrombosis, growing tumour etc.
- iv) Hormonal effects on smooth muscle.
- v) Obesity.
- vi) Chronic constipation.

MORPHOLOGIC FEATURES The affected veins, especially of the lower extremities, are dilated, tortuous, elongated and nodular. Intraluminal thrombosis and valvular deformities are often found.

Histologically, there is variable fibromuscular thickening of the wall of the veins due to alternate dilatation and hypertrophy. Degeneration of the medial elastic tissue may occur which may be followed by calcific foci. Mural thrombosis is commonly present which may get organised and hyalinised leading to irregular intimal thickening.

EFFECTS Varicose veins of the legs result in venous stasis which is followed by congestion, oedema, thrombosis, stasis, dermatitis, cellulitis and ulceration. Secondary infection results in chronic varicose ulcers.

PHLEBOTHROMBOSIS AND THROMBOPHLEBITIS

The terms '*phlebothrombosis*' or thrombus formation in veins, and '*thrombophlebitis*' or inflammatory changes within the vein wall, are currently used synonymously.

ETIOPATHOGENESIS Venous thrombosis that precedes thrombophlebitis is initiated by *triad* of changes: endothelial damage, alteration in the composition of blood and venous stasis. The factors that predispose to these changes are cardiac failure, malignancy, use of oestrogen-containing compounds, postoperative state and immobility due to various reasons.

MORPHOLOGIC FEATURES The most common locations for phlebothrombosis and thrombophlebitis are the deep veins of legs accounting for 90% of cases; it is commonly termed as *deep vein thrombosis (DVT)*. Other locations are periprostatic venous plexus in males, pelvic veins in the females, and near the foci of infection in the abdominal cavity such as acute appendicitis, peritonitis, acute salpingitis and pelvic abscesses.

Grossly, the affected veins may appear normal or may be distended and firm. Often, a mural or occlusive thrombus is present.

Histologically, the thrombus that is attached to the vein wall induces inflammatory-reparative response beginning from the intima and infiltrating into the thrombi. The response consists of mononuclear inflammatory cells and fibroblastic proliferation. In late stage, thrombus is either organised or resolved leading to a thick-walled fibrous vein.

EFFECTS The clinical effects due to phlebothrombosis and thrombophlebitis may be local or systemic.

Local effects are oedema distal to occlusion, heat, swelling, tenderness, redness and pain.

Systemic effects are more severe and occur due to embolic phenomena, pulmonary thromboembolism being the most common and most important. Other systemic manifestations include bacteraemia and septic embolisation to brain, meninges, liver etc.

Special Types of Phlebothrombosis

A few special variants of phlebothrombosis are considered below:

1. THROMBOPHLEBITIS MIGRANS Thrombophlebitis migrans or migratory thrombophlebitis or Trousseau's syndrome is the term used for multiple venous thrombi that disappear from one site so as to appear at another site. The condition is not a morphologic entity but a clinical one, seen most often in disseminated visceral cancers (e.g. cancer of lungs, prostate, female reproductive tract, breast, pancreas and gastrointestinal tract) as part of paraneoplastic syndrome and is also found in nonbacterial thrombotic endocarditis.

2. PHLEGMASIA ALBA DOLENS This term meaning 'painful white leg' refers to extensive swelling of the leg, occurring most frequently due to iliofemoral venous thrombosis. It occurs most often in women during late pregnancy or following delivery when the pregnant uterus causes pressure on the iliofemoral veins, or after extensive pelvic surgery. Development of pulmonary embolism may occur due to involvement of inferior vena cava.

3. PHLEGMASIA CERULEA DOLENS This term meaning 'painful blue leg' refers to markedly swollen bluish skin with superficial gangrene. It is a serious complication of massive iliofemoral venous thrombosis and decreased arterial blood flow.

4. SUPERIOR VENA CAVAL SYNDROME Superior vena caval syndrome refers to obstruction of the superior vena cava. The obstruction results most often from external compression or from thrombosis. Some of the common causes of superior vena caval syndrome are malignancy (especially lung cancer and lymphoma), syphilitic aortic aneurysm and tuberculous mediastinitis. Clinical features include dilated veins of neck and thorax, oedema of the face, neck and upper chest, visual disturbances and disturbed sensorium.

5. INFERIOR VENA CAVAL SYNDROME Inferior vena caval syndrome is the obstruction of the inferior vena cava. Most often, obstruction results from thrombosis by extension from iliofemoral veins. Other causes of obstruction are external compression and neoplastic invasion. Clinical features are oedema of lower extremities, dilated leg veins and collateral venous channels in the lower abdomen.

GIST BOX 13.6 Common Diseases of Veins

- ▣ Varicosities are abnormally dilated and tortuous veins.
- ▣ Varicose veins are permanently dilated and tortuous superficial veins of the lower extremities, especially the long saphenous vein and its tributaries.
- ▣ Phlebothrombosis is thrombus formation in veins, and thrombophlebitis is inflammatory changes within the vein wall.

DISEASES OF LYMPHATICS

LYMPHANGITIS

Inflammation of the lymphatics or lymphangitis may be acute or chronic.

Acute lymphangitis occurs in the course of many bacterial infections. The most common organisms are β -haemolytic streptococci and staphylococci. Acute lymphangitis is often associated with lymphadenitis.

Grossly, the affected lymphatics are dilated and appear as cutaneous streaks.

Microscopically, the dilated lumen contains acute inflammatory exudate, cell debris and clotted lymph. There is inflammatory infiltration into the perilymphatic tissues along with hyperaemia and oedema. Acute lymphangitis generally heals completely.

Chronic lymphangitis occurs due to persistent and recurrent acute lymphangitis or from chronic infections like tuberculosis, syphilis and actinomycosis.

Histologically, there is permanent obstruction due to fibrosis of affected lymphatics called chronic lymphoedema.

Lymphoedema

Lymphoedema is swelling of soft tissues due to localised increase in the quantity of lymph (page 82). It may be primary (idiopathic) or secondary (obstructive).

I. PRIMARY (IDIOPATHIC) LYMPHOEDEMA Lymphoedema occurring without underlying secondary cause is called primary or idiopathic lymphoedema. Its various types are as under:

1. Congenital lymphoedema Congenital lymphoedema has further 2 subtypes—familial hereditary form (Milroy's disease) and non-familial (simple) form.

i) *Milroy's disease* is a form of congenital and familial oedema generally affecting one limb but at times may be more extensive and involve the eyelids and lips. The disease is inherited as an autosomal dominant trait and is often associated with other congenital anomalies. The condition results from developmental defect of lymphatic channels so that the affected tissue shows abnormally dilated lymphatics and the area shows honey-combed appearance. Recurrent infection of the tissue causes cellulitis and fibrosis of lymphatic vessels.

ii) *Simple congenital lymphoedema* is non-familial form with unknown etiology. It is often associated with Turner's syndrome and affects one member of the family. The pathologic changes are similar to those of Milroy's disease.

2. Lymphoedema praecox This is a rare form of lymphoedema affecting chiefly young females. The oedema usually begins in the foot and progresses slowly upwards to involve the whole extremity. With passage of time, the affected area becomes rough and the oedema is non-pitting. The etiology is unknown but probably the condition is related to female reproductive system because of preponderance in females and aggravation during menses.

II. SECONDARY (OBSTRUCTIVE) LYMPHOEDEMA This is more common form of lymphoedema. Various causes of lymphatic obstruction causing lymphoedema are as under:

- i) Lymphatic invasion by malignant tumour.
- ii) Surgical removal of lymphatics e.g. in radical mastectomy.
- iii) Post-irradiation fibrosis.
- iv) Parasitic infestations e.g. in filariasis of lymphatics producing elephantiasis.
- v) Lymphangitis causing scarring and obstruction.

Obstructive lymphoedema occurs only when the obstruction is widespread as otherwise collaterals develop. The affected area consists of dilatation of lymphatics distal

to obstruction with increased interstitial fluid. With passage of time, there is inflammatory scarring and the lymphatics become fibrosed with enlargement of the affected part. Rupture of dilated large lymphatics may result in escape of milky chyle into the peritoneum (*chyloperitoneum*), into the pleural cavity (*chylothorax*), into pericardial cavity (*chylopericardium*) and into the urinary tract (*chyluria*).

GIST BOX 13.7 Diseases of Lymphatics

- ☐ Inflammation of the lymphatics or lymphangitis may be acute or chronic.
- ☐ Lymphoedema is swelling of soft tissues due to localised increase in the quantity of lymph which may be primary (idiopathic) or secondary (obstructive).

TUMOURS AND TUMOUR-LIKE LESIONS

Majority of benign vascular tumours are malformations or hamartomas. A hamartoma is a tumour-like lesion made up of tissues indigenous to the part but lacks the true growth potential of true neoplasms. However, there is no clear-cut distinction between vascular hamartomas and true benign tumours and are often described together. On the other hand, there are true vascular tumours which are of intermediate grade and there are frank malignant tumours.

A classification of vascular tumours and tumour-like conditions is given in **Table 13.5**.

A. BENIGN TUMOURS AND HAMARTOMAS

HAEMANGIOMA

Haemangiomas are quite common lesions, especially in infancy and childhood. The most common site is the skin of the face and mucosal surfaces. Amongst the various clinical and histologic types, three important forms are described below.

CAPILLARY HAEMANGIOMA These are the most common type. Clinically, they appear as small or large, flat or slightly elevated, red to purple, soft and lobulated lesions, varying in size from a few millimeters to a few centimeters in diameter.

Table 13.5 Tumours and tumour-like lesions of blood vessels and lymphatics.

- | | |
|----------------------------------|-----------------------------|
| A. BENIGN TUMOURS AND HAMARTOMAS | |
| 1. | Haemangioma |
| 2. | Lymphangioma |
| 3. | Glomus tumour (glomangioma) |
| 4. | Arteriovenous malformations |
| 5. | Bacillary angiomatosis |
| B. INTERMEDIATE GRADE TUMOURS | |
| Haemangioendothelioma | |
| C. MALIGNANT TUMOURS | |
| 1. | Haemangiopericytoma |
| 2. | Angiosarcoma |
| 3. | Kaposi's sarcoma |

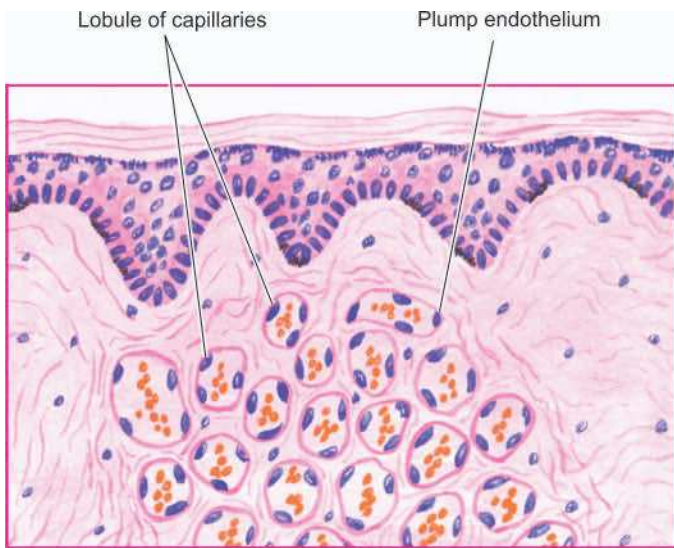

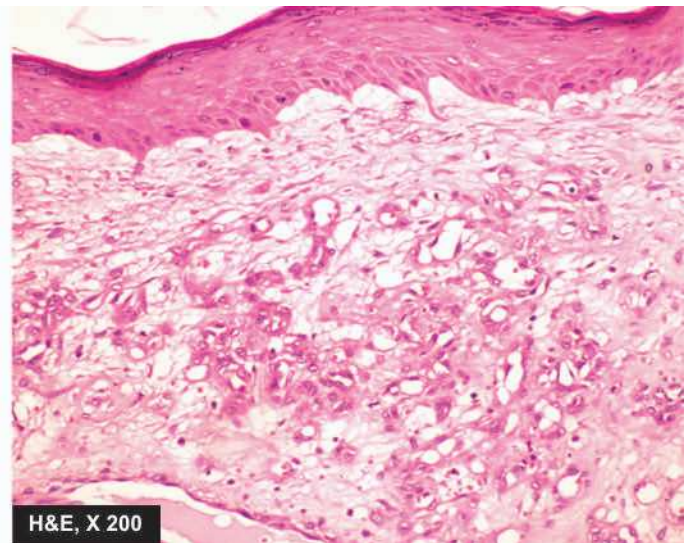

Figure 13.19 Capillary haemangioma of the skin. There are capillaries lined by plump endothelial cells and containing blood. The intervening stroma consists of scant connective tissue.

They may be present at birth or appear in early childhood. Strawberry birthmarks and 'port-wine mark' are some good examples. The common sites are the skin, subcutaneous tissue and mucous membranes of oral cavity and lips. Less common sites are internal visceral organs like liver, spleen and kidneys.

Histologically, capillary haemangiomas are well-defined but unencapsulated lobules. These lobules are composed of capillary-sized, thin-walled, blood-filled vessels. These vessels are lined by single layer of plump endothelial cells surrounded by a layer of pericytes. The vessels are separated by some connective tissue stroma (**Fig. 13.19**).

Many of the capillary haemangiomas regress spontaneously within a few years.

CAVERNOUS HAEMANGIOMA Cavernous haemangiomas are single or multiple, discrete or diffuse, red to blue, soft and

spongy masses. They are often 1 to 2 cm in diameter. They are most common in the skin (especially of the face and neck); other sites are mucosa of the oral cavity, stomach and small intestine, and internal visceral organs like the liver and spleen.

Histologically, cavernous haemangiomas are composed of thin-walled cavernous vascular spaces, filled partly or completely with blood. The vascular spaces are lined by flattened endothelial cells. They are separated by scanty connective tissue stroma (**Fig. 13.20**).

Cavernous haemangiomas rarely involute spontaneously.

GRANULOMA PYOGENICUM Granuloma pyogenicum is also referred to as *haemangioma of granulation tissue type*. True to its name, it appears as exophytic, red granulation tissue just like a nodule, commonly on the skin and mucosa of gingiva or oral cavity. *Pregnancy tumour* or *granuloma gravidarum*

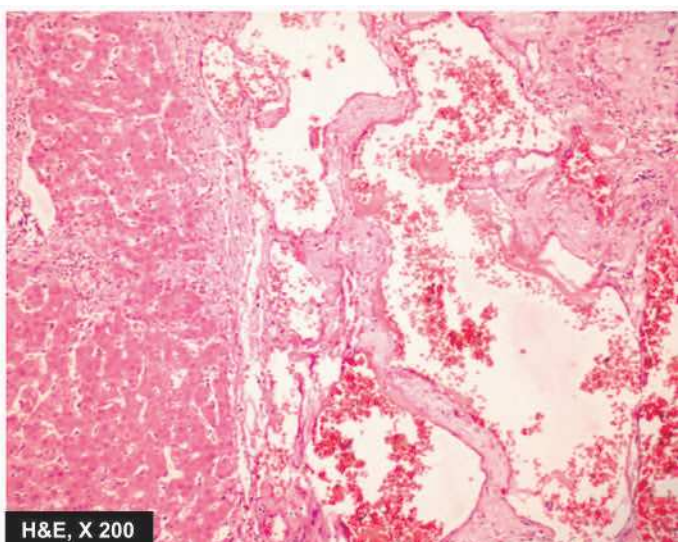

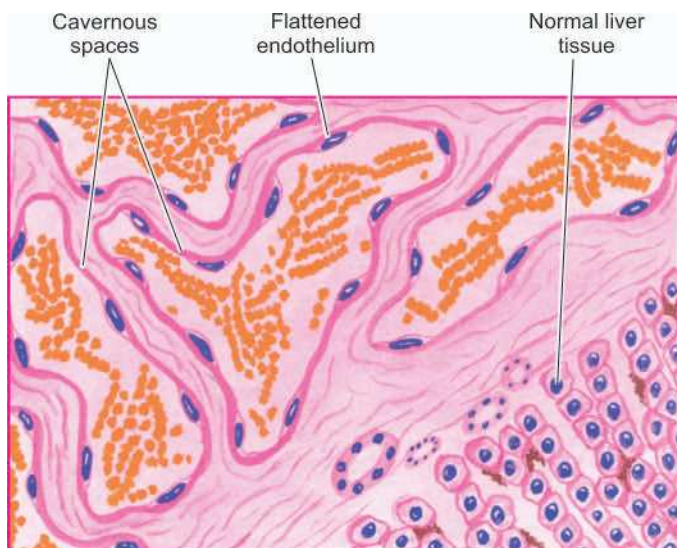

Figure 13.20 Cavernous haemangioma of the liver. The vascular spaces are large, dilated, many containing blood, and are lined by flattened endothelial cells. Scanty connective tissue stroma is seen between the cavernous spaces.

is a variant occurring on the gingiva during pregnancy and regresses after delivery. Granuloma pyogenicum often develops following trauma and is usually 1 to 2 cm in diameter.

Histologically, it shows proliferating capillaries similar to capillary haemangioma but the capillaries are separated by abundant oedema and inflammatory infiltrate, thus resembling inflammatory granulation tissue.

LYMPHANGIOMA

Lymphangiomas are lymphatic counterparts of vascular angiomas. Lymphangiomas are congenital lesions which are classified as capillary, cavernous and cystic hygroma. Combinations are also often seen.

CAPILLARY LYMPHANGIOMA It is also called as lymphangioma simplex. It is a small, circumscribed, slightly elevated lesion measuring 1 to 2 cm in diameter. The common locations are the skin of head and neck, axilla and mucous membranes. Rarely, these may be found in the internal organs.

Histologically, capillary lymphangioma is composed of a network of endothelium-lined, capillary-sized spaces containing lymph and often separated by lymphoid aggregates.

CAVERNOUS LYMPHANGIOMA It is more common than the capillary type. The common sites are in the region of head and neck or axilla. A large cystic variety called *cystic hygroma* occurs in the neck producing gross deformity in the neck.

Histologically, cavernous lymphangioma consists of large dilated lymphatic spaces lined by flattened endothelial cells and containing lymph. Scanty intervening stromal connective tissue is present (Fig. 13.21). These lesions, though benign, are often difficult to remove due to infiltration into adjacent tissues.

GLOMUS TUMOUR (GLOMANGIOMA)

Glomus tumour is an uncommon true benign tumour arising from contractile glomus cells that are present in the

arteriovenous shunts (Sucquet-Hoyer anastomosis). These tumours are found most often in the dermis of the fingers or toes under a nail; other sites are mucosa of the stomach and nasal cavity. These lesions are characterised by extreme pain. They may be single or multiple, small, often less than 1 cm in diameter, flat or slightly elevated, red-blue, painful nodules.

Histologically, the tumours are composed of small blood vessels lined by endothelium and surrounded by aggregates, nests and masses of glomus cells. The glomus cells are round to cuboidal cells with scanty cytoplasm (Fig. 13.22). The intervening connective tissue stroma contains some non-myelinated nerve fibres.

ARTERIOVENOUS MALFORMATIONS

An arteriovenous (AV) malformation is a communication between an artery and vein without an intervening capillary bed. It may be congenital or acquired type. Congenital AV malformations have thick-walled vessels with hyalinisation and calcification. Acquired AV malformations reveal changes mainly in the veins which are dilated and thick-walled.

BACILLARY ANGIOMATOSIS AND PELIOSIS HEPATIS

Bacillary angiomatosis is a tumour-like lesion reported in association with HIV-AIDS with CD4+ T cell counts below 100/ μ l. In fact, it is an opportunistic infection with gram-negative bacilli of *Bartonella* genus. Most common site of involvement is the skin and bones while a closely related condition peliosis hepatis is seen in the liver (page 589).

Grossly, the lesions on the skin are in the form of variable-sized red papules.

Histologically, lobules of proliferating blood vessels are seen lined by epithelioid endothelial cells having mild atypia. Mixed inflammatory cell infiltrate with nuclear debris of neutrophils is present in these areas.

The condition is treated with antibiotics.

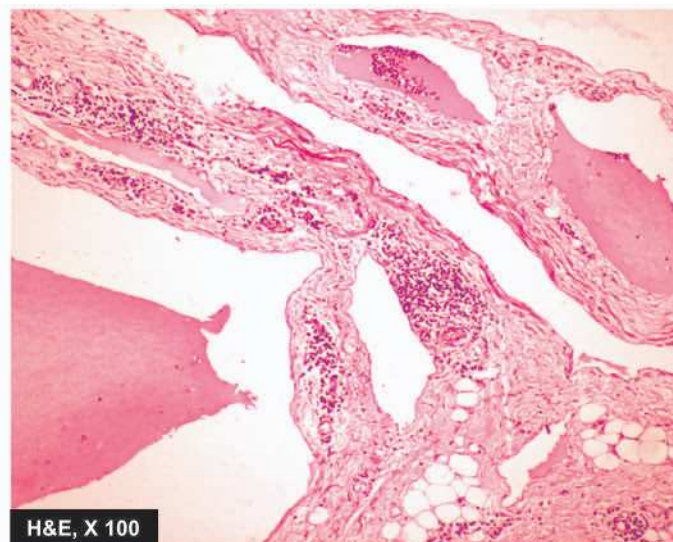

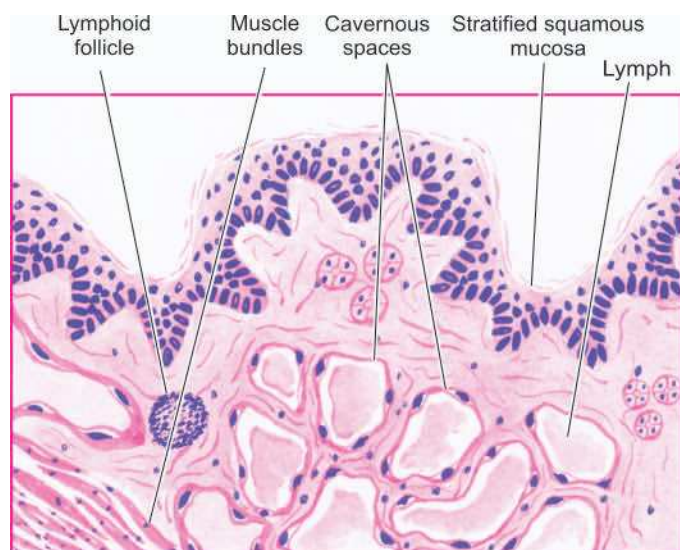

Figure 13.21 Cavernous lymphangioma of the tongue. Large cystic spaces lined by the flattened endothelial cells and containing lymph are present. Stroma shows scattered collection of lymphocytes.

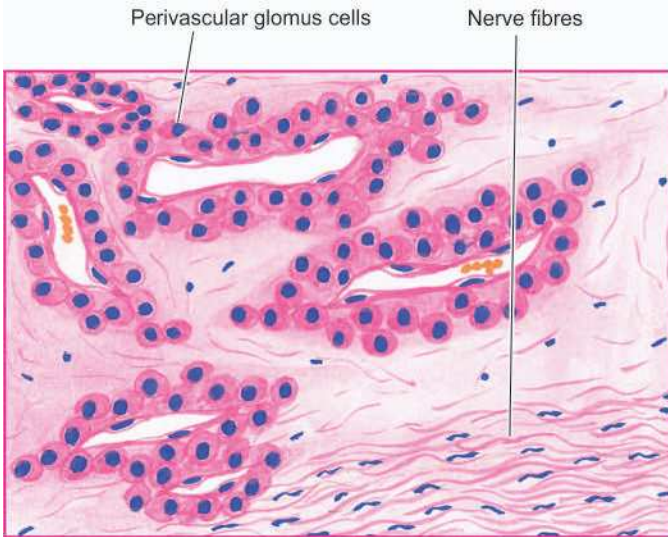

Figure 13.22 Glomus tumour. There are blood-filled vascular channels lined by endothelial cells and surrounded by nests and masses of glomus cells.

B. INTERMEDIATE GRADE TUMOURS

HAEMANGIOENDOTHELIOMA

Haemangioendothelioma is a true tumour of endothelial cells, the behaviour of which is intermediate between a haemangioma and haemangiosarcoma. It is found most often in the skin and subcutaneous tissue in relation to medium-sized and large veins. *Haemangioblastoma* is the term used for similar tumour occurring in the cerebellum (page 878).

Grossly, the tumour is usually well-defined, grey-red, polypoid mass.

Microscopically, there is an active proliferation of endothelial cells forming several layers around the blood vessels so that vascular lumina are difficult to identify. These cells may have variable mitotic activity. Reticulin stain delineates the pattern of cell proliferation inner to the basement membrane (**Fig. 13.23**).

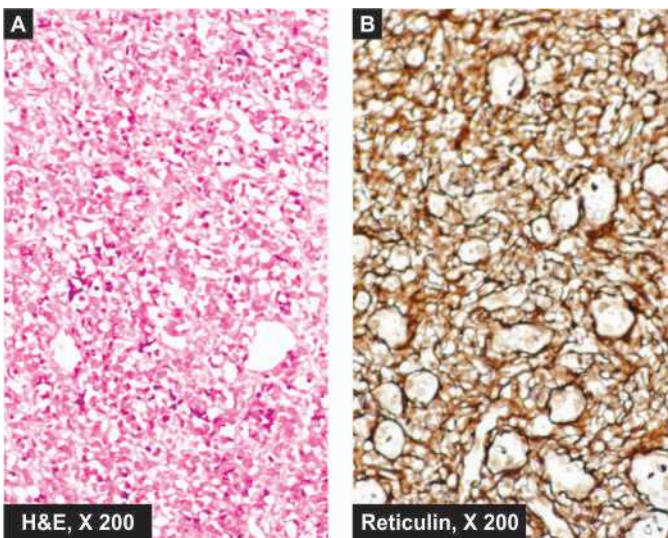

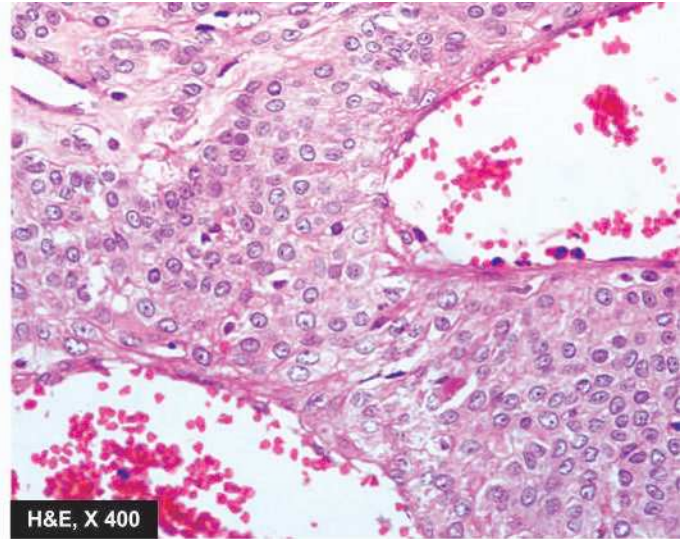

Figure 13.23 Haemangioendothelioma nose. A, The vascular channels are lined by multiple layers of plump endothelial cells having minimal mitotic activity obliterating the lumina. B, Reticulin stain shows condensation of reticulin around the vessel wall but not between the proliferating cells.

C. MALIGNANT TUMOURS

HAEMANGIOPERICYTOMA

Haemangiopericytoma is an uncommon tumour arising from pericytes. Pericytes are cells present external to the endothelial cells of capillaries and venules. This is a rare tumour that can occur at any site but is more common in lower extremities and the retroperitoneum. It may occur at any age and may vary in size from 1 to 8 cm.

Microscopically, the tumour is composed of capillaries surrounded by spindle-shaped pericytes outside the vascular basement membrane forming whorled arrangement. These tumour cells may have high mitotic rate and areas of necrosis. Silver impregnation stain (i.e. reticulin stain) is employed to confirm the presence of pericytes outside the basement membrane of capillaries and to distinguish it from haemangioendothelioma (**Fig. 13.24**).

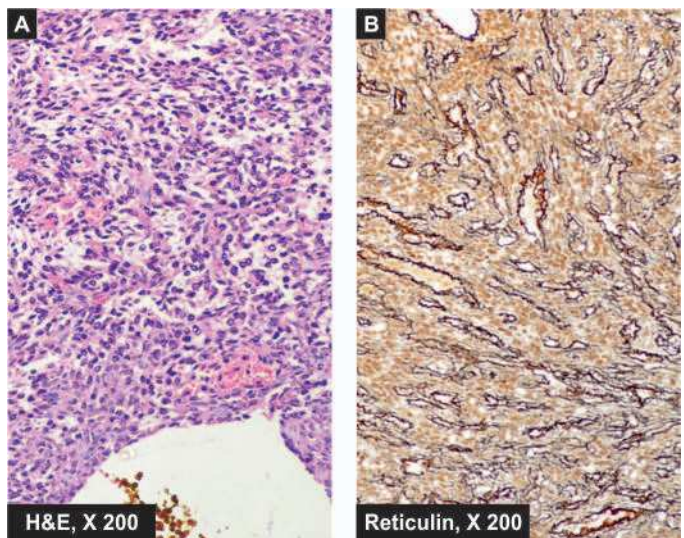

Figure 13.24 Haemangiopericytoma liver. Spindled cells surround the vascular lumina in a whorled fashion, highlighted by reticulin stain. These tumour cells have bland nuclei and few mitoses.

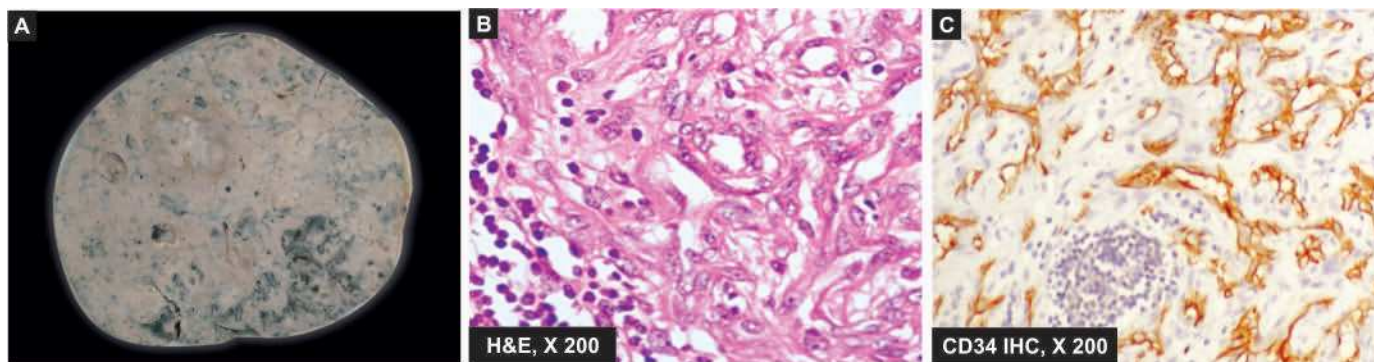

Figure 13.25 Angiosarcoma spleen. A, Gross appearance of lobulated masses of grey white necrotic and haemorrhagic parenchyma. B, The tumour cells show proliferation of moderately pleomorphic anaplastic cells. C, These tumour cells show positive staining for endothelial marker, CD34.

Local recurrences are common and distant spread occurs in about 20% of cases.

ANGIOSARCOMA

Also known as haemangiosarcoma and malignant haemangioendothelioma, it is a malignant vascular tumour occurring most frequently in the skin, subcutaneous tissue, liver, spleen, bone, lung and retroperitoneal tissues. It can occur in both sexes and at any age. *Hepatic angiosarcomas* are of special interest in view of their association with carcinogens like polyvinyl chloride, arsenical pesticides and radioactive contrast medium, thorotrast, used in the past.

Grossly, the tumours are usually bulky, pale grey-white, firm masses with poorly-defined margins. Areas of haemorrhage, necrosis and central softening are frequently present.

Microscopically, the tumours may be well-differentiated masses of proliferating endothelial cells around well-formed vascular channels, to poorly-differentiated lesions composed of plump, anaplastic and pleomorphic cells in solid clusters with poorly identifiable vascular channels (Fig. 13.25).

These tumours invade locally and frequently have distant metastases in the lungs and other organs. *Lymphangiosarcoma* is a histologically similar tumour occurring in obstructive lymphoedema of long duration.

KAPOSI'S SARCOMA

Kaposi's sarcoma is a malignant angiomatous tumour, first described by Kaposi, Hungarian dermatologist, in 1872. However, the tumour has attracted greater attention in the last two decades due to its frequent occurrence in patients with HIV/AIDS.

CLASSIFICATION Presently, four forms of Kaposi's sarcoma are described:

1. Classic (European) Kaposi's sarcoma This is the form which was first described by Kaposi. It is more common in men over 60 years of age of Eastern European descent. The disease is slow growing and appears as multiple, small, purple, dome-shaped nodules or plaques in the skin, especially on the legs. Involvement of visceral organs occurs in about 10% cases after many years.

2. African (Endemic) Kaposi's sarcoma This form is common in equatorial Africa. It is so common in Uganda that it comprises 9% of all malignant tumours in men. It is found in younger age, especially in boys and in young men and has a more aggressive course than the classic form. The disease begins in the skin but grows rapidly to involve other tissues, especially lymph nodes and the gut.

3. Epidemic (AIDS-associated) Kaposi's sarcoma This form is seen in about 30% cases of AIDS, especially in young male homosexuals than the other high-risk groups. The cutaneous lesions are not localised to lower legs but are more extensively distributed involving mucous membranes, lymph nodes and internal organs early in the course of disease.

4. Kaposi's sarcoma in renal transplant cases This form is associated with recipients of renal transplants who have been administered immunosuppressive therapy for a long time. The lesions may be localised to the skin or may have widespread systemic involvement.

PATHOGENESIS Pathogenesis of Kaposi's sarcoma is complex. It is an opportunistic neoplasm in immunosuppressed patients which has excessive proliferation of spindle cells of vascular origin having features of both endothelium and smooth muscle cells:

i) Epidemiological studies have suggested a *viral association* implicating HIV and human herpesvirus 8 (HSV 8, also called Kaposi's sarcoma-associated herpesvirus or KSHV).

ii) Occurrence of Kaposi's sarcoma involves interplay of HIV-1 infection, HHV-8 infection, activation of the immune system and secretion of cytokines (IL-6, TNF- α , GM-CSF, basic fibroblast factor, and oncostain M). Higher incidence of Kaposi's sarcoma in male homosexuals is explained by increased secretion of cytokines by their activated immune system.

iii) Defective immunoregulation plays a role in its pathogenesis is further substantiated by observation of *second malignancy* (e.g. leukaemia, lymphoma and myeloma) in about one-third of patients with Kaposi's sarcoma.

MORPHOLOGIC FEATURES Pathologically, all forms of Kaposi's sarcoma are similar

Grossly, the lesions in the skin, gut and other organs form prominent, irregular, purple, dome-shaped plaques or nodules.

Histologically, the changes are nonspecific in the *early patch stage* and more characteristic in the *late nodular stage*.

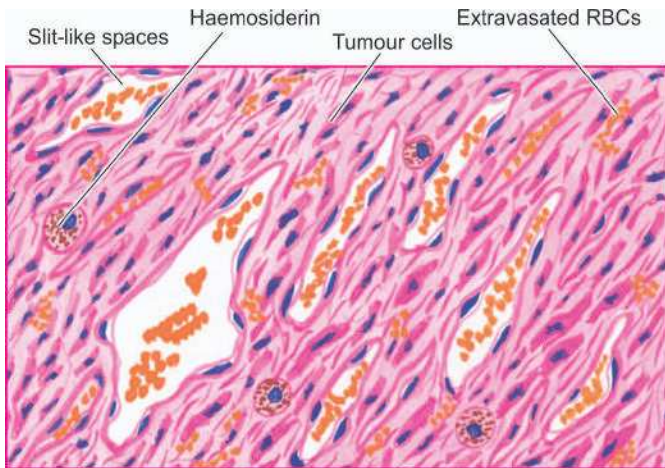

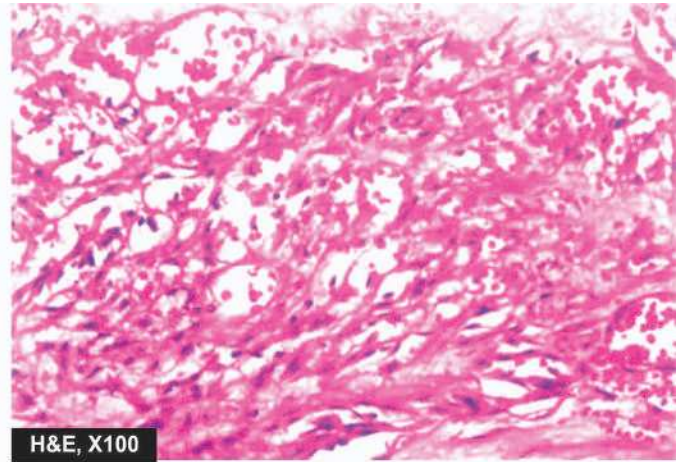

Figure 13.26 Kaposi's sarcoma in late nodular stage. There are slit-like blood-filled vascular spaces with extravasated RBCs. Between them are present bands of plump spindle-shaped tumour cells.

H&E, X100

Early patch stage There are irregular vascular spaces separated by interstitial inflammatory cells and extravasated blood and haemosiderin.

Late nodular stage There are slit-like vascular spaces containing red blood cells and separated by spindle-shaped, plump tumour cells. These spindle-shaped tumour cells are probably of endothelial origin (**Fig. 13.26**).

CLINICAL COURSE The clinical course and biologic behaviour of Kaposi's sarcoma is quite variable. The classic form of Kaposi's sarcoma is largely confined to skin and the course is generally slow and insidious with long survival. The endemic (African) and epidemic (AIDS-associated) Kaposi's sarcoma, on the other hand, has a rapidly progressive course, often with widespread cutaneous as well as visceral involvement, and high mortality.

GIST BOX 13.8 Tumours and Tumour-like Lesions

- ☐ Majority of benign vascular tumours are malformations or hamartomas. True vascular tumours are of intermediate grade and frank malignant tumours.
- ☐ Haemangiomas are quite common lesions on the skin and mucosal surfaces. These are of 3 histologic types: capillary, cavernous and lymphangioma.
- ☐ Glomus tumour is an uncommon true benign tumour arising from contractile glomus cells and is common in the fingers.

- ☐ Haemangioendothelioma is a true tumour of endothelial cells, having an intermediate behaviour. Its common locations are skin and mucosal surfaces.
- ☐ Haemangiopericytoma is an uncommon malignant tumour arising from pericytes, occurs commonly in the lower extremities.
- ☐ Angiosarcoma is a malignant vascular tumour most frequent in the skin, subcutaneous tissue, liver, spleen, bone, lung and retroperitoneal tissues. It metastasises widely.
- ☐ Kaposi's sarcoma is an opportunistic neoplasm seen in immunosuppressed patients and has association with HIV and HHV-8 infection.

✿ CLINICAL CASE 9

A 50 years old male bank officer feels sudden onset of severe constricting chest pain while attending a meeting in his office. He gives history of intermittent pain over the sternum earlier too almost once a week which would go away when he sits down. He has mild hypertension, for which he is on dietary therapy. He also gives family history of diabetes. His cholesterol level is elevated. He is not a smoker.

1. Discuss the clinical correlation with pathogenesis of the features.
2. What is the probable diagnosis?
3. How will you investigate and confirm the diagnosis?

14

The Heart

NORMAL STRUCTURE AND CLASSIFICATION**ANATOMY AND PHYSIOLOGY**

The heart is a muscular pump that ejects blood into the vascular tree with sufficient pressure to maintain optimal circulation. Average weight of the heart in an adult male is 300-350 gm while that of an adult female is 250-300 gm. Heart is divided into four chambers: a right and a left atrium both lying superiorly, and a right and a left ventricle both lying inferiorly and are larger. The atria are separated by a thin interatrial partition called *interatrial septum*, while the ventricles are separated by thick muscular partition called *interventricular septum*. The thickness of the right ventricular wall is 0.3 to 0.5 cm while that of the left ventricular wall is 1.3 to 1.5 cm. The blood in the heart chambers moves in a carefully prescribed pathway: venous blood from systemic circulation → right atrium → right ventricle → pulmonary arteries → lungs → pulmonary veins → left atrium → left ventricle → aorta → systemic arterial supply (Fig. 14.1).

The transport of blood is regulated by cardiac valves: two loose flap-like atrioventricular valves, tricuspid on the right and mitral (bicuspid) on the left; and two semilunar valves with three leaflets each, the pulmonary and aortic valves, guarding the outflow tracts. The normal circumference of the valvular openings measures about 12 cm in tricuspid, 8.5 cm in pulmonary, 10 cm in mitral and 7.5 cm in aortic valve.

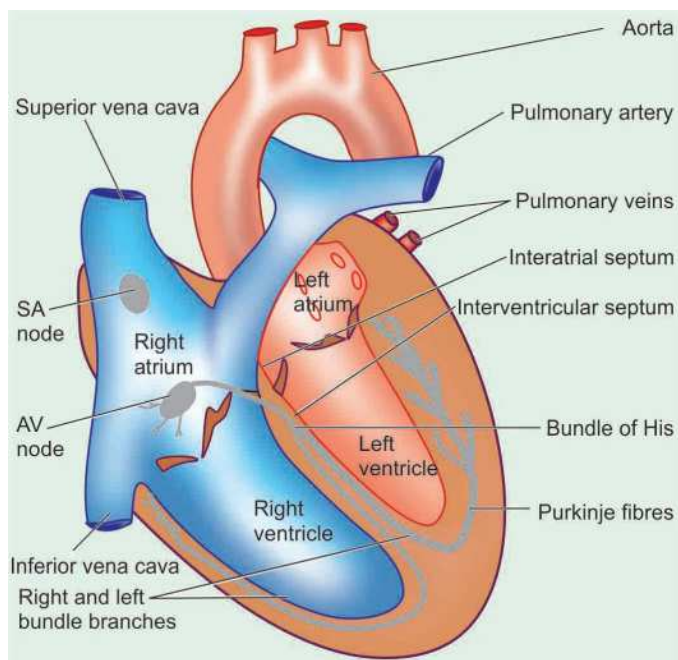

Figure 14.1 The normal structure of the heart.

Wall of the heart consists mainly of the *myocardium* which is covered externally by thin membrane, the *epicardium* or visceral pericardium, and lined internally by another thin layer, the *endocardium*.

◆ The **myocardium** is the muscle tissue of the heart composed of syncytium of branching and anastomosing, transversely striated muscle fibres arranged in parallel fashion. The space between myocardial fibres contains a rich capillary network and loose connective tissue. The myocardial fibres are connected to each other by irregular joints called as *intercalated discs*. They represent apposed cell membranes of individual cells which act as tight junctions for free transport of ions and action potentials. The cardiac myocyte is very rich in mitochondria which are the source of large amount of ATP required for cardiac contraction. The cardiac muscle fibre has abundant sarcoplasmic reticulum corresponding to endoplasmic reticulum of other cells. Transverse lines divide each fibre into *sarcomeres* which act as structural and functional subunits. Each sarcomere consists of prominent central *dark A-band* attributed to thick myosin filaments and flanked on either side by *light I-bands* consisting of thin actin filament. The actin bands are in the form of twisted rods overlying protein molecules called *tropomyosin*. These protein molecules are of 3 types: *troponin-I*, *troponin-T*, and *troponin-C*. Troponin molecules respond to calcium ions in cyclical contraction-relaxation of myocardial fibres. Myocardial fibres are terminally differentiated cells and do not regenerate but there is recent evidence that new cardiac myocytes can be formed from stem cells recruited from the circulation.

◆ The **conduction system** of the heart located in the myocardium is responsible for regulating rate and rhythm of the heart. It is composed of specialised Purkinje fibres which contain some contractile myofilaments and conduct action potentials rapidly. The conduction system consists of 4 major components:

1. The *sinoatrial (SA) node* is located in the posterior wall of the right atrium adjacent to the point at which the superior vena cava enters the heart. It is also called cardiac pacemaker since it is responsible for determining the rate of contraction for all cardiac muscle.
2. The *atrioventricular (AV) bundle* conducts the impulse from the SA node to the AV node.
3. The *atrioventricular (AV) node* is located on the top of the interventricular septum and receives impulses from the SA node via AV bundle and transmits them to the bundle of His.
4. The *bundle of His* extends through the interventricular septum and divides into right and left bundle branches which arborise in the respective ventricular walls. These fibres transmit impulses from the AV node to the ventricular walls.

◆ The **pericardium** consists of a closely apposed layer, *visceral pericardium* or *epicardium*, and an outer fibrous sac, the *parietal pericardium*. The two layers enclose a narrow pericardial cavity which is lined by mesothelial cells and

normally contains 10-30 ml of clear, watery serous fluid. This fluid functions as lubricant and shock absorbent to the heart.

◆ The **endocardium** is the smooth shiny inner lining of the myocardium that covers all the cardiac chambers, the cardiac valves, the chordae tendineae and the papillary muscles. It is lined by endothelium with connective tissue and elastic fibres in its deeper part.

◆ The **valve cusps and semilunar leaflets** are delicate and translucent structures. The valves are strengthened by collagen and elastic tissue and covered by a layer of endothelium (valvular endocardium).

Myocardial Blood Supply

The cardiac muscle, in order to function properly, must receive adequate supply of oxygen and nutrients. Blood is transported to myocardial cells by the coronary arteries which originate immediately above the aortic semilunar valve. Most of blood flow to the myocardium occurs during diastole. There are three major coronary trunks, each supplying blood to specific segments of the heart (**Fig. 14.2**):

1. The **anterior descending branch of the left coronary artery**, commonly called **LAD** (left anterior descending coronary) supplies most of the apex of the heart, the anterior surface of the left ventricle, the adjacent third of the anterior wall of the right ventricle, and the anterior two-third of the interventricular septum.
2. The **circumflex branch of the left coronary artery**, commonly called **LCX** (left circumflex coronary) supplies the left atrium and a small portion of the lateral aspect of the left ventricle.
3. The **right coronary artery**, abbreviated as **RCA** supplies the right atrium, the remainder of the anterior surface of the right ventricle, the adjacent half of the posterior wall of the left ventricle and the posterior third of the interventricular septum.

There are 3 anatomic patterns of distribution of the coronary blood supply, depending upon which coronary artery crosses the crux. *Crux* is the region on the posterior surface of the heart

where all the four cardiac chambers and the interatrial and interventricular septa meet. These patterns are as under:

◆ **Right coronary artery preponderance** is the most common pattern. In this, right coronary artery supplies blood to the whole of right ventricle, the posterior half of the interventricular septum and a part of the posterior wall of the left ventricle by crossing the crux.

◆ **Balanced cardiac circulation** is the next most frequent pattern. In this, the right and left ventricles receive blood supply entirely from right and left coronary arteries respectively. The posterior part of the interventricular septum is supplied by a branch of the right coronary while the anterior part is supplied by a branch of the left coronary artery.

◆ **Left coronary preponderance** is the least frequent pattern. In this, the left coronary artery supplies blood to the entire left ventricle, whole of interventricular septum and also supplies blood to a part of the posterior wall of the right ventricle by crossing the crux.

Coronary veins run parallel to the major coronary arteries to collect blood after the cellular needs of the heart are met. Subsequently, these veins drain into the *coronary sinus*.

PATTERNS AND CLASSIFICATION OF HEART DISEASES

For the purpose of pathologic discussion of heart diseases, they are categorised on the basis of *anatomic region involved* and *the functional impairment* as under:

1. Heart failure
2. Congenital heart diseases
3. Ischaemic heart disease
4. Hypertensive heart disease
5. Cor pulmonale
6. Rheumatic fever and rheumatic heart disease
7. Non-rheumatic endocarditis
8. Valvular diseases and deformities
9. Myocardial disease
10. Pericardial disease
11. Tumours of the heart
12. Pathology of cardiovascular interventions

It may be mentioned here that pattern of heart diseases in developing and developed countries is distinct due to differences in living standards:

◆ In children, valvular diseases are common all over the world. But in developing countries including India, *infectious cause*, particularly rheumatic valvular disease, is the dominant cause compared to *congenital* valvular disease in affluent countries.

◆ On the other hand, cardiovascular diseases due to ischaemic heart disease and hypertensive cardiomyopathy are the major heart diseases accounting for ~40% deaths in adults in high-income group countries compared to ~28% in low-income group countries.

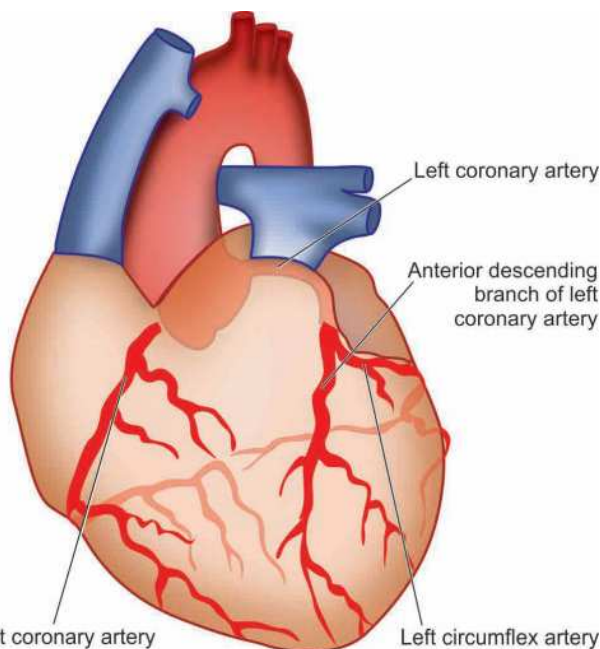

Figure 14.2 Distribution of blood supply to the heart.

GIST BOX 14.1

Normal Structure of Heart

- Average weight of the heart is 300-350 gm in adult male and 250-300 gm in adult female.
- The thickness of the right ventricular wall is 0.3 to 0.5 cm while that of the left ventricular wall is 1.3 to 1.5 cm.
- The normal circumference of the valvular openings measures about 12 cm in tricuspid, 8.5 cm in pulmonary, 10 cm in mitral and 7.5 cm in aortic valve.

- ▣ Wall of the heart consists mainly of the *myocardium* which is covered externally by the *epicardium*, and lined internally by the *endocardium*.
- ▣ There are three major coronary trunks, each supplying blood to specific segments of the heart: left anterior descending coronary (LAD), left circumflex coronary (LCX) and right coronary artery (RCA).
- ▣ There are 3 anatomic patterns of distribution of the coronary blood supply, depending upon which coronary artery crosses the crux: right coronary artery preponderance (the most common), balanced cardiac circulation and left coronary preponderance.

HEART FAILURE

DEFINITION

Heart failure is defined as the pathophysiologic state in which impaired cardiac function is unable to maintain an adequate circulation for the metabolic needs of the tissues of the body. It may be *acute* or *chronic*. The term congestive heart failure (CHF) is used for the chronic form of heart failure in which the patient has evidence of congestion of peripheral circulation and of lungs (page 90). CHF is the end-result of various forms of serious heart diseases.

ETIOLOGY

Heart failure may be caused by one of the following factors, either singly or in combination:

- 1. INTRINSIC PUMP FAILURE** The most common and most important cause of heart failure is weakening of the ventricular muscle due to disease so that the heart fails to act as an efficient pump. The various diseases which may culminate in pump failure by this mechanism are as under:
 - i) Ischaemic heart disease
 - ii) Myocarditis
 - iii) Cardiomyopathies
 - iv) Metabolic disorders e.g. beriberi
 - v) Disorders of the rhythm e.g. atrial fibrillation and flutter.
- 2. INCREASED WORKLOAD ON THE HEART** Increased mechanical load on the heart results in increased myocardial demand resulting in myocardial failure. Increased load on the heart may be in the form of pressure load or volume load.
 - i) Increased pressure load** may occur in the following states:
 - a) Systemic and pulmonary arterial hypertension.
 - b) Valvular disease e.g. mitral stenosis, aortic stenosis, pulmonary stenosis.
 - c) Chronic lung diseases.
 - ii) Increased volume load** occurs when a ventricle is required to eject more than normal volume of the blood resulting in cardiac failure. This is seen in the following conditions:
 - a) Valvular insufficiency
 - b) Severe anaemia
 - c) Thyrotoxicosis
 - d) Arteriovenous shunts
 - e) Hypoxia due to lung diseases.
- 3. IMPAIRED FILLING OF CARDIAC CHAMBERS** Decreased cardiac output and cardiac failure may result from extracardiac causes or defect in filling of the heart:

- a) Cardiac tamponade e.g. haemopericardium, hydropericardium
- b) Constrictive pericarditis.

TYPES OF HEART FAILURE

Heart failure may be acute or chronic, right-sided or left-sided, and forward or backward failure.

ACUTE AND CHRONIC HEART FAILURE

Depending upon whether the heart failure develops rapidly or slowly, it may be acute or chronic.

Acute heart failure Sudden and rapid development of heart failure occurs in the following conditions:

- i) Larger myocardial infarction
- ii) Valve rupture
- iii) Cardiac tamponade
- iv) Massive pulmonary embolism
- v) Acute viral myocarditis
- vi) Acute bacterial toxemia.

In acute heart failure, there is sudden reduction in cardiac output resulting in systemic hypotension but oedema does not occur. Instead, a state of cardiogenic shock and cerebral hypoxia develops.

Chronic heart failure More often, heart failure develops slowly as observed in the following states:

- i) Myocardial ischaemia from atherosclerotic coronary artery disease
- ii) Multivalvular heart disease
- iii) Systemic arterial hypertension
- iv) Chronic lung diseases resulting in hypoxia and pulmonary arterial hypertension
- v) Progression of acute into chronic failure.

In chronic heart failure, compensatory mechanisms like tachycardia, cardiac dilatation and cardiac hypertrophy try to make adjustments so as to maintain adequate cardiac output. This often results in well-maintained arterial pressure and there is accumulation of oedema.

LEFT-SIDED AND RIGHT-SIDED HEART FAILURE

Though heart as an organ eventually fails as a whole, but functionally, the left and right heart act as independent units. From clinical point of view, therefore, it is helpful to consider failure of the left and right heart separately. The clinical manifestations of heart failure result from accumulation of excess fluid *upstream* to the left or right cardiac chamber whichever is initially affected (**Fig. 14.3**):

Left-sided heart failure It is initiated by stress to the left heart. The major causes are as follows:

- i) Systemic hypertension
- ii) Mitral or aortic valve disease (stenosis)
- iii) Ischaemic heart disease
- iv) Myocardial diseases e.g. cardiomyopathies, myocarditis.
- v) Restrictive pericarditis.

The clinical manifestations of left-sided heart failure result from decreased left ventricular output and hence there is accumulation of fluid *upstream* in the lungs. Accordingly, the major pathologic changes are as under:

- i) Pulmonary congestion and oedema causes dyspnoea and orthopnoea (page 84).
- ii) Decreased left ventricular output causing hypoperfusion and diminished oxygenation of tissues e.g. in kidneys causing

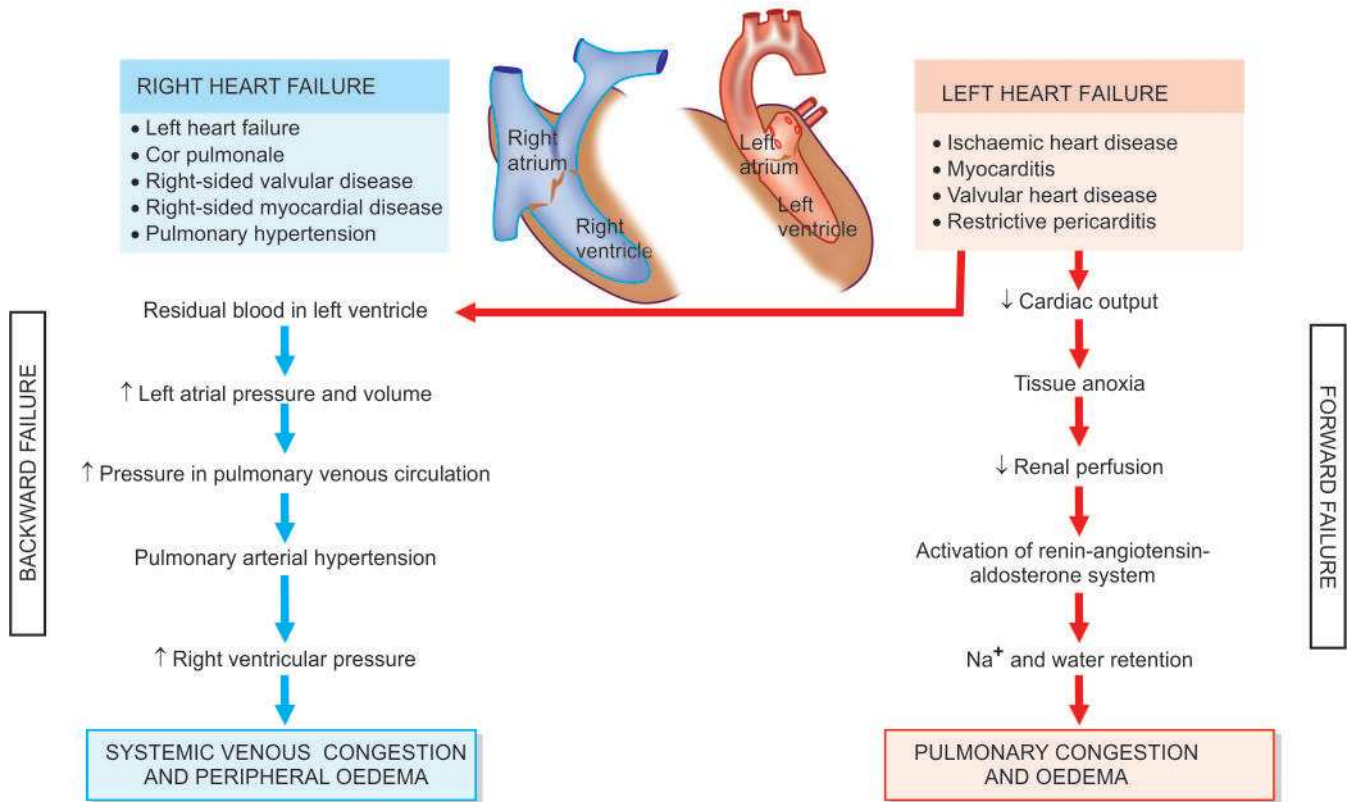

Figure 14.3 Schematic evolution of congestive heart failure and its effects.

ischaemic acute tubular necrosis (page 666), in brain causing hypoxic encephalopathy (page 871), and in skeletal muscles causing muscular weakness and fatigue.

Right-sided heart failure Right-sided heart failure occurs more often as a consequence of left-sided heart failure. However, some conditions affect the right ventricle primarily, producing right-sided heart failure. These are as follows:

- As a consequence of left ventricular failure.
- Cor pulmonale in which right heart failure occurs due to intrinsic lung diseases (page 447).
- Pulmonary or tricuspid valvular disease.
- Pulmonary hypertension secondary to pulmonary thromboembolism.
- Myocardial disease affecting right heart.
- Congenital heart disease with left-to-right shunt.

Whatever be the underlying cause, the clinical manifestations of right-sided heart failure are *upstream* of the right heart such as systemic (due to caval blood) and portal venous congestion, and reduced cardiac output. Accordingly, the pathologic changes are as under:

- Systemic venous congestion in different tissues and organs e.g. subcutaneous oedema on dependent parts, passive congestion of the liver, spleen, and kidneys (page 84), ascites, hydrothorax, congestion of leg veins and neck veins.
- Reduced cardiac output resulting in circulatory stagnation causing anoxia, cyanosis and coldness of extremities.

In summary, in early stage the left heart failure manifests with features of pulmonary congestion and decreased left ventricular output, while the right heart failure presents with systemic venous congestion and involvement of the liver and spleen. CHF, however, combines the features of both left and right heart failure.

BACKWARD AND FORWARD HEART FAILURE

The mechanism of clinical manifestations resulting from heart failure can be explained on the basis of mutually interdependent backward and forward failure.

Backward heart failure According to this concept, either of the ventricles fails to eject blood normally, resulting in rise of end-diastolic volume in the ventricle and increase in volume and pressure in the atrium which is transmitted *backward* producing elevated pressure in the veins.

Forward heart failure According to this hypothesis, clinical manifestations result directly from failure of the heart to pump blood causing diminished flow of blood to the tissues, especially diminished renal perfusion and activation of renin-angiotensin-aldosterone system.

COMPENSATORY MECHANISMS: CARDIAC HYPERTROPHY AND DILATATION

In order to maintain normal cardiac output, several compensatory mechanisms play a role as under:

- ◆ Compensatory enlargement in the form of *cardiac hypertrophy, cardiac dilatation, or both*.
- ◆ *Tachycardia* (i.e. increased heart rate) due to activation of neurohumoral system e.g. release of norepinephrine and atrial natriuretic peptide, activation of renin-angiotensin-aldosterone mechanism.

According to *Starling's law* on pathophysiology of heart, the failing dilated heart, in order to maintain cardiac performance, increases the myocardial contractility and thereby attempts to maintain stroke volume. This is achieved by increasing the length of sarcomeres in dilated heart. Ultimately, however,

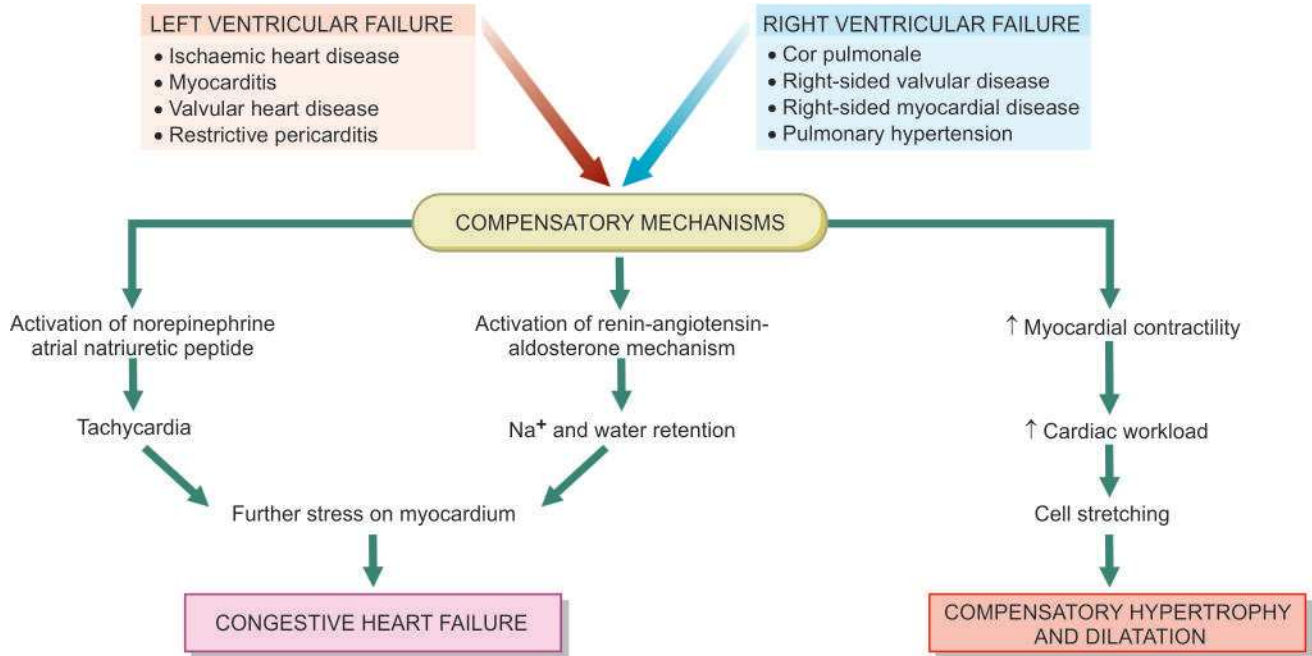

Figure 14.4 Schematic pathophysiology of compensatory mechanisms in cardiac failure.

dilatation decreases the force of contraction and leads to residual volume in the cardiac chambers causing volume overload resulting in cardiac failure that ends in death (Fig. 14.4).

CARDIAC HYPERTROPHY

Hypertrophy of the heart is defined as an increase in size and weight of the myocardium. It generally results from increased pressure load while increased volume load (e.g. valvular incompetence) results in hypertrophy with dilatation of the affected chamber due to regurgitation of the blood through incompetent valve. The atria may also undergo compensatory changes due to increased workload.

The basic factors that stimulate the hypertrophy of the myocardial fibres are not known. It appears that stretching of myocardial fibres in response to stress induces the cells to increase in length. The elongated fibres receive better nutrition and thus increase in size. Other factors which may stimulate increase in size of myocardial fibres are anoxia (e.g. in coronary atherosclerosis) and influence of certain hormones (e.g. catecholamines, pituitary growth hormone).

CAUSES Hypertrophy with or without dilatation may involve predominantly the left or the right heart, or both sides.

Left ventricular hypertrophy The common causes are as under:

- i) Systemic hypertension
- ii) Aortic stenosis and insufficiency
- iii) Mitral insufficiency
- iv) Coarctation of the aorta
- v) Occlusive coronary artery disease
- vi) Congenital anomalies like septal defects and patent ductus arteriosus
- vii) Conditions with increased cardiac output e.g. thyrotoxicosis, anaemia, arteriovenous fistulae.

Right ventricular hypertrophy Most of the causes of right ventricular hypertrophy are due to pulmonary arterial hypertension. These are as follows:

- i) Pulmonary stenosis and insufficiency
- ii) Tricuspid insufficiency
- iii) Mitral stenosis and/or insufficiency
- iv) Chronic lung diseases e.g. chronic emphysema, bronchiectasis, pneumoconiosis, pulmonary vascular disease etc.
- v) Left ventricular hypertrophy and failure of the left ventricle.

CARDIAC DILATATION

Quite often, hypertrophy of the heart is accompanied by cardiac dilatation. Stress leading to accumulation of excessive volume of blood in a chamber of the heart causes increase in length of myocardial fibres and hence cardiac dilatation as a compensatory mechanism.

CAUSES Accumulation of excessive volume of blood within the cardiac chambers from the following causes may result in dilatation of the respective ventricles or both:

- i) Valvular insufficiency (mitral and/or aortic insufficiency in left ventricular dilatation, tricuspid and/or pulmonary insufficiency in right ventricular dilatation)
- ii) Left-to-right shunts e.g. in VSD
- iii) Conditions with high cardiac output e.g. thyrotoxicosis, arteriovenous shunt
- iv) Myocardial diseases e.g. cardiomyopathies, myocarditis
- v) Systemic hypertension.

MORPHOLOGIC FEATURES

Hypertrophy of the myocardium without dilatation is referred to as *concentric*, and when associated with dilatation is called *eccentric* (Fig. 14.5). The weight of the heart is increased above normal, often over 500 gm. However, excessive epicardial fat is not indicative of true hypertrophy.

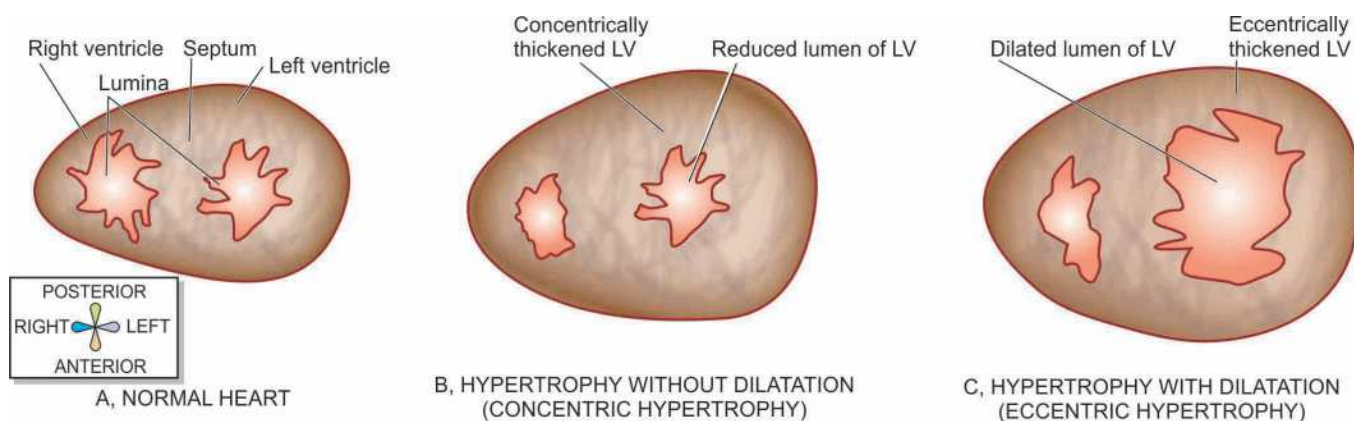

Figure 14.5 Schematic diagram showing transverse section through the ventricles with left ventricular hypertrophy (concentric and eccentric).

Grossly, thickness of the left ventricular wall (excluding trabeculae carneae and papillary muscles) above 15 mm is indicative of significant hypertrophy. In concentric hypertrophy, the lumen of the chamber is smaller than usual, while in eccentric hypertrophy the lumen is dilated (Fig. 14.6). In pure hypertrophy, the papillary muscles and trabeculae carneae are rounded and enlarged, while in hypertrophy with dilatation these are flattened.

Microscopically, there is increase in size of individual muscle fibres. There may be multiple minute foci of degenerative changes and necrosis in the hypertrophied myocardium (Fig. 14.7). These changes appear to arise as a result of relative hypoxia of the hypertrophied muscle as the blood supply is inadequate to meet the demands of the increased fibre size. Ventricular hypertrophy renders the inner part of the myocardium more liable to ischaemia.

Electron microscopy reveals increase in the number of myofilaments comprising myofibrils, mitochondrial changes and multiple intercalated discs which are active sites for the formation of new sarcomeres. Besides, the nucleic acid content determinations have shown increase in total RNA and increased ratio of RNA to DNA content of the hypertrophied myocardial fibres.

GIST BOX 14.2

Heart Failure

- ☐ Heart failure is a pathophysiologic state of impaired cardiac function when it is unable to maintain the metabolic needs of the tissues of the body.
- ☐ Heart failure may be caused by intrinsic pump failure, increased pressure or volume overload, or impaired filling.
- ☐ Heart failure may be acute or chronic, left-sided or right-sided, backward or forward failure.
- ☐ Compensatory mechanisms in heart failure are its enlargement in the form of cardiac hypertrophy (concentric or eccentric), cardiac dilatation, or both.

CONGENITAL HEART DISEASE

Congenital heart disease is the abnormality of the heart present from birth. It is the most common and important form of heart disease in the early years of life and is present in about 0.5% of newborn children. The incidence is higher in premature infants. The cause of congenital heart disease is unknown in majority of cases. It is attributed to multifactorial inheritance involving genetic and environmental influences. Other factors like rubella infection to the mother during pregnancy, drugs

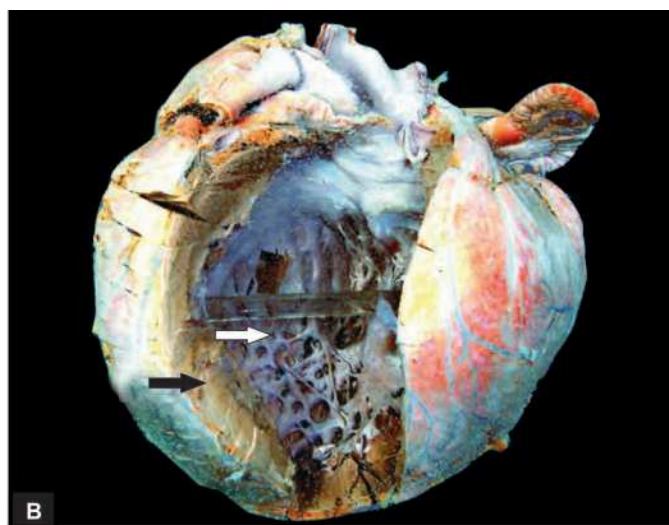

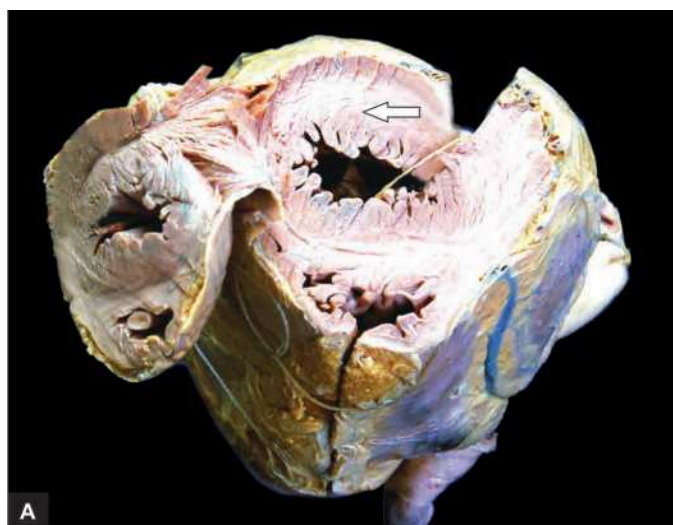

Figure 14.6 A, Concentric cardiac hypertrophy. Weight of the heart is increased. The chambers opened up at the apex show concentric thickening of left ventricular wall (white arrow) with obliterated lumen (hypertrophy without dilatation). B, Eccentric cardiac hypertrophy. The heart is heavier. The free left ventricular wall is thickened (black arrow) while the lumen is dilated (white arrow) (hypertrophy with dilatation).

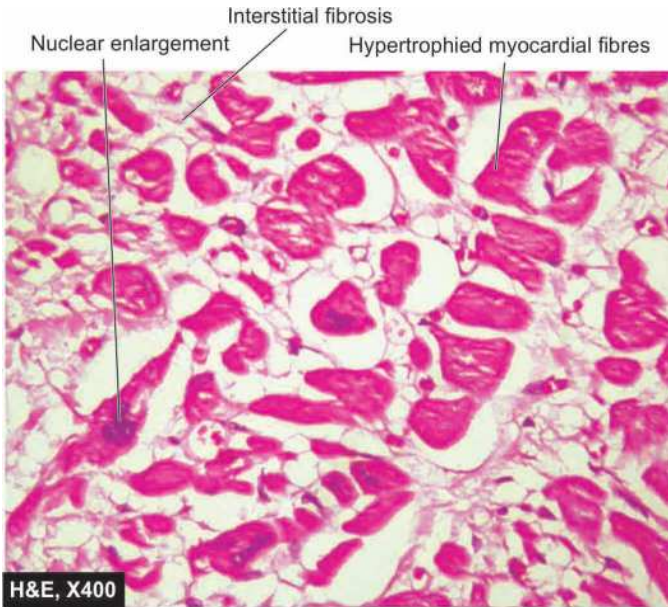

Figure 14.7 Cardiac hypertrophy. Individual myocardial fibres are thick with prominent vesicular nuclei.

taken by the mother and heavy alcohol drinking by the mother, have all been implicated in causing *in utero* foetal injury resulting in congenital malformations of the heart.

CLASSIFICATION Congenital anomalies of the heart may be either *shunts* (left-to-right or right-to-left), or defects causing *obstructions* to flow. However, complex anomalies involving *combinations* of shunts and obstructions are also often present.

A simple classification of important and common examples of these groups is given in **Table 14.1**.

I. MALPOSITIONS OF THE HEART

Dextrocardia is the condition when the apex of the heart points to the right side of the chest. It may be accompanied by *situs inversus* so that all other organs of the body are also transposed

Table 14.1 Classification of congenital heart diseases.

| | | |
|------|---|--------|
| I. | MALPOSITIONS OF THE HEART | |
| II. | SHUNTS (CYANOTIC CONGENITAL HEART DISEASE) | |
| | A. <i>Left-to-right shunts</i> (<i>Acyanotic or late cyanotic group</i>) | |
| | 1. Ventricular septal defect (VSD) | 25-30% |
| | 2. Atrial septal defect (ASD) | 10-15% |
| | 3. Patent ductus arteriosus (PDA) | 10-20% |
| | B. <i>Right-to-left shunts</i> (<i>Cyanotic group</i>) | |
| | 1. Tetralogy of Fallot | 6-15% |
| | 2. Transposition of great arteries | 4-10% |
| | 3. Persistent truncus arteriosus | 2% |
| | 4. Tricuspid atresia and stenosis | 1% |
| III. | OBSTRUCTIONS (OBSTRUCTIVE CONGENITAL HEART DISEASE) | |
| | 1. Coarctation of aorta | 5-7% |
| | 2. Aortic stenosis and atresia | 4-6% |
| | 3. Pulmonary stenosis and atresia | 5-7% |

in similar way and thus heart is in normal position in relation to them. However, isolated *dextrocardia* is associated with major anomalies of the heart such as transposition of the atria in relation to ventricles or transposition of the great arteries.

II. SHUNTS (CYANOTIC CONGENITAL HEART DISEASE)

A shunt may be left-to-right side or right-to-left side of the circulation.

A. LEFT-TO-RIGHT SHUNTS (ACYANOTIC OR LATE CYANOTIC GROUP)

In conditions where there is shunting of blood from left-to-right side of the heart, there is volume overload on the right heart producing pulmonary hypertension and right ventricular hypertrophy. At a later stage, the pressure on the right side is higher than on the left side creating late cyanotic heart disease. The important conditions included in this category are described below:

VENTRICULAR SEPTAL DEFECT (VSD) VSD is the most common congenital anomaly of the heart and comprises about 30% of all congenital heart diseases. The condition is recognised early in life. The smaller defects often close spontaneously, while larger defects remain patent and produce significant effects.

Depending upon the location of the defect, VSD may be of the following types:

1. In 90% of cases, the defect involves *membranous septum* and is very close to the bundle of His (**Fig. 14.8**).
2. The remaining 10% cases have VSD immediately below the pulmonary valve (*subpulmonic*), below the aortic valve (*subaortic*), or exist in the form of multiple defects in the muscular septum.

MORPHOLOGIC FEATURES The *effects* of VSD are produced due to left-to-right shunt at the ventricular level, increased pulmonary flow and increased volume in the left side of the heart. These effects are as under:

- i) Volume hypertrophy of the right ventricle.
- ii) Enlargement and haemodynamic changes in the tricuspid and pulmonary valves.
- iii) Endocardial hypertrophy of the right ventricle.
- iv) Pressure hypertrophy of the right atrium.
- v) Volume hypertrophy of the left atrium and left ventricle.
- vi) Enlargement and haemodynamic changes in the mitral and aortic valves.

ATRIAL SEPTAL DEFECT (ASD) Isolated ASD comprises about 10% of congenital heart diseases. The condition remains unnoticed in infancy and childhood till pulmonary hypertension is induced causing late cyanotic heart disease and right-sided heart failure.

Depending upon the location of the defect, there are 3 types of ASD:

i) Fossa ovalis type or ostium secundum type is the most common form comprising about 90% cases of ASD. The defect is situated in the region of the fossa ovalis (**Fig. 14.9**).

ii) Ostium primum type comprises about 5% cases of ASD. The defect lies low in the interatrial septum adjacent to atrioventricular valves. There may be cleft in the aortic leaflet of the mitral valve producing mitral insufficiency.

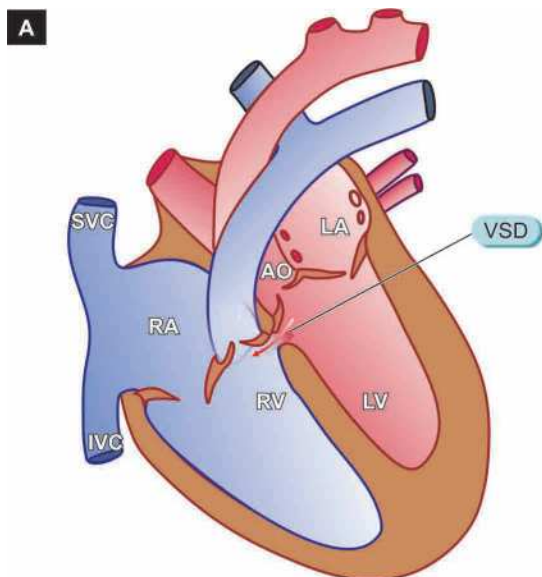

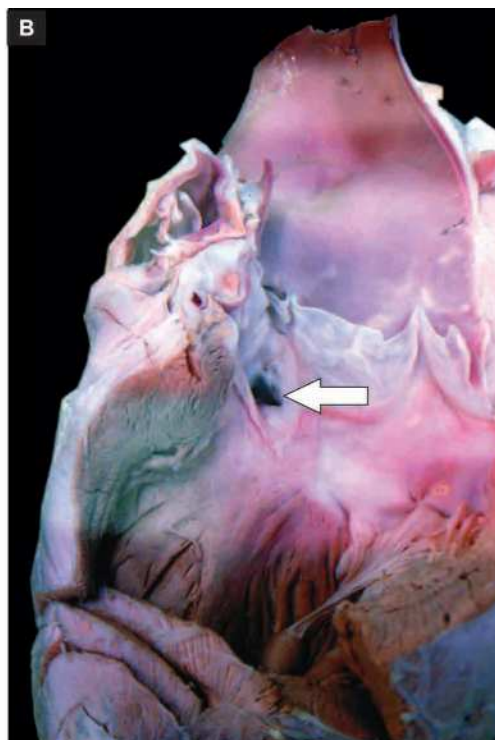

Figure 14.8 Ventricular septal defect. A, Schematic representation (LA = Left atrium; LV = Left ventricle; AO = Aorta; PV = Pulmonary valve; PT = Pulmonary trunk; RA = Right atrium; RV = Right ventricle; SVC = Superior vena cava; IVC = Inferior vena cava). B, The opened up chambers of the heart show a communication in the inter-ventricular septum superiorly (white arrow).

iii) Sinus venosus type accounts for about 5% cases of ASD. The defect is located high in the interatrial septum near the entry of the superior vena cava.

MORPHOLOGIC FEATURES The effects of ASD are produced due to left-to-right shunt at the atrial level with increased pulmonary flow. These effects are as follows:

- i) Volume hypertrophy of the right atrium and right ventricle.
- ii) Enlargement and haemodynamic changes of tricuspid and pulmonary valves.

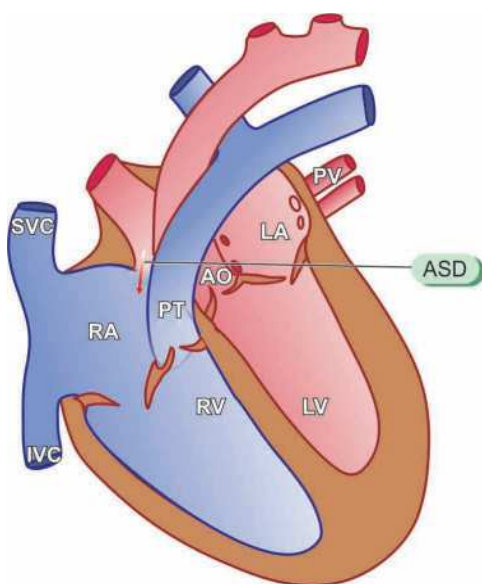

Figure 14.9 Atrial septal defect fossa ovalis type, a schematic representation (LA = Left atrium; LV = Left ventricle; PV = Pulmonary vein; AO = Aorta; PT = Pulmonary trunk; RA = Right atrium; RV = Right ventricle; SVC = Superior vena cava; IVC = Inferior vena cava).

- iii) Focal or diffuse endocardial hypertrophy of the right atrium and right ventricle.
- iv) Volume atrophy of the left atrium and left ventricle.
- v) Small-sized mitral and aortic orifices.

PATENT DUCTUS ARTERIOSUS (PDA) The ductus arteriosus is a normal vascular connection between the aorta and the bifurcation of the pulmonary artery. Normally, the ductus closes functionally within the first or second day of life. Its persistence after 3 months of age is considered abnormal. The cause for patency of ductus arteriosus is not known but possibly it is due to continued synthesis of PGE₂ after birth which keeps it patent as evidenced by association of PDA with respiratory distress syndrome in infants and pharmacologic closure of PDA with administration of indomethacin to suppress PGE₂ synthesis. PDA constitutes about 10% of congenital malformations of the heart and great vessels. In about 90% of cases, it occurs as an isolated defect, while in the remaining cases it may be associated with other anomalies like VSD, coarctation of aorta and pulmonary or aortic stenosis. A patent ductus may be upto 2 cm in length and upto 1 cm in diameter (**Fig. 14.10**).

MORPHOLOGIC FEATURES The effects of PDA on heart occur due to left-to-right shunt at the level of ductus resulting in increased pulmonary flow and increased volume in the left heart. These effects are as follows:

- i) Volume hypertrophy of the left atrium and left ventricle.
- ii) Enlargement and haemodynamic changes of the mitral and pulmonary valves.
- iii) Enlargement of the ascending aorta.

B. RIGHT-TO-LEFT SHUNTS (CYANOTIC GROUP)

In conditions where there is shunting of blood from right side to the left side of the heart, there is entry of poorly-oxygenated

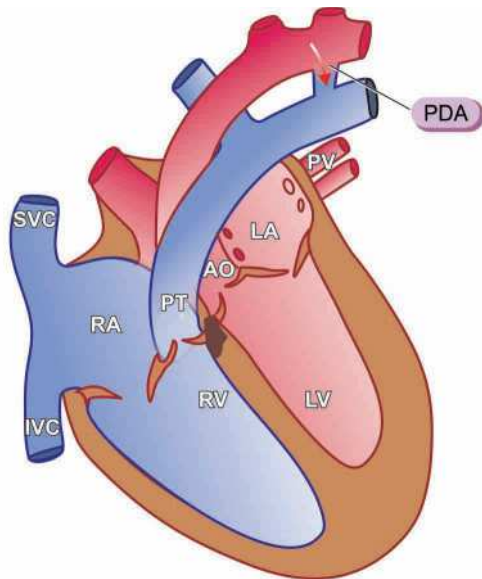

Figure 14.10 Patent ductus arteriosus, a schematic representation (LA = Left atrium; LV = Left ventricle; PT = Pulmonary trunk; PV = Pulmonary vein, AO = Aorta; RA = Right atrium; RV = Right ventricle; SVC = Superior vena cava; IVC = Inferior vena cava).

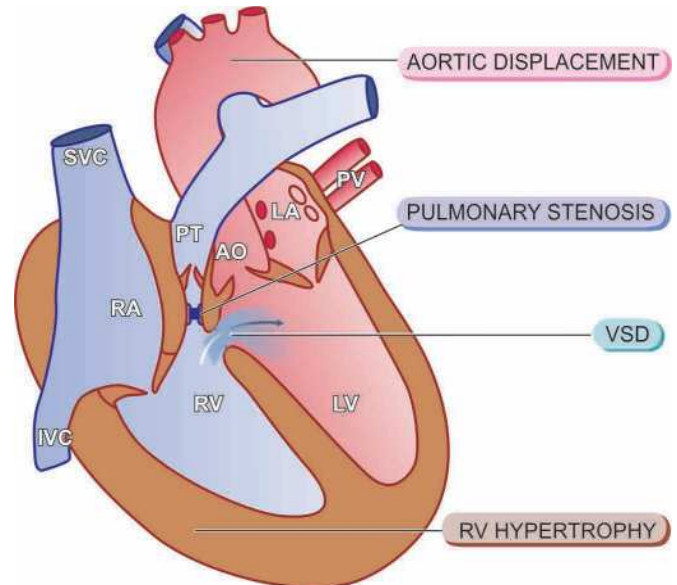

Figure 14.11 Tetralogy of Fallot, a schematic representation (LA = Left atrium; LV = Left ventricle; PT = Pulmonary trunk; PV = Pulmonary vein; AO = Aorta; RA = Right atrium; RV = Right ventricle; SVC = Superior vena cava; IVC = Inferior vena cava).

blood into systemic circulation resulting in early cyanosis. The examples described below are not pure shunts but are combinations of shunts with obstructions but are described here since there is functional shunting of blood from one to the other side of circulation.

TETRALOGY OF FALLOT Tetralogy of Fallot is the most common cyanotic congenital heart disease, found in about 10% of children with anomalies of the heart.

MORPHOLOGIC FEATURES The four features of tetralogy are as under (**Fig. 14.11**):

- i) Ventricular septal defect (VSD) ('shunt').
- ii) Displacement of the aorta to right so that it overrides the VSD.
- iii) Pulmonary stenosis ('obstruction').
- iv) Right ventricular hypertrophy.

The severity of the clinical manifestations is related to two factors: extent of pulmonary stenosis and the size of VSD. Accordingly, there are two forms of tetralogy: cyanotic and acyanotic:

a) Cyanotic tetralogy Pulmonary stenosis is greater and the VSD is mild so that there is more resistance to the outflow of blood from right ventricle resulting in right-to-left shunt at the ventricular level and cyanosis. The effects on the heart are as follows:

- i) Pressure hypertrophy of the right atrium and right ventricle.
- ii) Smaller and abnormal tricuspid valve.
- iii) Smaller left atrium and left ventricle.
- iv) Enlarged aortic orifice.

b) Acyanotic tetralogy The VSD is larger and pulmonary stenosis is mild so that there is mainly left-to-right shunt with increased pulmonary flow and increased volume in the left heart but no cyanosis. The effects on the heart are as under:

- i) Pressure hypertrophy of the right ventricle and right atrium.
- ii) Volume hypertrophy of the left atrium and left ventricle.
- iii) Enlargement of mitral and aortic orifices.

TRANSPOSITION OF GREAT ARTERIES The term transposition is used for complex malformations as regards position of the aorta, pulmonary trunk, atrioventricular orifices and the position of atria in relation to ventricles.

MORPHOLOGIC FEATURES There are several forms of transpositions. The common ones are described below:

i) Regular transposition is the most common type. In this, the aorta which is normally situated to the right and posterior with respect to the pulmonary trunk, is instead displaced anteriorly and to right. In regular complete transposition, the aorta emerges from the right ventricle and the pulmonary trunk from the left ventricle so that there is cyanosis from birth.

ii) Corrected transposition is an uncommon anomaly. There is complete transposition of the great arteries with aorta arising from the right ventricle and the pulmonary trunk from the left ventricle, as well as transposition of the great veins so that the pulmonary veins enter the right atrium and the systemic veins drain into the left atrium. This results in a physiologically corrected circulation.

PERSISTENT TRUNCUS ARTERIOSUS Persistent truncus arteriosus (PTA) is a rare anomaly.

MORPHOLOGIC FEATURES In PTA, the arch that normally separates the aorta from the pulmonary artery fails to develop. This results in a single large common vessel receiving blood from the right as well as left ventricle. The orifice may have 3 to 6 cusps. There is often an associated VSD. There is left-to-right shunt and frequently early systemic cyanosis. The prognosis is generally poor.

TRICUSPID ATRESIA AND STENOSIS Tricuspid atresia and stenosis are rare anomalies. There is often associated pulmonary stenosis or pulmonary atresia.

MORPHOLOGIC FEATURES In tricuspid atresia, there is absence of tricuspid orifice and instead there is a dimple in the floor of the right atrium. In tricuspid stenosis, the tricuspid ring is small and the valve cusps are malformed. In both the conditions, there is often an interatrial defect through which right-to-left shunt of blood takes place. Children are cyanotic since birth and live for a few weeks or months.

III. OBSTRUCTIONS (OBSTRUCTIVE CONGENITAL HEART DISEASE)

Congenital obstruction to blood flow may result from obstruction in the aorta due to narrowing (*coarctation of aorta*), obstruction to outflow from the left ventricle (*aortic stenosis and atresia*), and obstruction to outflow from the right ventricle (*pulmonary stenosis and atresia*).

COARCTATION OF AORTA The word 'coarctation' means contracted or compressed. Coarctation of aorta is localised narrowing in any part of aorta, but the constriction is more often just distal to ductus arteriosus (*postductal or adult*), or occasionally proximal to the ductus arteriosus (*preductal or infantile type*) in the region of transverse aorta:

MORPHOLOGIC FEATURES The two common forms of coarctation of the aorta are as under:

i) Postductal or adult type The obstruction is just distal to the point of entry of ductus arteriosus which is often closed (**Fig. 14.12**). In the stenotic segment, the aorta is drawn in as if a suture has been tied around it. The aorta is dilated on either side of the constriction. The condition is recognised in adulthood, characterised by hypertension in the upper extremities, weak pulses and low blood pressure in the lower extremities and effects of arterial insufficiency such as claudication and coldness. In time, there is development of collateral circulation between pre-stenotic and post-

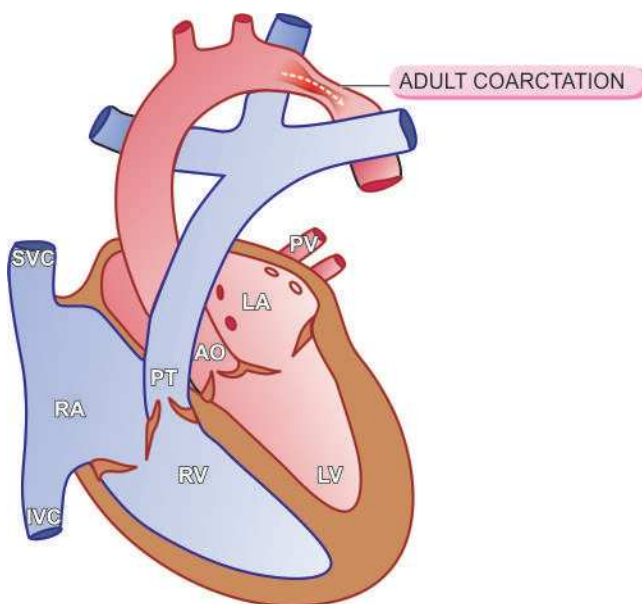

Figure 14.12 Postductal or adult type coarctation of the aorta, a schematic representation (LA = Left atrium; LV = Left ventricle; PT = Pulmonary trunk; PV = Pulmonary vein; AO = Aorta; RA = Right atrium; RV = Right ventricle; SVC = Superior vena cava; IVC = Inferior vena cava).

stenotic arterial branches so that intercostal arteries are enlarged and palpable and may produce erosions on the inner surface of the ribs.

ii) Preductal or infantile type The manifestations are produced early in life. The narrowing is proximal to the ductus arteriosus which usually remains patent. The narrowing is generally gradual and involves larger segment of the proximal aorta. There is often associated interatrial septal defect. Preductal coarctation results in right ventricular hypertrophy while the left ventricle is small. Cyanosis develops in the lower half of the body while the upper half remains unaffected since it is supplied by vessels originating proximal to the coarctation. Children with this defect have poor prognosis.

AORTIC STENOSIS AND ATRESIA The most common congenital anomaly of the aorta is bicuspid aortic valve which does not have much functional significance but predisposes it to calcification (page 430). Congenital aortic atresia is rare and incompatible with survival. Aortic stenosis may be acquired (e.g. in rheumatic heart disease, calcific aortic stenosis) or congenital.

MORPHOLOGIC FEATURES Congenital aortic stenosis may be of three types: valvular, subvalvular and supra-valvular.

i) Valvular stenosis The aortic valve cusps are malformed and are irregularly thickened. The aortic valve may have one, two or three such maldeveloped cusps.

ii) Subvalvular stenosis There is thick fibrous ring under the aortic valve causing subaortic stenosis.

iii) Supra-valvular stenosis The most uncommon type, there is fibrous constriction above the sinuses of Valsalva.

In all these cases, there is pressure hypertrophy of the left ventricle and left atrium, and dilatation of the aortic root.

PULMONARY STENOSIS AND ATRESIA Isolated pulmonary stenosis and atresia do not cause cyanosis and hence are included under acyanotic heart diseases.

MORPHOLOGIC FEATURES The changes in these conditions are as under:

Pulmonary stenosis It is the commonest form of obstructive congenital heart disease comprising about 7% of all congenital heart diseases. It may occur as a component of tetralogy of Fallot or as an isolated defect. Pulmonary stenosis is caused by fusion of cusps of the pulmonary valve forming a diaphragm-like obstruction to the outflow of blood from the right ventricle and dilatation of the pulmonary trunk.

Pulmonary atresia There is no communication between the right ventricle and lungs so that the blood bypasses the right ventricle through an interatrial septal defect. It then enters the lungs via patent ductus arteriosus.

GIST BOX 14.3

Congenital Heart Disease

☐ Congenital anomalies of the heart may be either *shunts* (left-to-right or right-to-left), or defects causing *obstructions* to flow.

- ☐ Left-to-right shunts are acyanotic group of heart diseases; e.g. ventricular and atrial septal defects, and patent ductus arteriosus.
- ☐ Right-to-left shunts are a cyanotic group of heart disease. Examples are tetralogy of Fallot, transposition of great arteries, persistent truncus arteriosus and tricuspid atresia and stenosis.
- ☐ Obstructive congenital heart diseases are coarctation of aorta, and stenosis and atresia of aorta or pulmonary artery.

ISCHAEMIC HEART DISEASE

Ischaemic heart disease (IHD) is defined as acute or chronic form of cardiac disability arising from imbalance between the myocardial supply and demand for oxygenated blood. Since narrowing or obstruction of the coronary arterial system is the most common cause of myocardial anoxia, the alternate term '*coronary artery disease (CAD)*' is used synonymously with IHD. IHD or CAD is the leading cause of death in most developed countries (about one-third of all deaths) and somewhat low incidence is observed in the developing countries. Men develop IHD earlier than women and death rates are also slightly higher for men than for women until the menopause. As per rising trends of IHD worldwide, it is estimated that by the year 2020 it would become the most common cause of death throughout world.

ETIOPATHOGENESIS

IHD is invariably caused by disease affecting the coronary arteries, the most prevalent being atherosclerosis accounting for more than 90% cases, while other causes are responsible for less than 10% cases of IHD. Therefore, it is convenient to consider the etiology of IHD under three broad headings:

- i) coronary atherosclerosis;
- ii) superadded changes in coronary atherosclerosis; and
- iii) non-atherosclerotic causes.

I. CORONARY ATHEROSCLEROSIS

Coronary atherosclerosis resulting in 'fixed' obstruction is the major cause of IHD in more than 90% cases. The general aspects of atherosclerosis as regards its etiology, pathogenesis and the morphologic features of atherosclerotic lesions have already been dealt with at length in the preceding (page 373). Here, a brief account of the specific features in pathology of lesions in *atherosclerotic coronary artery disease* in particular is presented.

1. Distribution Atherosclerotic lesions in coronary arteries are distributed in one or more of the three major coronary arterial trunks, the highest incidence being in the anterior descending branch of the left coronary (LAD), followed in decreasing frequency, by the right coronary artery (RCA) and still less in circumflex branch of the left coronary (CXA). About one-third of cases have *single-vessel disease*, most often left anterior descending arterial involvement; another one-third have *two-vessel disease*, and the remainder has *three major vessel disease*.

2. Location Almost all adults show atherosclerotic plaques scattered throughout the coronary arterial system.

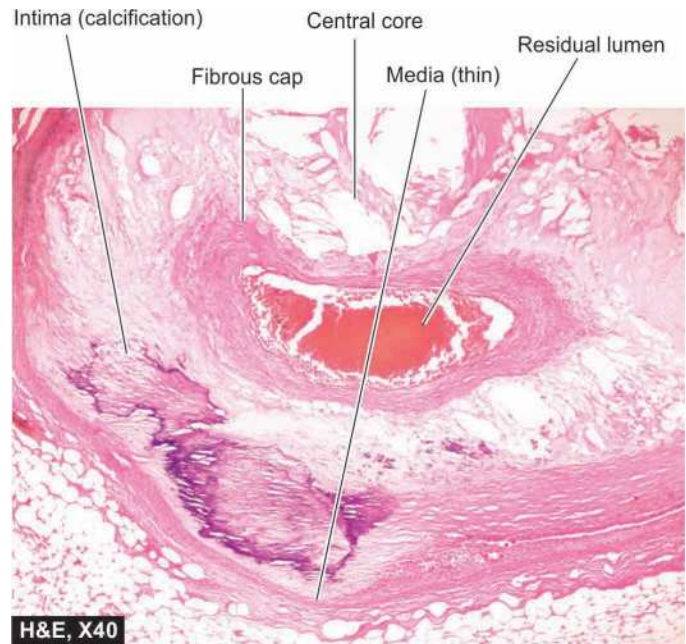

Figure 14.13 Left anterior descending (LAD) coronary artery showing critical narrowing with eccentric luminal obliteration due to complicated atheromatous plaque.

However, significant stenotic lesions that may produce chronic myocardial ischaemia show more than 75% (three-fourth) reduction in the cross-sectional area of a coronary artery or its branch. The area of severest involvement is about 3 to 4 cm from the coronary ostia, more often at or near the bifurcation of the arteries, suggesting the role of haemodynamic forces in atherogenesis.

3. Fixed atherosclerotic plaques The atherosclerotic plaques in the coronaries are more often eccentrically located bulging into the lumen from one side (**Fig. 14.13**). Occasionally, there may be concentric thickening of the wall of the artery. Atherosclerosis produces gradual luminal narrowing that may eventually lead to 'fixed' coronary obstruction. The general features of atheromas of coronary arteries are similar to those affecting elsewhere in the body and may develop similar complications like calcification, coronary thrombosis, ulceration, haemorrhage, rupture and aneurysm formation.

II. SUPERADDED CHANGES IN CORONARY ATHEROSCLEROSIS

The attacks of *acute coronary syndromes*, which include acute myocardial infarction, unstable angina and sudden ischaemic death, are precipitated by certain changes superimposed on a pre-existing fixed coronary atheromatous plaque. These changes are as under:

1. Acute changes in chronic atheromatous plaque Though chronic fixed obstructions are the most frequent cause of IHD, acute coronary episodes are often precipitated by sudden changes in chronic plaques such as plaque haemorrhage, fissuring, or ulceration that results in thrombosis and embolisation of atheromatous debris. Acute plaque changes are brought about by factors such as sudden coronary artery spasm, tachycardia, intraplaque haemorrhage and hypercholesterolaemia.

2. Coronary artery thrombosis Transmural acute myocardial infarction is often precipitated by partial or complete coronary thrombosis. The initiation of thrombus occurs due to surface ulceration of fixed chronic atheromatous plaque, ultimately causing complete luminal occlusion. The lipid core of plaque, in particular, is highly thrombogenic. Small fragments of thrombotic material are then dislodged which are embolised to terminal coronary branches and cause microinfarcts of the myocardium.

3. Local platelet aggregation and coronary artery spasm Some cases of acute coronary episodes are caused by local aggregates of platelets on the atheromatous plaque, short of forming a thrombus. The aggregated platelets release vasospastic mediators such as thromboxane A₂ which may probably be responsible for coronary vasospasm in the already atherosclerotic vessel.

Based on progressive pathological changes and clinical correlation, American Heart Association (1995) has classified human coronary atherosclerosis into 6 sequential types in ascending order of grades of lesions as shown in **Table 14.2**.

III. NON-ATHEROSCLEROTIC CAUSES

Several other coronary lesions may cause IHD in less than 10% of cases. These are as under:

1. Vasospasm It has been possible to document vasospasm of one of the major coronary arterial trunks in patients with no significant atherosclerotic coronary narrowing which may cause angina or myocardial infarction.

2. Stenosis of coronary ostia Coronary ostial narrowing may result from extension of syphilitic aortitis or from aortic atherosclerotic plaques encroaching on the opening.

3. Arteritis Various types of inflammatory involvements of coronary arteries or small branches like in rheumatic arteritis, polyarteritis nodosa, thrombo-angiitis obliterans (Buerger's disease), Takayasu's disease, Kawasaki's disease, tuberculosis and other bacterial infections may contribute to myocardial damage.

4. Embolism Rarely, emboli originating from elsewhere in the body may occlude the left coronary artery and its branches and produce IHD. The emboli may originate from bland thrombi, or from vegetations of bacterial endocarditis; rarely

fat embolism and air embolism of coronary circulation may occur.

5. Thrombotic diseases Another infrequent cause of coronary occlusion is from hypercoagulability of the blood such as in shock, polycythaemia vera, sickle cell anaemia and thrombotic thrombocytopenic purpura.

6. Trauma Contusion of a coronary artery from penetrating injuries may produce thrombotic occlusion.

7. Aneurysms Extension of dissecting aneurysm of the aorta into the coronary artery may produce thrombotic coronary occlusion. Rarely, congenital, mycotic and syphilitic aneurysms may occur in coronary arteries and produce similar occlusive effects.

8. Compression Compression of a coronary from outside by a primary or secondary tumour of the heart may result in coronary occlusion.

EFFECTS OF MYOCARDIAL ISCHAEMIA

Development of lesions in the coronaries is not always accompanied by cardiac disease. Depending upon the suddenness of onset, duration, degree, location and extent of the area affected by myocardial ischaemia, the range of changes and clinical features may range from an asymptomatic state at one extreme to immediate mortality at another (**Fig. 14.14**):

- A. Asymptomatic state
- B. Angina pectoris (AP)
- C. Acute myocardial infarction (MI)
- D. Chronic ischaemic heart disease (CIHD)/Ischaemic cardiomyopathy/ Myocardial fibrosis
- E. Sudden cardiac death

The term *acute coronary syndromes* include a triad of acute myocardial infarction, unstable angina and sudden cardiac death.

ANGINA PECTORIS

Angina pectoris is a clinical syndrome of IHD resulting from transient myocardial ischaemia. It is characterised by paroxysmal pain in the substernal or precordial region of the chest which is aggravated by an increase in the demand of the heart and relieved by a decrease in the work of the heart. Often,

Table 14.2 Classification of human atherosclerosis proposed by American Heart Association.

| TYPES | MAIN HISTOLOGY | MAIN PATHOGENESIS | AGE AT ONSET | CLINICAL EFFECTS |
|-----------------------------------|---|---|--------------|-----------------------------------|
| Type I: Initial lesions | Macrophages, occasional foam cell | Accumulation of lipoprotein | 1st decade | Asymptomatic |
| Type II: Fatty streaks | Many layers of macrophages and foam cells | Accumulation of lipoprotein | 1st decade | Asymptomatic |
| Type III: Intermediate lesions | Many lipid-laden cells and scattered extracellular lipid droplets | Accumulation of lipoprotein | 3rd decade | Asymptomatic |
| Type IV: Atheromatous lesions | Intra- as well as extracellular lipid pool | Accumulation of lipid | 3rd decade | Asymptomatic or manifest symptoms |
| Type V: Fibrofatty lesions | Fibrotic cap and lipid core (V a), may have calcification (V b) | Smooth muscle cell proliferation and increased collagen | 4th decade | Asymptomatic or manifest symptoms |
| Type VI: Complicated lesions | Ulceration, haemorrhage, haematoma, thrombosis | Haemodynamic stress, thrombosis, haematoma | 4th decade | Asymptomatic or manifest symptoms |

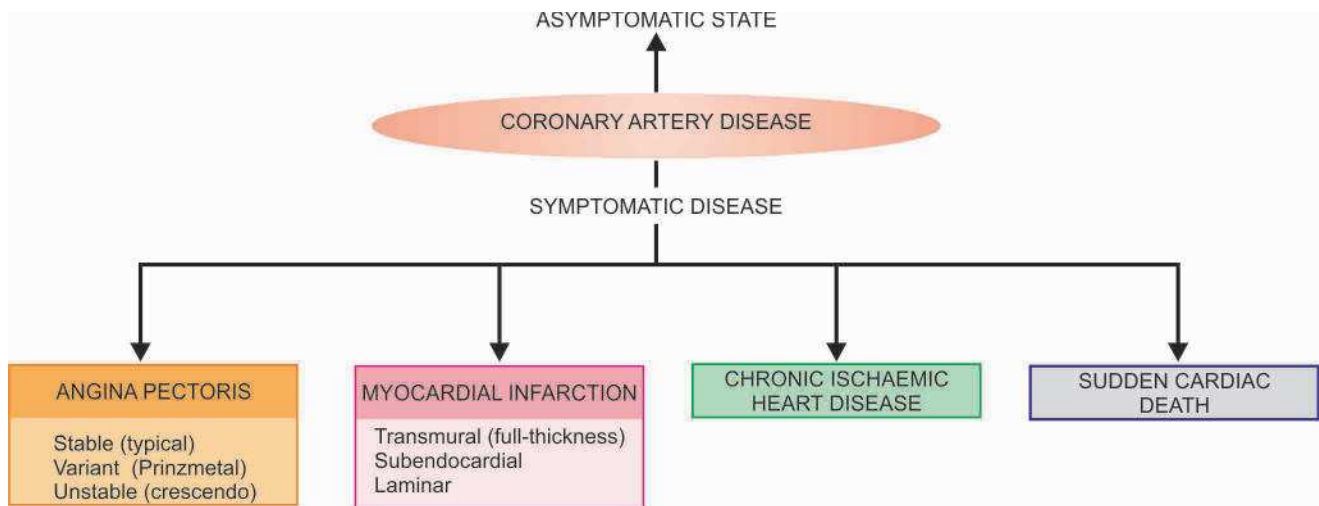

Figure 14.14 Spectrum of coronary ischaemic manifestations.

the pain radiates to the left arm, neck, jaw or right arm. It is more common in men past 5th decade of life.

There are 3 overlapping clinical patterns of angina pectoris with some differences in their pathogenesis:

- i) Stable or typical angina
- ii) Prinzmetal's variant angina
- iii) Unstable or crescendo angina

STABLE OR TYPICAL ANGINA This is the most common pattern. Stable or typical angina is characterised by attacks of pain following physical exertion or emotional excitement and is relieved by rest. The pathogenesis of condition lies in *chronic stenosing coronary atherosclerosis* that cannot perfuse the myocardium adequately when the workload on the heart increases. During the attacks, there is depression of ST segment in the ECG due to poor perfusion of the subendocardial region of the left ventricle but there is no elevation of enzymes in the blood as there is no irreversible myocardial injury.

PRINZMETAL'S VARIANT ANGINA This pattern of angina is characterised by pain at rest and has no relationship with physical activity. The exact pathogenesis of Prinzmetal's angina is not known. It may occur due to *sudden vasospasm* of a coronary trunk induced by coronary atherosclerosis, or may be due to release of humoral vasoconstrictors by mast cells in the coronary adventitia. ECG shows ST segment elevation due to transmural ischaemia. These patients respond well to vasodilators like nitroglycerin.

UNSTABLE OR CRESCENDO ANGINA Also referred to as 'pre-infarction angina' or 'acute coronary insufficiency', this is the most serious pattern of angina. It is characterised by more frequent onset of pain of prolonged duration and occurring often at rest. It is thus indicative of an impending acute myocardial infarction. Distinction between unstable angina and acute MI is made by ST segment changes on ECG—acute MI characterised by ST segment elevation while unstable angina may have non-ST segment elevation MI. *Multiple factors* are involved in the pathogenesis of unstable angina which include: stenosing coronary atherosclerosis, complicated coronary plaques (e.g. superimposed thrombosis, haemorrhage, rupture, ulceration etc), platelet thrombi over atherosclerotic plaques and vasospasm of coronary arteries. More often, the lesions lie in a branch of the major coronary trunk so that collaterals prevent infarction.

ACUTE MYOCARDIAL INFARCTION

Acute myocardial infarction (MI) is the most important and feared consequence of coronary artery disease. Many patients may die within the first few hours of the onset, while remainder suffer from effects of impaired cardiac function. A significant factor that may prevent or diminish the myocardial damage is the development of collateral circulation through anastomotic channels over a period of time. A regular and well-planned exercise programme encourages good collateral circulation and improved cardiac performance.

INCIDENCE In developed countries, acute MI accounts for 10-25% of all deaths. Due to the dominant etiologic role of coronary atherosclerosis in acute MI, the incidence of acute MI correlates well with the incidence of atherosclerosis in a geographic area.

Age Acute MI may virtually occur at all ages, though the incidence is higher in the elderly. About 5% of heart attacks occur in young people under the age of 40 years, particularly in those with major risk factors to develop atherosclerosis like hypertension, diabetes mellitus, cigarette smoking and dyslipidaemia including familial hypercholesterolaemia.

Sex Males throughout their life are at a significantly higher risk of developing acute MI as compared to females. Women during reproductive period have remarkably low incidence of acute MI, probably due to the protective influence of oestrogen. The use of oral contraceptives is associated with high risk of developing acute MI. After menopause, this gender difference gradually declines but the incidence of disease among women never reaches that among men of the same age.

ETIOPATHOGENESIS The etiologic role of severe coronary atherosclerosis (more than 75% compromise of lumen) of one or more of the three major coronary arterial trunks in the pathogenesis of about 90% cases of acute MI is well documented by autopsy studies as well as by coronary angiographic studies. A few notable features in the development of acute MI are as under:

1. Myocardial ischaemia Myocardial ischaemia is brought about by one or more of the following mechanisms:

- i) Diminished coronary blood flow e.g. in coronary artery disease, shock.
- ii) Increased myocardial demand e.g. in exercise, emotions.

iii) Hypertrophy of the heart without simultaneous increase of coronary blood flow e.g. in hypertension, valvular heart disease.

2. Role of platelets Rupture of an atherosclerotic plaque exposes the subendothelial collagen to platelets which undergo aggregation, activation and release reaction. These events contribute to the build-up of the platelet mass that may give rise to emboli or initiate thrombosis.

3. Acute plaque rupture In general, slowly-developing coronary ischaemia from stenosing coronary atherosclerosis of high-grade may not cause acute MI but continue to produce episodes of angina pectoris. But acute complications in coronary atherosclerotic plaques in the form of superimposed coronary thrombosis due to plaque rupture and plaque haemorrhage is frequently encountered in cases of acute MI:

i) *Superimposed coronary thrombosis* due to disruption of plaque is seen in about half the cases of acute MI. Infusion of intracoronary fibrinolytics in the first half an hour of development of acute MI in such cases restores blood flow in the blocked vessel in majority of cases.

ii) *Intramural haemorrhage* is found in about one-third cases of acute MI.

Plaque haemorrhage and thrombosis may occur together in some cases.

4. Non-atherosclerotic causes About 10% cases of acute MI are caused by non-atherosclerotic factors such as coronary vasospasm, arteritis, coronary ostial stenosis, embolism, thrombotic diseases, trauma and outside compression as already described.

5. Transmural versus subendocardial infarcts There are some differences in the pathogenesis of the *transmural infarcts* involving the full thickness of ventricular wall and the *subendocardial (laminar) infarcts* affecting the inner subendocardial one-third to half. These are as under (Table 14.3):

i) *Transmural (full thickness) infarcts* are the most common type seen in 95% cases. Critical coronary narrowing (more than 75% compromised lumen) is of great significance in the causation of such infarcts. Atherosclerotic plaques with superimposed thrombosis and intramural haemorrhage are significant in about 90% cases, and non-atherosclerotic causes in the remaining 10% cases.

ii) *Subendocardial (laminar) infarcts* have their genesis in reduced coronary perfusion due to coronary atherosclerosis but without critical stenosis (not necessarily 75% compromised lumen), aortic stenosis or haemorrhagic shock. This is because subendocardial myocardium is normally least well perfused by coronaries and thus is more vulnerable to any reduction

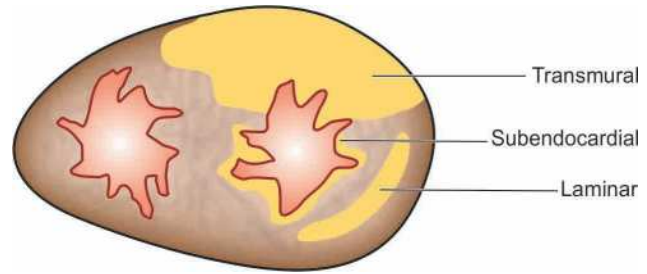

Figure 14.15 Diagrammatic representation of extent of myocardial infarction in the depth of myocardium.

in the coronary flow. Superimposed coronary thrombosis is frequently encountered in these cases too, and hence the beneficial role of fibrinolytic treatment in such patients.

TYPES OF INFARCTS Infarcts have been classified in a number of ways by the physicians and the pathologists:

1. *According to the anatomic region of the left ventricle involved*, they are called anterior, posterior (inferior), lateral, septal and circumferential, and their combinations like anterolateral, posterolateral (or inferolateral) and anteroseptal.

2. *According to the degree of thickness of the ventricular wall involved*, infarcts are of two types (Fig. 14.15):

i) Full-thickness or transmural, when they involve the entire thickness of the ventricular wall.

ii) Subendocardial or laminar, when they occupy the inner subendocardial half of the myocardium.

3. *According to the age of infarcts*, they are of two types:

i) Newly-formed infarcts called as acute, recent or fresh.

ii) Advanced infarcts called as old, healed or organised.

LOCATION OF INFARCTS Infarcts are most frequently located in the left ventricle. Right ventricle is less susceptible to infarction due to its thin wall, having less metabolic requirements and is thus adequately nourished by the thebesian vessels. Atrial infarcts, whenever present, are more often in the right atrium, usually accompanying the infarct of the left ventricle. Left atrium is relatively protected from infarction because it is supplied by the oxygenated blood in the left atrial chamber.

The region of infarction depends upon the area of obstructed blood supply by one or more of the three coronary arterial trunks. Accordingly, there are three regions of myocardial infarction (Fig. 14.16):

1. *Stenosis of the left anterior descending coronary artery* is the most common (40-50%). The region of infarction is the anterior part of the left ventricle including the apex and the anterior two-thirds of the interventricular septum.

Table 14.3 Contrasting features of subendocardial and transmural infarcts.

| FEATURE | TRANSMURAL INFARCT | SUBENDOCARDIAL INFARCT |
|------------------------|----------------------------------|-----------------------------|
| 1. Definition | Full-thickness, solid | Inner third to half, patchy |
| 2. Frequency | Most frequent (95%) | Less frequent |
| 3. Distribution | Specific area of coronary supply | Circumferential |
| 4. Pathogenesis | > 75% coronary stenosis | Hypoperfusion of myocardium |
| 5. Coronary thrombosis | Common | Rare |
| 6. Epicarditis | Common | None |

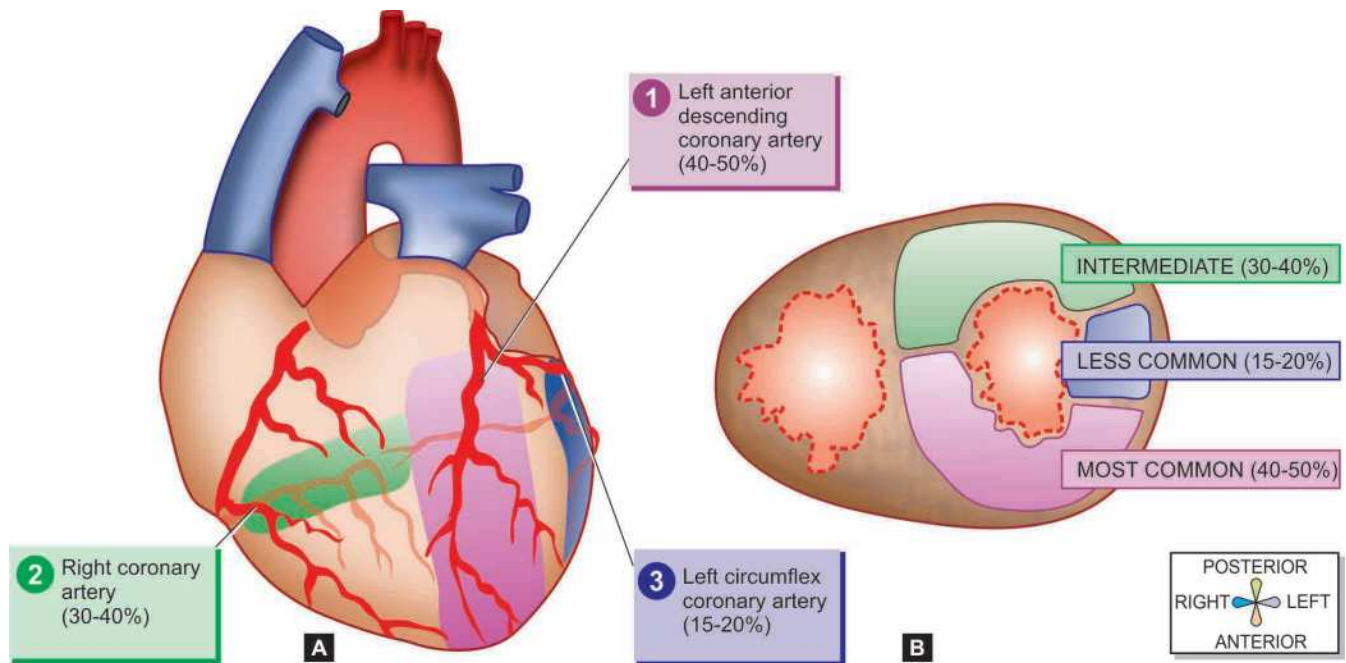

Figure 14.16 Common locations and the regions of involvement in myocardial infarction. The figure shows region of myocardium affected by stenosis of three respective coronary trunks in descending order shown as: 1) left anterior descending coronary, 2) right coronary and 3) left circumflex coronary artery. A, As viewed from anterior surface. B, As viewed on transverse section at the apex of the heart.

2. *Stenosis of the right coronary artery* is the next most frequent (30-40%). It involves the posterior part of the left ventricle and the posterior one-third of the interventricular septum.
3. *Stenosis of the left circumflex coronary artery* is seen least frequently (15-20%). Its area of involvement is the lateral wall of the left ventricle.

MORPHOLOGIC FEATURES The gross and microscopic changes in the myocardial infarction vary according to the age of the infarct and are therefore described sequentially ([Table 14.4](#)).

Grossly, most infarcts occur singly and vary in size from 4 to 10 cm. As explained above, they are found most often in

Table 14.4 Sequential pathologic changes in myocardial infarction.

| TIME | GROSS CHANGES | LIGHT MICROSCOPY |
|-----------------------------|---|--|
| FIRST WEEK | | |
| 0-6 hours | No change or pale; TTC/ NBT test negative in infarcted area | No change; (?) stretching and waviness of fibres |
| 6-12 hours | -do- | Coagulative necrosis begins; neutrophilic infiltration begins; oedema and haemorrhages present |
| 24 hours | Cyanotic red-purple area of haemorrhage | Coagulative necrosis progresses; marginal neutrophilic infiltrate |
| 48-72 hours | Pale, hyperaemic | Coagulative necrosis complete, neutrophilic infiltrate well developed |
| 3rd -7th day | Hyperaemic border, centre yellow and soft | Neutrophils are necrosed and gradually disappear, beginning of resorption of necrosed fibres by macrophages, onset of fibrovascular response |
| SECOND WEEK | | |
| 10th day | Red-purple periphery | Most of the necrosed muscle in a small infarct removed; fibrovascular reaction more prominent; pigmented macrophages, eosinophils, lymphocytes, plasma cells present |
| 14th day | — | Necrosed muscle mostly removed; neutrophils disappear; fibrocollagenic tissue at the periphery |
| THIRD WEEK | | |
| — | — | Necrosed muscle fibres from larger infarcts removed; more ingrowth of fibrocollagenic tissue |
| FOURTH TO SIXTH WEEK | | |
| — | Thin, grey-white, hard, shrunken fibrous scar | Increased fibrocollagenic tissue, decreased vascularity; fewer pigmented macrophages, lymphocytes and plasma cells |

the left ventricle. Less often, there are multifocal lesions. The transmural infarcts, which by definition involve the entire thickness of the ventricular wall, usually have a thin rim of preserved subendocardial myocardium which is perfused directly by the blood in the ventricular chamber. The subendocardial infarcts which affect the inner subendocardial half of the myocardium produce less well-defined gross changes than the transmural infarcts. The sequence of macroscopic changes in all myocardial infarcts is as under:

1. *In 6 to 12 hours old infarcts*, no striking gross changes are discernible except that the affected myocardium is slightly paler and drier than normal. However, the early infarcts (3 to 6 hours old) can be detected by histochemical staining for *dehydrogenases* on unfixed slice of the heart. This consists of immersing a slice of unfixed heart in the solution of triphenyltetrazolium chloride (TTC) which imparts red brown colour to the normal heart muscle, while the area of infarcted muscle fails to stain due to lack of dehydrogenases. Another stain for viability of cardiac muscle is nitroblue tetrazolium (NBT) dye which imparts blue colour to unaffected cardiac muscle while infarcted myocardium remains unstained.
2. *By about 24 hours*, the infarct develops cyanotic, red-purple, blotchy areas of haemorrhage due to stagnation of blood.
3. *During the next 48 to 72 hours*, the infarct develops a yellow border due to neutrophilic infiltration and thus becomes more well-defined.
4. *In 3-7 days*, the infarct has hyperaemic border while the centre is yellow and soft.
5. *By 10 days*, the periphery of the infarct appears reddish-purple due to growth of granulation tissue. With the passage of time, further healing takes place; the necrotic muscle is resorbed and the infarct shrinks and becomes pale grey.
6. *By the end of 6 weeks*, the infarcted area is replaced by a thin, grey-white, hard, shrunken fibrous scar which is well developed in about 2 to 3 months. However, the time taken by an infarct to heal by fibrous scar may vary depending upon the size of the infarct and adequacy of collateral circulation (Fig. 14.17).

Microscopically, the changes are similar in both transmural and subendocardial infarcts. As elsewhere in the

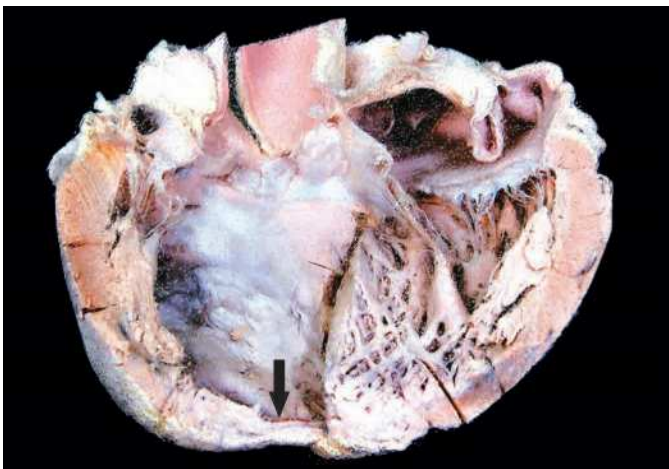

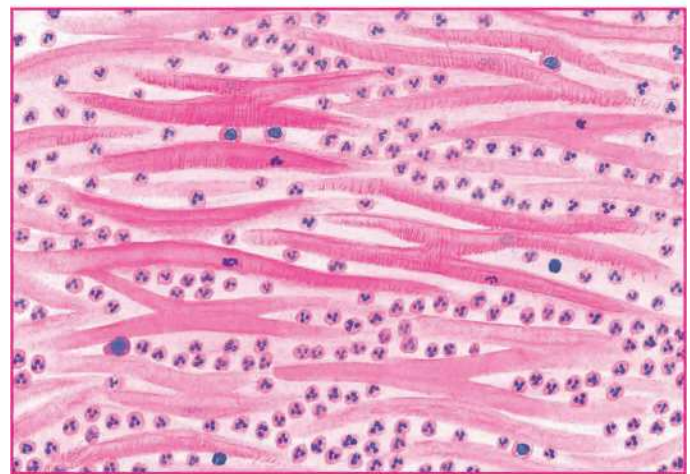

Figure 14.17 Myocardial infarction, healed. Opened up left heart shows grey white thinning of myocardium at the apex (arrow) due to healed fibrous scarring.

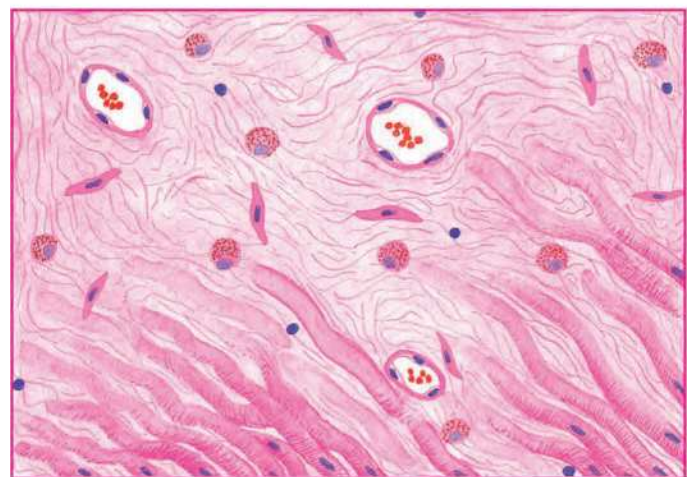

body, myocardial ischaemia induces ischaemic coagulative necrosis of the myocardium which eventually heals by fibrosis. However, sequential light microscopic changes are observed as described here and diagrammatically shown in Fig. 14.18.

A, CHANGES DURING THE FIRST 24 HOURS

B, CHANGES DURING THE FIRST 48-72 HOURS

C, CHANGES BY THE END OF FIRST WEEK

Figure 14.18 Sequence of light microscopic changes in myocardial infarction (For details, consult the text).

1. First week The progression of changes takes place in the following way:

- i) In the *first 6 hours* after infarction, usually no detectable histologic change is observed in routine light microscopy. However, some investigators have described stretching and waviness of the myocardial fibres within one hour of the onset of ischaemia.
- ii) *After 6 hours*, there is appearance of some oedema fluid between the myocardial fibres. The muscle fibres at the margin of the infarct show vacuolar degeneration called myocytolysis.
- iii) By *12 hours*, coagulative necrosis of the myocardial fibres sets in and neutrophils begin to appear at the margin of the infarct. Coagulative necrosis of fibres is characterised by loss of striations and intense eosinophilic, hyaline appearance and may show nuclear changes like karyolysis, pyknosis and karyorrhexis. Haemorrhages and oedema are present in the interstitium.
- iv) During *first 24 hours*, coagulative necrosis progresses further as evidenced by shrunken eosinophilic cytoplasm and pyknosis of the nuclei. The neutrophilic infiltrate at the margins of the infarct is slight.
- v) During *first 48 to 72 hours*, coagulative necrosis is complete with loss of nuclei. The neutrophilic infiltrate is well developed and extends centrally into the interstitium.
- vi) *In 3-7 days*, neutrophils are necrosed and gradually disappear. The process of resorption of necrosed muscle fibres by macrophages begins. Simultaneously, there is onset of proliferation of capillaries and fibroblasts from the margins of the infarct (**Fig. 14.19**).

2. Second week The changes are as under:

- i) By *10th day*, most of the necrosed muscle at the periphery of infarct is removed. The fibrovascular reaction at the margin of infarct is more prominent. Many pigmented macrophages containing yellow-brown lipofuscin (derived from breakdown of myocardial cells) and golden brown haemosiderin (derived from lysed erythrocytes in haemorrhagic areas) are seen. Also present are a few other inflammatory cells like eosinophils, lymphocytes and plasma cells.
- ii) By the *end of the 2nd week*, most of the necrosed muscle in small infarcts is removed, neutrophils have almost disappeared, and newly laid collagen fibres replace the periphery of the infarct.

3. Third week Necrosed muscle fibres from larger infarcts continue to be removed and replaced by ingrowth of newly formed collagen fibres. Pigmented macrophages as well as lymphocytes and plasma cells are prominent while eosinophils gradually disappear.

4. Fourth to sixth week With further removal of necrotic tissue, there is increase in collagenous connective tissue, decreased vascularity and fewer pigmented macrophages, lymphocytes and plasma cells. Thus, at the end of 6 weeks, a contracted fibrocollagenic scar with diminished vascularity is formed. The pigmented macrophages may persist for a long duration in the scar, sometimes for years.

A summary of the sequence of gross and microscopic changes in myocardial infarction of varying duration is presented in **Table 14.4**.

SALVAGE IN EARLY INFARCTS AND REPERFUSION INJURY In vast majority of cases of acute MI, occlusive

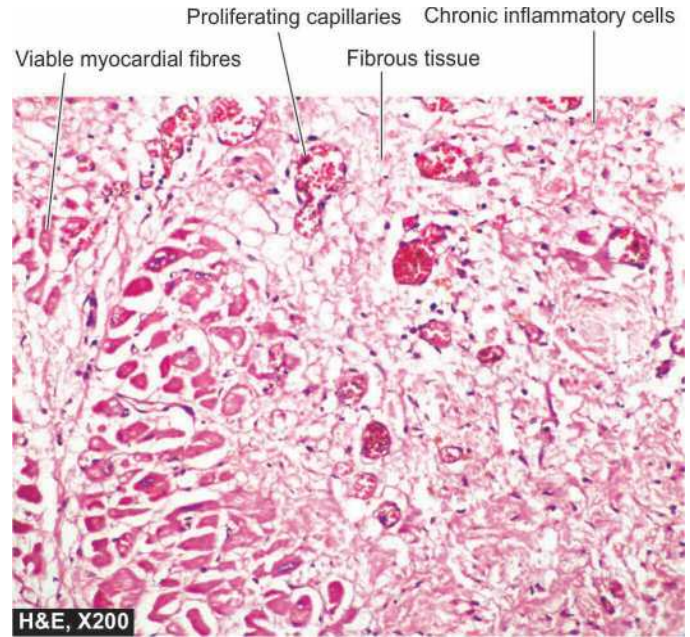

Figure 14.19 Old myocardial infarct. The infarcted area shows ingrowth of inflammatory granulation tissue.

coronary artery thrombosis has been demonstrated superimposed on fibrofatty plaque. The ischaemic injury to myocardium is reversible if perfusion is restored within the first 30 minutes of onset of infarction failing which irreversible ischaemic necrosis of myocardium sets in. The salvage in early infarcts can be achieved by the following interventions:

1. Institution of *thrombolytic therapy* with thrombolytic agents such as streptokinase and tissue plasminogen activator (door-to-needle time ≤ 30 minutes).
2. *Percutaneous transluminal coronary angioplasty (PTCA)*.
3. *Coronary artery stenting*.
4. *Coronary artery bypass surgery*.

However, late attempt at reperfusion is fraught with the risk of ischaemic reperfusion injury (page 14). Further myonecrosis during reperfusion occurs due to rapid influx of calcium ions and generation of toxic oxygen free radicals.

Grossly, the myocardial infarct following reperfusion injury appears *haemorrhagic* rather than pale.

Microscopically, myofibres show *contraction band necrosis* which are transverse and thick eosinophilic bands.

CHANGES IN EARLY INFARCTS By special techniques like electron microscopy, chemical and histochemical studies, changes can be demonstrated in early infarcts before detectable light microscopic alterations appear.

1. Electron microscopic changes Changes by EM examination are evident in less than half an hour on onset of infarction. These changes are as under:

- i) Disappearance of perinuclear glycogen granules within 5 minutes of ischaemia.
- ii) Swelling of mitochondria in 20 to 30 minutes.
- iii) Disruption of sarcolemma.
- iv) Nuclear alterations like peripheral clumping of nuclear chromatin.

2. Chemical and histochemical changes Analysis of tissues from early infarcts by chemical and histochemical techniques has shown a number of findings. These are as follows:

- i) Glycogen depletion in myocardial fibres within 30 to 60 minutes of infarction.
- ii) Increase in lactic acid in the myocardial fibres.
- iii) Loss of K^+ from the ischaemic fibres.
- iv) Increase of Na^+ in the ischaemic cells.
- v) Influx of Ca^{++} into the cells causing irreversible cell injury.

Based on the above observations and on leakage of enzymes from the ischaemic myocardium, alterations in the concentrations of various enzymes are detected in the blood of these patients.

DIAGNOSIS The diagnosis of acute MI is made on the observations of 3 types of features—clinical features, ECG changes, and serum enzyme determinations.

1. Clinical features Typically, acute MI has a sudden onset. The following clinical features usually characterise a case of acute MI.

- i) **Pain:** Usually sudden, severe, crushing and prolonged, substernal or precordial in location, unrelieved by rest or nitroglycerin, often radiating to one or both the arms, neck and back.
- ii) **Indigestion:** Pain is often accompanied by epigastric or substernal discomfort interpreted as 'heartburn' with nausea and vomiting.
- iii) **Apprehension:** The patient is often terrified, restless and apprehensive due to great fear of death.
- iv) **Shock:** Systolic blood pressure is below 80 mmHg; lethargy, cold clammy limbs, peripheral cyanosis, weak pulse, tachycardia or bradycardia are often present.
- v) **Oliguria:** Urine flow is usually less than 20 ml per hour.
- vi) **Low grade fever:** Mild rise in temperature occurs within 24 hours and lasts up to one week, accompanied by leucocytosis and elevated ESR.
- vii) **Acute pulmonary oedema:** Some cases develop severe pulmonary congestion due to left ventricular failure and develop suffocation, dyspnoea, orthopnoea and bubbling respiration.

2. ECG changes The ECG changes are one of the most important parameters. Most characteristic ECG change is ST segment elevation in acute MI (termed as STEMI); other changes include T wave inversion and appearance of wide deep Q waves (Fig. 14.20).

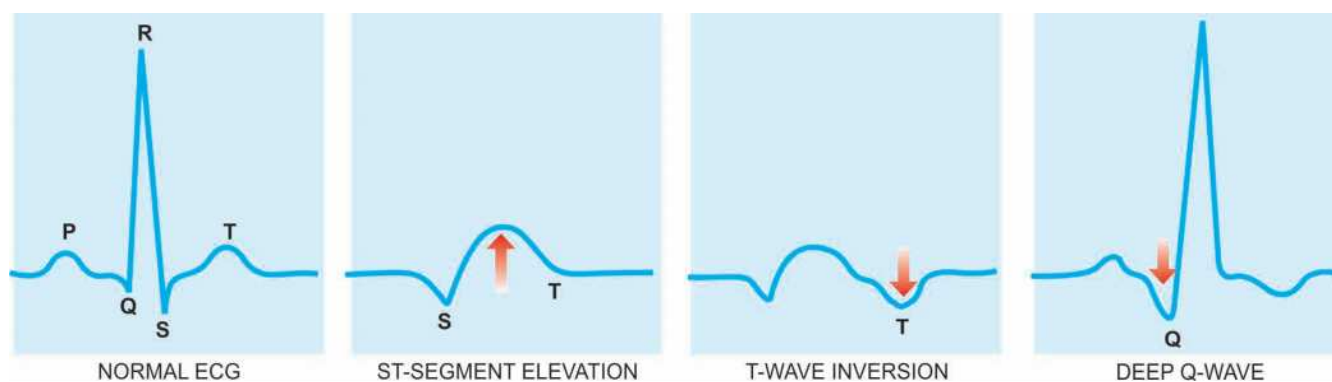

Figure 14.20 Some common ECG changes in acute myocardial infarction.

3. Serum cardiac markers Certain proteins and enzymes are released into the blood from necrotic heart muscle after acute MI. Measurement of their levels in serum is helpful in making a diagnosis and plan management. Rapid assay of some more specific cardiac proteins is available rendering the estimation of non-specific estimation of SGOT of historical importance only in current practice. Important myocardial markers in use nowadays are as under (Fig. 14.21):

- i) **Creatine phosphokinase (CK) and CK-MB** CK has three forms—
 - a) CK-MM derived from skeletal muscle;
 - b) CK-BB derived from brain and lungs; and
 - c) CK-MB, mainly from cardiac muscles and insignificant amount from extracardiac tissue.

Thus, total CK estimation lacks specificity while elevation of CK-MB isoenzyme is considerably specific for myocardial damage. CK-MB has further 2 forms—CK-MB2 is the myocardial form while CK-MB1 is extracardiac form. A ratio of CK-MB2: CK-MB1 above 1.5 is highly sensitive for the diagnosis of acute MI after 4-6 hours of onset of myocardial ischaemia. CK-MB disappears from blood by 48 hours.

- ii) **Lactate dehydrogenase (LDH)** Total LDH estimation also lacks specificity since this enzyme is present in various tissues besides myocardium such as in skeletal muscle, kidneys, liver, lungs and red blood cells. However, like CK, LDH too has two isoforms of which LDH-1 is myocardial-specific. Estimation of ratio of LDH-1: LDH-2 above 1 is reasonably helpful in making a diagnosis. LDH levels begin to rise after 24 hours, reach peak in 3 to 6 days and return to normal in 14 days.

- iii) **Cardiac-specific troponins (cTn)** Immunoassay of cTn as a serum cardiac marker has rendered LDH estimation obsolete. Troponins are contractile muscle proteins present in human cardiac and skeletal muscle but cardiac troponins are specific for myocardium. There are two types of cTn:

- a) cardiac troponin T (cTnT); and
- b) cardiac troponin I (cTnI).

Both cTnT and cTnI are not found in the blood normally, but after myocardial injury their levels rise very high around the same time when CK-MB is elevated (i.e. after 4-6 hours). Both troponin levels remain high for much longer duration; cTnI for 7-10 days and cTnT for 10-14 days.

- iv) **Myoglobin** Though myoglobin is the first cardiac marker to become elevated after myocardial infarction, it lacks cardiac specificity and is excreted in the urine rapidly. Its levels, thus, return to normal within 24 hours of attack of acute MI.

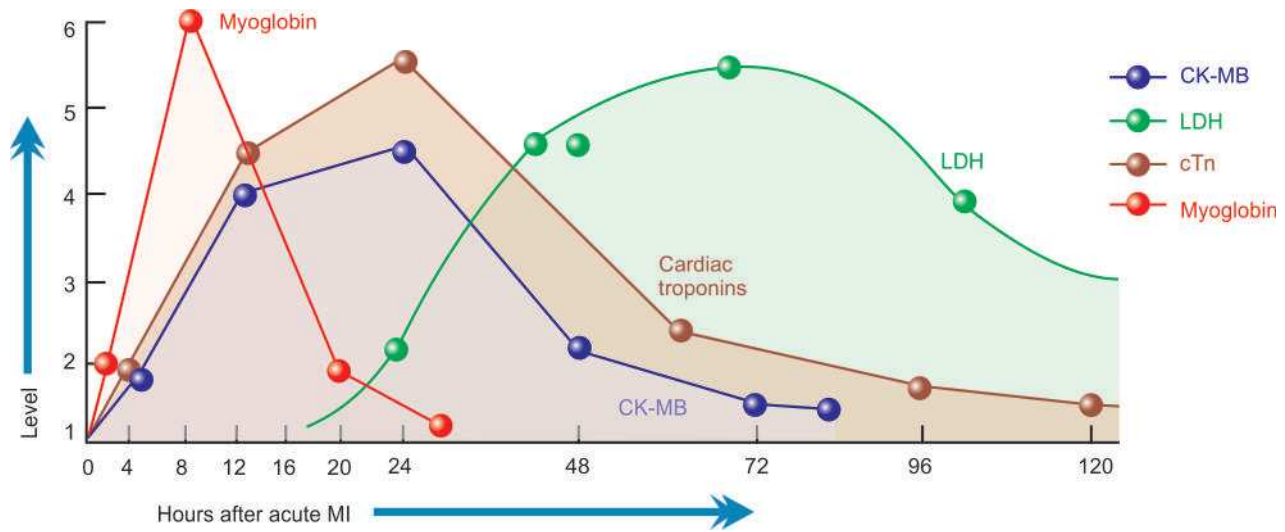

Figure 14.21 Time course of serum cardiac markers for the diagnosis of acute MI.

COMPLICATIONS Following an attack of acute MI, only 10-20% cases do not develop major complications and recover. The remainder 80-90% cases develop one or more major complications, some of which are fatal. The immediate mortality from acute MI (sudden cardiac death) is about 25%. The important complications which may develop following acute MI are as follows:

1. Arrhythmias Arrhythmias (or abnormalities in the normal heart rhythm) are the most common complication in acute MI. These occur due to ischaemic injury or irritation to the conduction system, resulting in abnormal rhythm. Other causes of arrhythmias include leakage of K^+ from ischaemic muscle cells and increased concentration of lactate and free fatty acids in the tissue fluid. Arrhythmias may be in the form of sinus tachycardia or sinus bradycardia, atrial fibrillation, premature systoles, and the most serious ventricular fibrillation responsible for many sudden cardiac deaths.

2. Congestive heart failure About half the patients with MI develop CHF which may be in the form of right ventricular failure, left ventricular failure or both. CHF is responsible for about 40% of deaths from acute MI. If the patient survives, healing may restore normal cardiac function but in some CHF may persist and require regular treatment later.

3. Cardiogenic shock About 10% of patients with acute MI develop cardiogenic shock characterised by hypotension with systolic blood pressure of 80 mmHg or less for many days. Shock may be accompanied by peripheral circulatory failure, oliguria and mental confusion.

4. Mural thrombosis and thromboembolism The incidence of thromboembolism from intracardiac thrombi and from thrombosis in the leg veins is 15-45% in cases of acute MI and is the major cause of death in 12% cases. Mural thrombosis in the heart develops due to involvement of the endocardium and subendocardium in the infarct and due to slowing of the heart rate. Mural thrombi often form thromboemboli. Another source of thromboemboli is the venous thrombosis in the leg veins due to prolonged bed rest. Thromboemboli from either source may cause occlusion of the pulmonary, renal, mesenteric, splenic, pancreatic or cerebral arteries and cause infarcts in these organs.

5. Rupture Rupture of the heart occurs in up to 5% cases of acute MI causing death. Rupture occurs most often from the infarcted ventricular wall into the pericardial cavity causing haemopericardium and tamponade. Other sites of rupture are through interventricular septum and rupture of a papillary muscle in infarct of the left ventricle. Rupture at any of these sites occurs usually in the first week and is often fatal.

6. Cardiac aneurysm Another 5% of patients of acute MI develop aneurysm, often of the left ventricle. It occurs in healed infarcts through thin, fibrous, non-elastic scar tissue. Cardiac aneurysms impair the function of the heart and are the common sites for mural thrombi. Rarely, calcification of the wall of aneurysm may occur.

7. Pericarditis Sterile pericarditis appearing on about the second day is common over transmural infarcts. It is characterised by fibrinous pericarditis and may be associated with pericardial effusion. Often, it is of no functional significance and resolves spontaneously.

8. Postmyocardial infarction syndrome About 3 to 4% of patients who suffered from acute MI develop postmyocardial infarction syndrome or *Dressler's syndrome* subsequently. It usually occurs 1 to 6 weeks after the attack of MI. It is characterised by pneumonitis. The symptoms are usually mild and disappear in a few weeks. The exact pathogenesis of this syndrome is not known. It may be due to autoimmune reaction as evidenced by circulating anti-heart antibodies in the serum of these patients. But these antibodies are also present in some patients with acute MI who do not develop this syndrome.

CHRONIC ISCHAEMIC HEART DISEASE

Chronic ischaemic heart disease, ischaemic cardiomyopathy or myocardial fibrosis, are the terms used for focal or diffuse fibrosis in the myocardium characteristically found in elderly patients of progressive IHD. Such small areas of fibrous scarring are commonly found in the heart of patients who have history of episodes of angina and attacks of MI some years back. The patients generally have gradually developing CHF due to decompensation over a period of years. Occasionally, serious cardiac arrhythmias or infarction may supervene and cause death.

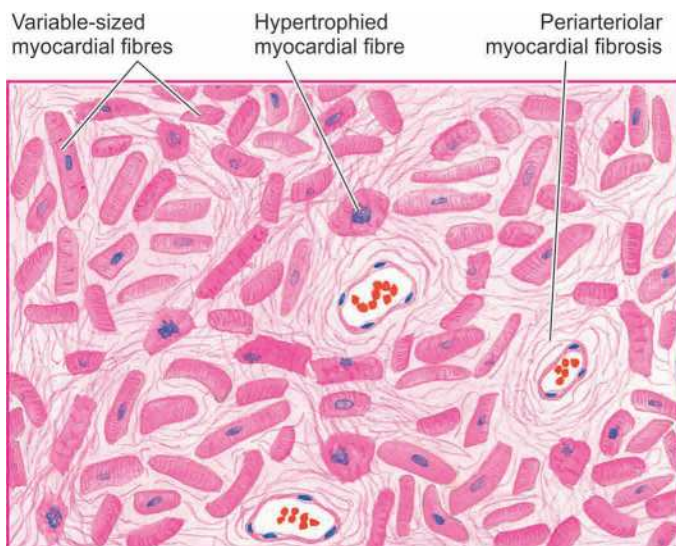

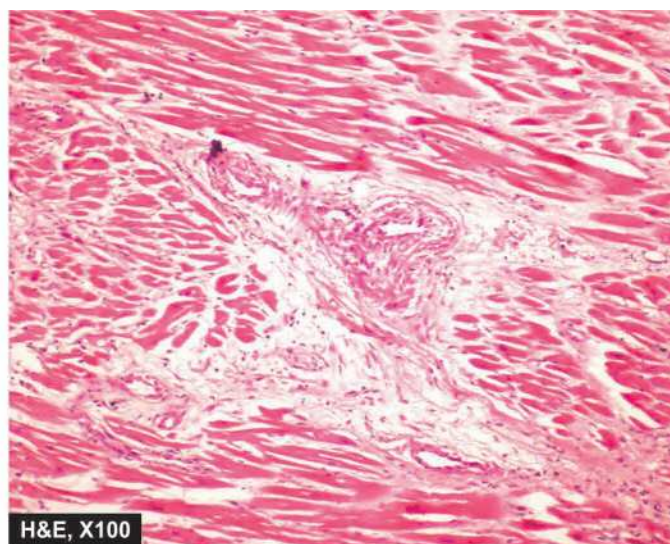

Figure 14.22 Chronic ischaemic heart disease. There is patchy myocardial fibrosis, especially around small blood vessels in the interstitium. The intervening single cells and groups of myocardial cells show myocytolysis.

ETIOPATHOGENESIS In majority of cases, coronary atherosclerosis causes progressive ischaemic myocardial damage and replacement by myocardial fibrosis. A small percentage of cases may result from other causes such as emboli, coronary arteritis and myocarditis.

The mechanism of development of myocardial fibrosis can be explained by one of the following concepts:

- Myocardial fibrosis represents healing of minute infarcts involving small scattered groups of myocardial fibres.
- An alternate concept of development of myocardial fibrosis is healing of minute areas of focal myocytolysis—the myocardial fibres in a small area undergo slow degeneration due to myocardial ischaemia. These fibres lose their myofibrils but nuclei remain intact. These foci are infiltrated by macrophages and eventually are replaced by proliferating fibroblasts and collagen.

MORPHOLOGIC FEATURES *Grossly*, the heart may be normal in size or hypertrophied. The left ventricular wall generally shows foci of grey-white fibrosis in brown myocardium. Healed scars of previous MI may be present. Valves of the left heart may be distorted, thickened and show calcification. Coronary arteries invariably show moderate to severe atherosclerosis.

Microscopically, the characteristic features are as follows (**Fig. 14.22**):

- There are scattered areas of diffuse myocardial fibrosis, especially around the small blood vessels in the interstitial tissue of the myocardium.
- Intervening single fibres and groups of myocardial fibres show variation in fibre size and foci of myocytolysis.
- Areas of brown atrophy of the myocardium may also be present.
- Coronary arteries show atherosclerotic plaques and may have complicated lesions in the form of superimposed thrombosis.

SUDDEN CARDIAC DEATH

Sudden cardiac death is defined as sudden death within 24 hours of the onset of cardiac symptoms. The most important

cause is coronary atherosclerosis; less commonly it may be due to coronary vasospasm and other non-ischaemic causes. These include: calcific aortic stenosis, myocarditis of various types, hypertrophic cardiomyopathy, mitral valve prolapse, endocarditis, and hereditary and acquired defects of the conduction system. The mechanism of sudden death by myocardial ischaemia is almost always by fatal arrhythmias, chiefly ventricular asystole or fibrillation.

MORPHOLOGIC FEATURES At autopsy, such cases reveal most commonly critical atherosclerotic coronary narrowing (more than 75% compromised lumen) in one or more of the three major coronary arterial trunks with superimposed thrombosis or plaque-haemorrhage. Healed and new myocardial infarcts are found in many cases.

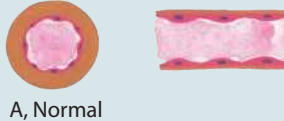

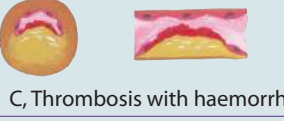

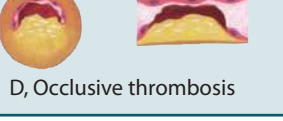

Table 14.5 lists the important forms of coronary artery pathology in various types of IHD.

GIST BOX 14.4 Ischaemic Heart Disease

- ☐ Ischaemic heart disease (IHD) is acute or chronic cardiac disability arising from imbalance between the myocardial supply and demand for oxygenated blood.
- ☐ Atherosclerotic coronary artery disease (CAD) is the most common cause of IHD, most commonly of LAD, others are RCA and CXA. Often, there are superimposed changes on the plaque.
- ☐ *Acute coronary syndromes* include a triad of acute myocardial infarction, unstable angina and sudden cardiac death
- ☐ Angina pectoris results from transient myocardial ischaemia and is characterised by paroxysmal pain in the substernal or precordial region.
- ☐ Acute myocardial infarction (MI) is the most important and feared consequence of coronary artery disease. Early thrombolytic therapy within 30 minutes of occurrence may help in restoration of blood supply.
- ☐ The gross and microscopic changes in the myocardial infarction, most often in the left ventricle, vary according to the age of the infarct.

Table 14.5 Lesions in coronary artery in various forms of IHD.

| TYPES OF IHD | CORONARY LESION | MORPHOLOGY | CLINICAL EFFECTS |
|--|--|--|-------------------------------------|
| 1. <i>Stable angina</i> | • Critical coronary narrowing (3/4th) |  A, Normal | Nil |
| 2. <i>Chronic IHD</i> | • Chronic progressive coronary atherosclerosis |  B, Severe, fixed 3/4th narrowing | Stable angina, CIHD |
| 3. <i>Unstable (pre-infarction) angina</i> | • Plaque rupture, haemorrhage, ulceration • Mural thrombosis with thromboembolism | | |
| 4. <i>Myocardial infarction</i> | • Plaque haemorrhage • Fissuring and ulceration • Complete mural thrombosis |  C, Thrombosis with haemorrhage | Plaque haemorrhage, unstable angina |
| 5. <i>Sudden ischaemic death</i> | • Severe multivessel disease • Acute changes in plaque • Thrombosis with thromboembolism |  D, Occlusive thrombosis | Acute coronary syndromes |

- ▣ The diagnosis of acute MI is made by clinical features, ECG changes, and serum enzyme determinations.
- ▣ Chronic ischaemic heart disease is focal or diffuse fibrosis in the myocardium characteristically found in elderly patients of progressive IHD.
- ▣ Sudden death by myocardial ischaemia is almost always by fatal arrhythmias, chiefly ventricular asystole or fibrillation.

HYPERTENSIVE HEART DISEASE

Hypertensive heart disease or hypertensive cardiomyopathy is the disease of the heart resulting from systemic hypertension of prolonged duration and manifesting by left ventricular hypertrophy. Even mild hypertension (blood pressure higher than 140/90 mmHg) of sufficient duration may induce hypertensive heart disease. It is the second most common form of heart disease after IHD. As already pointed out, hypertension predisposes to atherosclerosis. Therefore, most patients of hypertensive heart disease have advanced coronary atherosclerosis and may develop progressive IHD.

Amongst the causes of death in hypertensive patients, cardiac decompensation leading to CHF accounts for about one-third of the patients; other causes of death are IHD, cerebrovascular stroke, renal failure following arteriolar nephrosclerosis, dissecting aneurysm of the aorta and sudden cardiac death.

PATHOGENESIS The pathogenesis of systemic hypertension is discussed later (page 675). Pathogenesis of left ventricular hypertrophy (LVH) which is most commonly caused by systemic hypertension is described here.

Stimulus to LVH is pressure overload in systemic hypertension. Both genetic and haemodynamic factors contribute to LVH. The stress of pressure on the ventricular wall causes increased production of myofilaments, myofibrils, other cell organelles and nuclear enlargement. Since the adult myo-

cardial fibres do not divide, the fibres are hypertrophied. However, the sarcomeres may divide to increase the cell width.

LVH can be diagnosed by ECG. Aggressive control of hypertension can regress the left ventricular mass but which antihypertensive agents would do this, in addition to their role in controlling blood pressure, is not clearly known. Abnormalities of diastolic function in hypertension are more common in hypertension and is present in about one-third of patients with normal systolic function.

MORPHOLOGIC FEATURES *Grossly*, the most significant finding is marked hypertrophy of the heart, chiefly of the left ventricle (*see* Fig. 14.6). The weight of the heart increases to 500 gm or more (normal weight about 300 gm). The thickness of the left ventricular wall increases from its normal 13 to 15 mm up to 20 mm or more. The papillary muscles and trabeculae carneae are rounded and prominent. Initially, there is *concentric hypertrophy* of the left ventricle (without dilatation). But when decompensation and cardiac failure supervene, there is *eccentric hypertrophy* (with dilatation) with thinning of the ventricular wall and there may be dilatation and hypertrophy of right heart as well.

Microscopically, the features are not as prominent as gross appearance. The changes include enlargement and degeneration of myocardial fibres with focal areas of myocardial fibrosis. In advanced cases, there may be myocardial oedema and foci of necrosis in the myocardium.

GIST BOX 14.5 Hypertensive Heart Disease

- ▣ Hypertensive heart disease results from systemic hypertension of prolonged duration and manifests by left ventricular hypertrophy.
- ▣ Initially, there is *concentric hypertrophy* of the left ventricle (without dilatation). But when decompensation and cardiac failure supervene, there is *eccentric hypertrophy* (with dilatation).

Cor pulmonale (*cor* = heart; *pulmonale* = lung) or pulmonary heart disease is the disease of right side of the heart resulting from disorders of the lungs. It is characterised by right ventricular dilatation or hypertrophy, or both. Thus, cor pulmonale is the right-sided counterpart of the hypertensive heart disease just described.

Depending upon the rapidity of development, cor pulmonale may be acute or chronic:

◆ *Acute cor pulmonale* occurs following massive pulmonary embolism resulting in sudden dilatation of the pulmonary trunk, conus and right ventricle.

◆ *Chronic cor pulmonale* is more common and is often preceded by chronic pulmonary hypertension (page 446). Following chronic lung diseases can cause chronic pulmonary hypertension and subsequent cor pulmonale:

- i) Chronic emphysema
- ii) Chronic bronchitis
- iii) Pulmonary tuberculosis
- iv) Pneumoconiosis
- v) Cystic fibrosis
- vi) Hyperventilation in marked obesity (Pickwickian syndrome)
- vii) Multiple organised pulmonary emboli.

PATHOGENESIS Chronic lung diseases as well as diseases of the pulmonary vessels cause increased pulmonary vascular resistance. The most common underlying mechanism causing increased pulmonary blood pressure (pulmonary hypertension) is by pulmonary vasoconstriction, activation of coagulation pathway and obliteration of pulmonary arterial vessels. Pulmonary hypertension causes pressure overload on the right ventricle and hence right ventricular enlargement. Initially, there is right ventricular hypertrophy, but as cardiac decompensation sets in and right heart failure ensues, dilatation of right ventricle occurs.

The sequence of events involved in the pathogenesis of cor pulmonale is summarised in **Fig. 14.23**.

MORPHOLOGIC FEATURES In *acute cor pulmonale*, there is characteristic ovoid dilatation of the right ventricle, and sometimes of the right atrium. In *chronic cor pulmonale*,

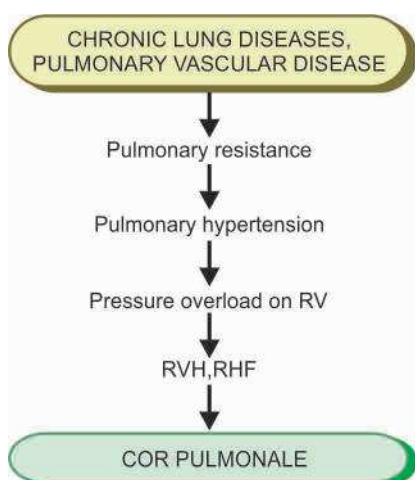

Figure 14.23 Pathogenesis of cor pulmonale (RVH= right ventricular hypertrophy, RHF= right heart failure).

there is increase in thickness of the right ventricular wall from its normal 3 to 5 mm up to 10 mm or more. Often, there is dilatation of the right ventricle too.

GIST BOX 14.6

Cor Pulmonale

- ☐ Cor pulmonale or pulmonary heart disease is the disease of right side of the heart resulting from disorders of the lungs.
- ☐ It may be acute or chronic; the latter is more common.
- ☐ There is thickened right ventricular wall, often with dilatation.

RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

DEFINITION

Rheumatic fever (RF) is a systemic, post-streptococcal, non-suppurative inflammatory disease, principally affecting the heart, joints, central nervous system, skin and subcutaneous tissues. The chronic stage of RF involves all the layers of the heart (pancarditis) causing major cardiac sequelae referred to as rheumatic heart disease (RHD). In spite of its name suggesting an acute arthritis migrating from joint to joint, it is well known that it is the heart rather than the joints which is first and major organ affected. Decades ago, William Boyd gave the dictum '*rheumatism licks the joint, but bites the whole heart*'.

INCIDENCE

The disease appears most commonly in children between the age of 5 to 15 years when the streptococcal infection is most frequent and intense. Both the sexes are affected equally, though some investigators have noted a slight female preponderance.

The geographic distribution, incidence and severity of RF and RHD are generally related to the frequency and severity of streptococcal pharyngeal infection. The disease is seen more commonly in poor socioeconomic strata of the society living in damp and overcrowded places which promote interpersonal spread of the streptococcal infection. Its incidence has declined in the developed countries as a result of improved living conditions and early use of antibiotics in streptococcal infection. But it is still common in the developing countries of the world, particularly prevalent in Indian subcontinent (India, Pakistan, Bangladesh, Nepal, Afghanistan), some Arab countries, sub-Saharan Africa and some South American countries. In India, RHD and RF continue to be a major public health problem. In a multicentric survey in school-going children by the Indian Council of Medical Research, an incidence of 1 to 5.5 per 1000 children has been reported.

ETIOPATHOGENESIS

After a long controversy, the etiologic role of preceding throat infection with β -haemolytic streptococci of group A in RF is now well accepted. However, the mechanism of lesions in the heart, joints and other tissues is not by direct infection but by induction of hypersensitivity or autoimmunity in a susceptible host. Thus, there are 3 types of factors in the etiology and

pathogenesis of RF and RHD: *environmental factors, host susceptibility and immunologic evidences.*

A. ENVIRONMENTAL FACTORS There is sufficient clinical and epidemiological evidence to support the concept that RF occurs following infection of the throat and upper respiratory tract with β -haemolytic streptococci of Lancefield group A. These evidences are as under:

1. There is often a *history* of infection of the pharynx, upper respiratory tract with this microorganism about 2 to 3 weeks prior to the attack of RF. This period is usually the latent period required for sensitisation to the bacteria.
2. *Subsequent or ongoing attacks* of streptococcal infection are generally associated with recurrent episodes of acute RF.
3. A higher incidence of RF has been observed after outbreaks and *epidemics* of streptococcal infection of throat in children from schools or in young men from training camps.
4. Administration of *antibiotics* leads to lowering of the incidence as well as severity of RF and its recurrences.
5. Cardiac lesions similar to those seen in RHD have been produced in experimental animals by *induction* of repeated infection with β -haemolytic streptococci of group A.
6. *Socioeconomic factors* like poverty, poor nutrition, density of population, overcrowding in quarters for sleeping etc are associated with spread of infection, lack of proper medical attention, and hence higher incidence of RF.
7. The *geographic distribution* of the disease, as already pointed out, shows higher frequency and severity of the disease in the developing countries of the world where the living conditions in underprivileged populations are substandard and medical facilities are insufficient. Children in these regions develop recurrent throat infections which remain untreated and have higher incidence of RF.
8. The role of *climate* in the development of RF has been reported by some workers. The incidence of the disease is higher in subtropical and tropical regions with cold, damp climate near the rivers and waterways which favour the spread of infection.

Despite all these evidences, only a small proportion of patients with streptococcal pharyngeal infection develop RF—the attack rate is less than 3%. There is a suggestion that a *concomitant virus* enhances the effect of streptococci in individuals who develop RF.

B. HOST SUSCEPTIBILITY Since all individuals with streptococcal infections do not develop RF, role of inherited characteristic for the disease has been reported:

1. Clustering of disease in *families*.
2. Occurrence in *identical twins*.
3. Individuals with *HLA class II* alleles have strong association with RF.
4. First-degree relatives of patients with RF and RHD have increased expression of a particular alloantigen, *D8-17*, on B cells, which may act as a marker for *inherited susceptibility* for the disease.

C. IMMUNOLOGIC EVIDENCE It has been observed that though throat of patients during acute RF may contain streptococci, the clinical symptoms of RF appear after a delay of 2-3 weeks and the organisms cannot be grown from the lesions in the target tissues. This has led to the concept that lesions have immune pathogenesis. Evidences in support are as under:

1. Patients with RF have *elevated titres* of antibodies to the antigens of β -haemolytic streptococci of group A such as anti-streptolysin O (ASO) and S, anti-streptokinase, anti-streptohyaluronidase and anti-DNAase B.
2. *Cell wall polysaccharide* of group A *Streptococcus* forms antibodies which are reactive against cardiac valves. This is supported by observation of persistently elevated corresponding autoantibodies in patients who have cardiac valvular involvement than those without cardiac valve involvement.
3. *Hyaluronate capsule* of group A *Streptococcus* is identical to human hyaluronate present in joint tissues and thus these tissues are the target of attack.
4. *Membrane antigens* of group A *Streptococcus* react with sarcolemma of smooth and cardiac muscle, dermal fibroblasts and neurons of caudate nucleus.

SUMMARY OF ORGANISM-HOST SUSCEPTIBILITY-IMMUNITY HYPOTHESIS Combining the three types of evidences given above, pathogenesis of RF-RHD can be summed up as under (**Fig. 14.24**):

1. A susceptible host, on being encountered with group A *Streptococcus* infection, mounts an *autoimmune reaction* by formation of autoantibodies against bacteria.
2. These autoantibodies cause damage to human tissues due to *cross-reactivity* between epitopes in the components of bacteria and the host.

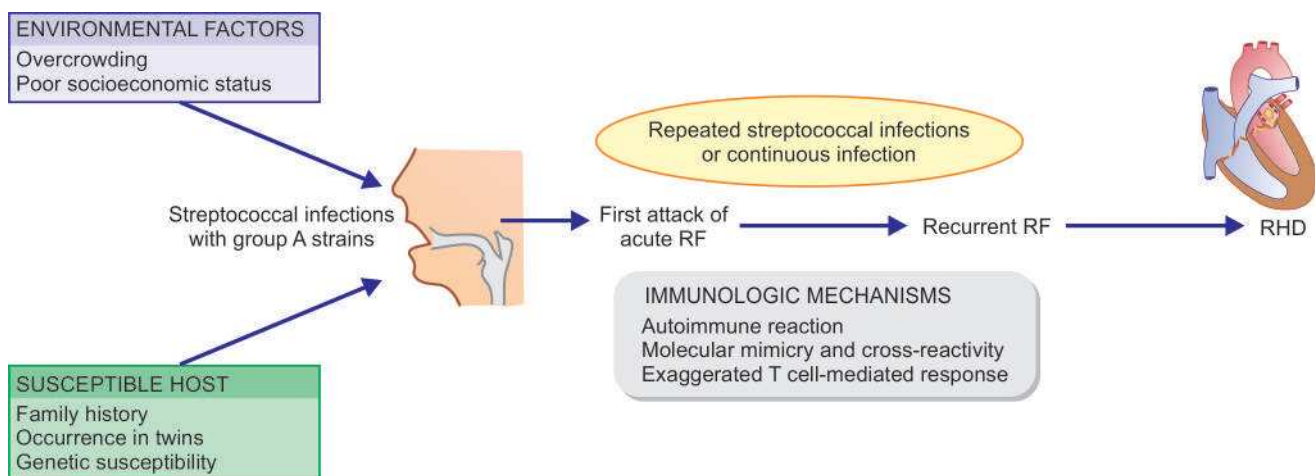

Figure 14.24 Pathogenesis of RHD, schematic evolution.

3. Streptococcal epitopes present on the bacterial cell wall, cell membrane and the *streptococcal M protein*, are immunologically identical to human molecules on myosin, keratin, actin, laminin, vimentin and N-acetylglucosamine.

4. *Molecular mimicry and cross-reactivity* between streptococcal M protein in particular and the human molecules forms the basis of autoimmune damage to human target tissues in RHD i.e. cardiac muscle, valves, joints, skin, neurons etc.

MORPHOLOGIC FEATURES

RF is generally regarded as an autoimmune focal inflammatory disorder of the connective tissues throughout the body. The *cardiac lesions* of RF in the form of pancarditis, particularly the valvular lesions, are its major manifestations. However, supportive connective tissues at other sites like the synovial membrane, periarticular tissue, skin and subcutaneous tissue, arterial wall, lungs, pleura and the CNS are all affected (*extracardiac lesions*).

A. Cardiac Lesions

The cardiac manifestations of RF are in the form of focal inflammatory involvement of the interstitial tissue of all the three layers of the heart, the so-called *pancarditis*. The pathognomonic feature of pancarditis in RF is the presence of distinctive *Aschoff nodules* or *Aschoff bodies*.

THE ASCHOFF NODULES OR BODIES The Aschoff nodules or the Aschoff bodies are spheroidal or fusiform distinct tiny structures, 1-2 mm in size, occurring in the interstitium of the heart in RF and may be visible to naked eye. They are especially found in the vicinity of small blood vessels in the myocardium and endocardium and occasionally in the pericardium and the adventitia of the proximal part of the aorta. Lesions similar to the Aschoff nodules may be found in the extracardiac tissues.

Evolution of fully-developed Aschoff bodies occurs through 3 stages all of which may be found in the same heart at different stages of development. These are as follows:

1. Early (exudative or degenerative) stage The earliest sign of injury in the heart in RF is apparent by *about 4th week* of illness. Initially, there is oedema of the connective tissue and increase in acid mucopolysaccharide in the ground substance. This results in separation of the collagen fibres by accumulating ground substance. Eventually, the collagen fibres are fragmented and disintegrated and the affected focus takes the appearance and staining characteristics of fibrin. This change is referred to as *fibrinoid degeneration*.

2. Intermediate (proliferative or granulomatous) stage It is this stage of the Aschoff body which is pathognomonic of rheumatic conditions (**Fig. 14.25**). This stage is apparent in 4th to 13th week of illness. The early stage of fibrinoid change is followed by proliferation of cells that includes infiltration by lymphocytes (mostly T cells), plasma cells, a few neutrophils and the characteristic *cardiac histiocytes* (*Anitschkow cells*) at the margin of the lesion. Cardiac histiocytes or Anitschkow cells are present in small numbers in normal heart but their number is increased in the Aschoff bodies; therefore they are not characteristic of RHD. These are large mononuclear cells having central round nuclei and contain moderate amount of amphophilic cytoplasm.

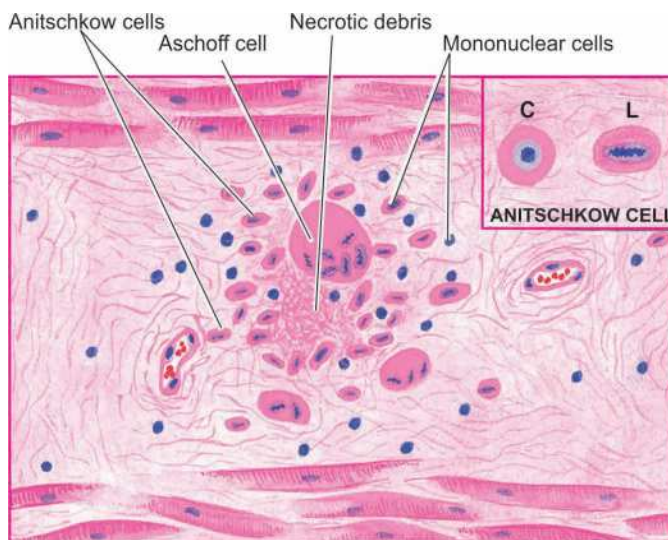

Figure 14.25 An Aschoff body (granulomatous stage) in the myocardium. *Inbox* shows Anitschkow cell in longitudinal section (LS) with caterpillar-like serrated nuclear chromatin, while cross section (CS) shows owl-eye appearance of central chromatin mass and perinuclear halo.

The nuclei are vesicular and contain prominent central chromatin mass which in longitudinal section appears serrated or caterpillar-like, while in cross-section the chromatin mass appears as a small rounded body in the centre of the vesicular nucleus, just like an owl's eye. Some of these modified cardiac histiocytes become multinucleate cells containing 1 to 4 nuclei and are called *Aschoff cells* and are pathognomonic of RHD.

3. Late (healing or fibrous) stage The stage of healing by fibrosis of the Aschoff nodule occurs in about *12 to 16 weeks* after the illness. The nodule becomes oval or fusiform in shape, about 200 μm wide and 600 μm long. The Anitschkow cells in the nodule become spindle-shaped with diminished cytoplasm and the nuclei stain solidly rather than showing vesicular character. These cells tend to be arranged in a palisaded manner. With passage of months and years, the Aschoff body becomes less cellular and the collagenous tissue is increased. Eventually, it is replaced by a small fibrocollagenous scar with little cellularity, frequently in perivascular location.

RHEUMATIC PANCARDITIS Although all the three layers of the heart are affected in RF, the intensity of their involvement is variable.

1. RHEUMATIC ENDOCARDITIS Endocardial lesions of RF may involve the valvular and mural endocardium, causing *rheumatic valvulitis* and *mural endocarditis*, respectively. Rheumatic valvulitis is chiefly responsible for the major cardiac manifestations in chronic RHD.

RHEUMATIC VALVULITIS *Grossly*, the valves in **acute RF** show thickening and loss of translucency of the valve leaflets or cusps. This is followed by the formation of characteristic, small (1 to 3 mm in diameter), multiple, warty *vegetations* or *verrucae*, chiefly along the line of closure of the leaflets and cusps. These tiny vegetations are almost continuous so that the free margin of the cusps or leaflets appears as a rough and irregular ridge.

The vegetations in RF appear grey-brown, translucent and are firmly attached so that they are not likely to get detached to form emboli, unlike the friable vegetations of infective endocarditis (page 425).

Though all the four heart valves are affected, their frequency and severity of involvement varies: mitral valve alone being the most common site, followed in decreasing order of frequency, by combined mitral and aortic valve (Fig. 14.26). The tricuspid and pulmonary valves usually show infrequent and slight involvement. The higher incidence of vegetations on left side of the heart is possibly because of the greater mechanical stresses on the valves of the left heart, especially along the line of closure of the valve cusps (Fig. 14.27, A). The occurrence of vegetations on the atrial surfaces of the atrioventricular valves (mitral and tricuspid) and on the ventricular surface of the semilunar valves (aortic and pulmonary) further lends support to the role of mechanical pressure on the valves in the pathogenesis of vegetations.

The **chronic stage of RHD** is characterised by permanent deformity of one or more valves, especially the mitral (in 98% cases alone or along with other valves) and aortic. The approximate frequency of deformity of various valves is as under:

- ◆ Mitral alone = 37% cases.
- ◆ Mitral + aortic = 27% cases.
- ◆ Mitral + aortic + tricuspid = 22% cases.
- ◆ Mitral + tricuspid = 11% cases.
- ◆ Aortic alone = 2%.
- ◆ Mitral + aortic + tricuspid + pulmonary = less than 1% cases.

Thus, mitral valve is almost always involved in RHD. Gross appearance of chronic healed mitral valve in RHD is characteristically 'fish mouth' or 'button hole' stenosis. Mitral stenosis and insufficiency are commonly combined in chronic RHD; calcific aortic stenosis may also be found. These healed chronic valvular lesions in RHD occur due to diffuse fibrocollagenous thickening and calcification of the valve cusps or leaflets which cause adhesions between the

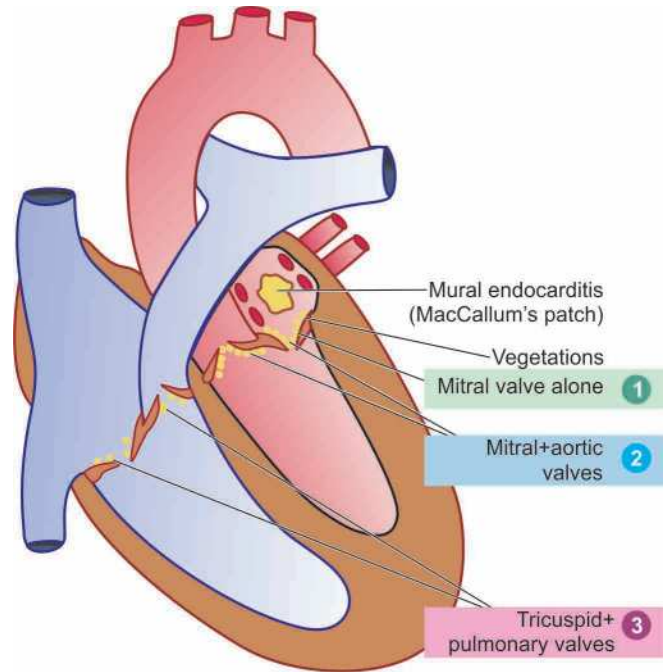

Figure 14.26 Schematic representation of the anatomic regions of involvement and location of vegetations in rheumatic endocarditis (both valvular and mural). Serial numbers 1, 2 and 3 are denoted for the frequency of valvular involvement.

lateral portions, especially in the region of the commissures. Thickening, shortening and fusion of the chordae tendineae further contribute to the chronic valvular lesions (Fig. 14.27, B).

Microscopically, the inflammatory changes begin in the region of the valve rings (where the leaflets are attached to the fibrous annulus) and then extend throughout the entire leaflet, whereas vegetations are usually located on the free margin of the leaflets and cusps.

i) In the **early (acute) stage**, the histological changes are oedema of the valve leaflet, presence of increased number

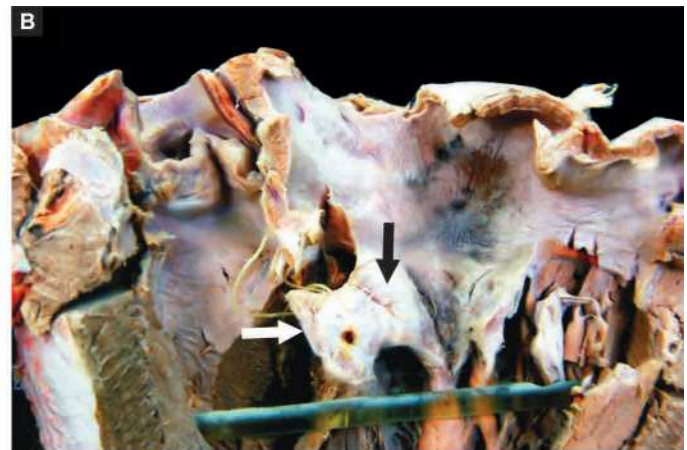

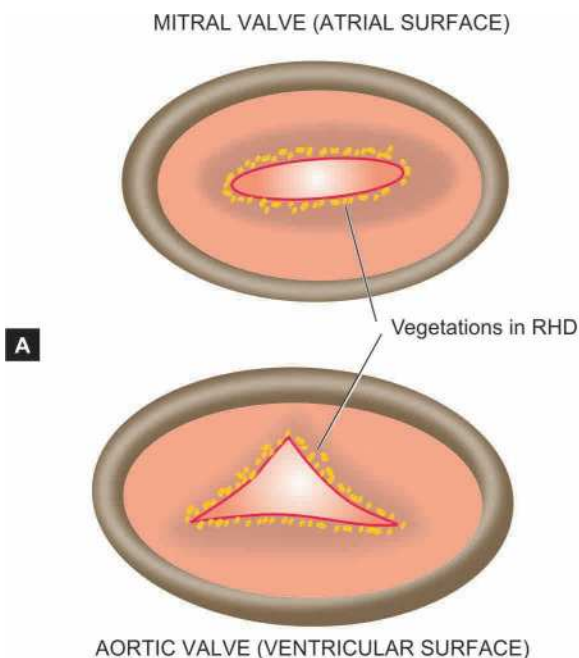

Figure 14.27 Rheumatic valvulitis. A, Location of vegetations on the valves of the left heart. The location of vegetations on mitral valve (left upper diagram) is shown as viewed from the left atrium, while the vegetations on aortic valve (left lower diagram) are shown as seen from the left ventricular surface. B, Opened up chambers and valves of the left heart show irregularly scarred mitral valve leaving a fish-mouth or buttonhole opening between its two cusps (black arrow). The free surface and margin of the mitral valve shows tiny firm granular vegetations (white arrow).

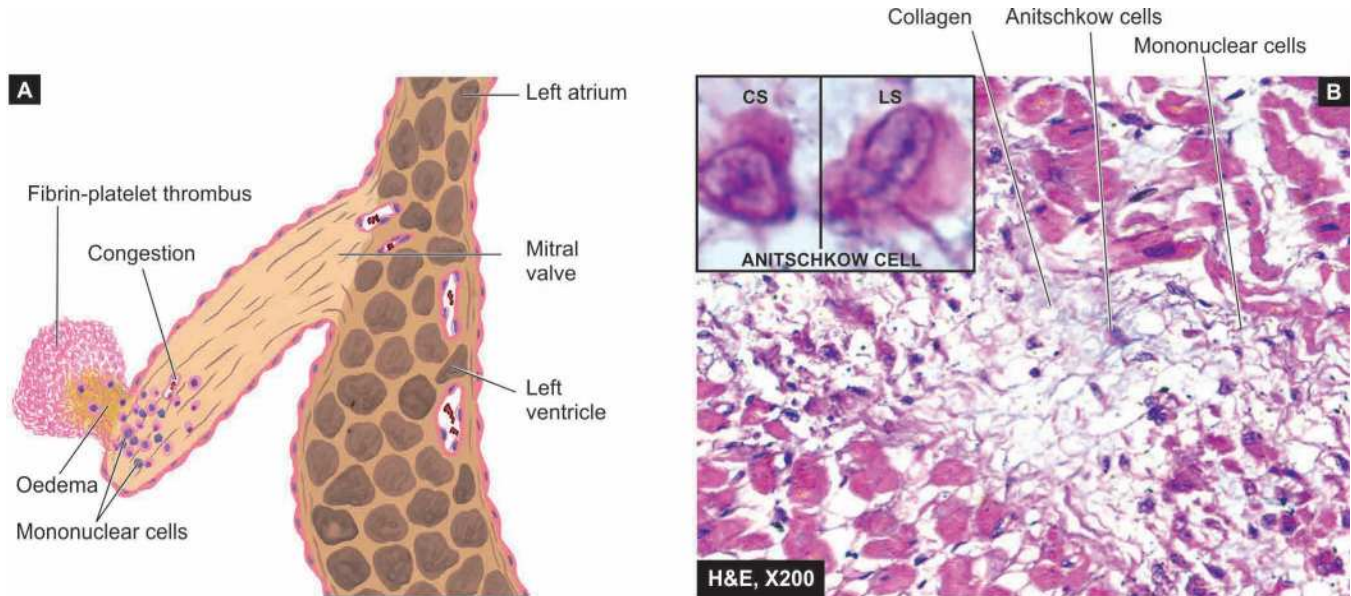

Figure 14.28 Rheumatic heart disease. A, Microscopic structure of the rheumatic valvulitis and a vegetation on the cusp of mitral valve in sagittal section. B, Section of the myocardium shows a healed Aschoff nodule in the interstitium having collagen, sparse cellularity, a multinucleate giant cell and Anitschkow cells. Inset shows an Anitschkow cell in cross section (CS) and in longitudinal section (LS).

of capillaries and infiltration with lymphocytes, plasma cells, histiocytes with many Anitschkow cells and a few polymorphs. Occasionally, Aschoff bodies with central foci of fibrinoid necrosis and surrounded by palisade of cardiac histiocytes are seen, but more often the cellular infiltration is diffuse in acute stage of RF. Vegetations present at the free margins of cusps appear as eosinophilic, tiny structures mainly consisting of fibrin with superimposed platelet-thrombi and do not contain bacteria (Fig. 14.28, A).

ii) In the **healed (chronic) stage**, the vegetations have undergone organisation. The valves show diffuse thickening as a result of fibrous tissue with hyalinisation, and often calcification. Vascularisation of the valve cusps may still be evident in the form of thick-walled blood vessels with narrowed lumina (Fig. 14.28, B). Typical Aschoff bodies are rarely seen in the valves at this stage.

RHEUMATIC MURAL ENDOCARDITIS Mural endocardium may also show features of rheumatic carditis though the changes are less conspicuous as compared to valvular changes.

Grossly, the lesions are seen most commonly as *MacCallum's patch* which is the region of endocardial surface in the posterior wall of the left atrium just above the posterior leaflet of the mitral valve. MacCallum's patch appears as a map-like area of thickened, roughened and wrinkled part of the endocardium (see Fig. 14.26).

Microscopically, the appearance of MacCallum's patch is similar to that seen in rheumatic valvulitis. The affected area shows oedema, fibrinoid change in the collagen, and cellular infiltrate of lymphocytes, plasma cells and macrophages with many Anitschkow cells. Typical Aschoff bodies may sometimes be found.

2. RHEUMATIC MYOCARDITIS **Grossly**, in the *early (acute) stage*, the myocardium, especially of the left ventricle, is soft and flabby. In the *intermediate stage*, the interstitial tissue of the myocardium shows small foci of

necrosis. Later, tiny pale foci of the Aschoff bodies may be visible throughout the myocardium.

Microscopically, the most characteristic feature of rheumatic myocarditis is the presence of distinctive Aschoff bodies. These diagnostic nodules are scattered throughout the interstitial tissue of the myocardium and are most frequent in the interventricular septum, left ventricle and left atrium. Derangements of the conduction system may, thus, be present. The Aschoff bodies are best identified in the intermediate stage when they appear as granulomas with central fibrinoid necrosis and are surrounded by palisade of Anitschkow cells and multinucleate Aschoff cells. There is infiltration by lymphocytes, plasma cells and some neutrophils. In the late stage, the Aschoff bodies are gradually replaced by small fibrous scars in the vicinity of blood vessels and the inflammatory infiltrate subsides. Presence of active Aschoff bodies along with old healed lesions is indicative of rheumatic activity.

3. RHEUMATIC PERICARDITIS Inflammatory involvement of the pericardium commonly accompanies RHD.

Grossly, the usual finding is fibrinous pericarditis in which there is loss of normal shiny pericardial surface due to deposition of fibrin on its surface and accumulation of slight amount of fibrinous exudate in the pericardial sac. If the parietal pericardium is pulled off from the visceral pericardium, the two separated surfaces are shaggy due to thick fibrin covering them. This appearance is often likened to '*bread and butter appearance*' i.e. resembling the buttered surfaces of two slices in a sandwich when they are gently pulled apart. If fibrinous pericarditis fails to resolve and, instead, undergoes organisation, the two layers of the pericardium form fibrous adhesions resulting in chronic adhesive pericarditis.

Microscopically, fibrin is identified on the surfaces. The subserosal connective tissue is infiltrated by lymphocytes, plasma cells, histiocytes and a few neutrophils.

Characteristic Aschoff bodies may be seen which later undergo organisation and fibrosis. Organisation of the exudate causes fibrous adhesions between the visceral and parietal surfaces of the pericardial sac and obliterates the pericardial cavity.

B. Extracardiac Lesions

Patients of the syndrome of acute rheumatism develop lesions in connective tissue elsewhere in the body, chiefly the joints, subcutaneous tissue, arteries, brain and lungs.

1. POLYARTHRITIS Acute and painful inflammation of the synovial membranes of some of the joints, especially the larger joints of the limbs, is seen in about 90% cases of RF in adults and less often in children. As pain and swelling subside in one joint, others tend to get involved, producing the characteristic '*migratory polyarthritis*' involving two or more joints at a time.

Histologically, the changes are transitory. The synovial membrane and the periarticular connective tissue show hyperaemia, oedema, fibrinoid change and neutrophilic infiltration. Sometimes, focal lesions resembling Aschoff bodies are observed. A serous effusion into the joint cavity is commonly present.

2. SUBCUTANEOUS NODULES The subcutaneous nodules of RF occur more often in children than in adult. These nodules are small (0.5 to 2 cm in diameter), spherical or ovoid and painless. They are attached to deeper structures like tendons, ligaments, fascia or periosteum and therefore often remain unnoticed by the patient. Characteristic locations are extensor surfaces of the wrists, elbows, ankles and knees.

Histologically, the subcutaneous nodules of RF are representative of giant Aschoff bodies of the heart. They consist of 3 distinct zones: a central area with fibrinoid changes, surrounded by a zone of histiocytes and fibroblasts forming a palisade arrangement, and the outermost zone of connective tissue which is infiltrated by non-specific chronic inflammatory cells and proliferating blood vessels.

It may be mentioned here that histologically similar but clinically different subcutaneous lesions appear in rheumatoid arthritis; they are larger, painful and tender and persist for months to years (page 844).

3. ERYTHEMA MARGINATUM This non-pruritic erythematous rash is characteristic of RF. The lesions occur mainly on the trunk and proximal parts of the extremities. The erythematous area develops central clearing and has slightly elevated red margins. The erythema is transient and migratory.

4. RHEUMATIC ARTERITIS Arteritis in RF involves not only the coronary arteries and the aorta but also occurs in arteries of various other organs such as renal, mesenteric and cerebral arteries. The lesions in the coronaries are seen mainly in the small intramyocardial branches.

Histologically, the lesions may be like those of hypersensitivity angiitis (page 385), or sometimes may resemble polyarteritis nodosa. Occasionally, foci of fibrinoid necrosis or ill-formed Aschoff bodies may be present close to the vessel wall.

5. CHOREA MINOR Chorea minor or Sydenham's chorea or Saint Vitus' dance is a delayed manifestation of RF as a result of involvement of the central nervous system. The condition is characterised by disordered and involuntary jerky movements of the trunk and the extremities accompanied by some degree of emotional instability. The condition occurs more often in younger age, particularly in girls.

Histologically, the lesions are located in the cerebral hemispheres, brainstem and the basal ganglia. They consist of small haemorrhages, oedema and perivascular infiltration of lymphocytes. There may be endarteritis obliterans and thrombosis of cortical and meningeal vessels.

6. RHEUMATIC PNEUMONITIS AND PLEURITIS Involvement of the lungs and pleura occurs rarely in RF. Pleuritis is often accompanied with serofibrinous pleural effusion but definite Aschoff bodies are not present. In rheumatic pneumonitis, the lungs are large, firm and rubbery.

Histologically, the changes are oedema, capillary haemorrhages and focal areas of fibrinous exudate in the alveoli. Aschoff bodies are generally not found.

CLINICAL FEATURES AND PROGNOSIS

The first attack of acute RF generally appears 2 to 3 weeks after streptococcal pharyngitis, most often in children between the age of 5 to 15 years. With subsequent streptococcal pharyngitis, there is reactivation of the disease and similar clinical manifestations appear with each recurrent attack. The disease generally presents with migratory polyarthritis and fever. However, RF has widespread systemic involvement and no single specific laboratory diagnostic test is available. As per revised WHO criteria (2004) based on *revised Jones' criteria* (first described by Dr. TD Jones in 1944, and last revised in 1992), following major and minor criteria and some supportive evidence of preceding infection are included for diagnosis:

A. Major criteria:

1. Carditis
2. Polyarthritis
3. Chorea (Sydenham's chorea)
4. Erythema marginatum
5. Subcutaneous nodules

B. Minor criteria:

1. Fever
2. Arthralgia
3. Previous history of RF
4. Laboratory findings of elevated ESR, raised C-reactive protein, and leucocytosis
5. ECG finding of prolonged PR interval.

C. Supportive evidence of preceding group A streptococcal infection include: positive throat culture for group A streptococci, raised titres of streptococcal antibodies (antistreptolysin O and S, antistreptokinase, anti-streptohyaluronidase and anti DNAase B).

Clinical **diagnosis of RF** and RHD is made in a case with antecedent laboratory evidence of streptococcal throat infection in the presence of *any two of the major criteria, or occurrence of one major and two minor criteria.*

If the heart is spared in a case of acute RF, the patient may have complete recovery without any sequelae. However, once the heart is involved, it is often associated with reactivation and recurrences of the disease. Myocarditis, in particular, is the most life-threatening due to involvement of the conduction system of the heart and results in serious arrhythmias. The long-term sequelae or **stigmata** are the chronic valvular deformities, especially the mitral stenosis, as already just explained. Initially, a state of compensation occurs, while later decompensation of the heart leads to full-blown cardiac failure. Currently, surgical replacement of the damaged valves can alter the clinical course of the disease.

The major **causes of death** in RHD are cardiac failure, bacterial endocarditis and embolism:

1. *Cardiac failure* is the most common cause of death from RHD. In young patients, cardiac failure occurs due to the chronic valvular deformities, while in older patients coronary artery disease may be superimposed on the old RHD.
2. *Bacterial endocarditis* of both acute and subacute type may supervene due to inadequate use of antibiotics.
3. *Embolism* in RHD originates most commonly from mural thrombi in the left atrium and its appendages, in association with mitral stenosis. The organs most frequently affected are the brain, kidneys, spleen and lungs.
4. *Sudden death* may occur in RHD as a result of ball thrombus in the left atrium or due to acute coronary insufficiency in association with aortic stenosis.

**GIST BOX 14.7****Rheumatic Fever and Rheumatic Heart Disease**

- ▣ Rheumatic fever is a systemic, post-streptococcal, non-suppurative inflammatory disease, principally affecting the heart, joints, central nervous system, skin and subcutaneous tissues.
- ▣ The chronic stage of RF involves all the layers of the heart (pancarditis) causing major cardiac sequelae referred to as rheumatic heart disease (RHD).
- ▣ The disease is more common in children between the age of 5 to 15 years.
- ▣ There are 3 types of factors in the etiology and pathogenesis of RF and RHD: *environmental factors, host susceptibility and immunologic evidences.*
- ▣ The pathognomonic feature of pancarditis in RF is the presence of distinctive *Aschoff nodules* or *Aschoff bodies*.
- ▣ The chronic stage of RHD is characterised by permanent deformity of one or more valves, especially the mitral (alone or with other valves) and aortic.
- ▣ Patients of RF-RHD develop extra-cardiac lesions in connective tissue elsewhere in the body, chiefly the joints, subcutaneous tissue, arteries, brain and lungs.

NON-RHEUMATIC ENDOCARDITIS

Inflammatory involvement of the endocardial layer of the heart is called endocarditis. Though in common usage, if not specified endocarditis would mean inflammation of the valvular endocardium, several workers designate endocarditis on the basis of anatomic area of the involved endocardium such as: *valvular* for valvular endocardium, *mural* for inner lining of the lumina of cardiac chambers, *chordal* for the endocardium

Table 14.6 Classification of endocarditis.

| | |
|----|--|
| A. | NON-INFECTIVE |
| | 1. Rheumatic endocarditis (page 420) |
| | 2. Atypical verrucous (Libman-Sacks) endocarditis |
| | 3. Non-bacterial thrombotic (cachectic, marantic) endocarditis |
| B. | INFECTIVE |
| | 1. Bacterial endocarditis |
| | 2. Other infective types (tuberculous, syphilitic, fungal, viral, rickettsial) |

of the chordae tendineae, *trabecular* for the endocardium of trabeculae carneae, and *papillary* for the endocardium covering the papillary muscles. Endocarditis can be broadly grouped into *non-infective* and *infective* types (**Table 14.6**). Most types of endocarditis are characterised by the presence of 'vegetations' or 'verrucae' which have distinct features.

ATYPICAL VERRUCOUS (LIBMAN-SACKS) ENDOCARDITIS

Libman and Sacks, two American physicians, described a form of endocarditis in 1924 that is characterised by sterile endocardial vegetations which are distinguishable from the vegetations of RHD and bacterial endocarditis.

ETIOPATHOGENESIS Atypical verrucous endocarditis is one of the manifestations of 'collagen diseases'. Characteristic lesions of Libman-Sacks endocarditis are seen in 50% cases of *acute systemic lupus erythematosus (SLE)*; other diseases associated with this form of endocarditis are systemic sclerosis, thrombotic thrombocytopenic purpura (TTP) and other collagen diseases.

MORPHOLOGIC FEATURES *Grossly*, characteristic vegetations occur most frequently on the mitral and tricuspid valves. The vegetations of atypical verrucous endocarditis are small (1 to 4 mm in diameter), granular, multiple and tend to occur on both surfaces of affected valves, in the valve pockets and on the adjoining ventricular and atrial endocardium. The vegetations are sterile unless superimposed by bacterial endocarditis. Unlike vegetations of RHD, the healed vegetations of Libman-Sacks endocarditis do not produce any significant valvular deformity. Frequently, fibrinous or serofibrinous pericarditis with pericardial effusion is associated.

Microscopically, the verrucae of Libman-Sacks endocarditis are composed of fibrinoid material with superimposed fibrin and platelet thrombi. The endocardium underlying the verrucae shows characteristic histological changes which include fibrinoid necrosis, proliferation of capillaries and infiltration by histiocytes, plasma cells, lymphocytes, neutrophils and the pathognomonic *haematoxylin bodies* of *Gross* which are counterparts of LE cells of the blood. Similar inflammatory changes may be found in the interstitial connective tissue of the myocardium. The Aschoff bodies are never found in the endocardium or myocardium.

NON-BACTERIAL THROMBOTIC (CACHECTIC, MARANTIC) ENDOCARDITIS

Non-bacterial thrombotic, cachectic, marantic or terminal endocarditis or endocarditis simplex is an involvement of the heart valves by sterile thrombotic vegetations.

ETIOPATHOGENESIS The exact pathogenesis of lesions in non-bacterial thrombotic endocarditis (NBTE) is not clear. Vegetations are found at autopsy in 0.5 to 5% of cases. Following diseases and conditions are frequently associated with their presence:

1. In patients having *hypercoagulable state* from various etiologies e.g. advanced cancer (in 50% case of NBTE) especially mucinous adenocarcinomas, chronic tuberculosis, renal failure and chronic sepsis. In view of its association with chronic debilitating and wasting diseases, alternate names for NBTE such as 'cachectic', 'marantic' and 'terminal' endocarditis are used synonymously.

2. Occurrence of these lesions in young and well-nourished patients is explained on the basis of *alternative hypothesis* such as allergy, vitamin C deficiency, deep vein thrombosis, and endocardial trauma (e.g. due to catheter in pulmonary artery and haemodynamic trauma to the valves).

MORPHOLOGIC FEATURES *Grossly*, the verrucae of NBTE are located on cardiac valves, chiefly mitral, and less often aortic and tricuspid valve. These verrucae are usually small (1 to 5 mm in diameter), single or multiple, brownish and occur along the line of closure of the leaflets but are more friable than the vegetations of RHD. Organised and healed vegetations appear as fibrous nodules. Normal age-related appearance of tag-like appendage at the margin of the valve cusps known as 'Lamb's excrescences' is an example of such healed lesions.

Microscopically, the vegetations in NBTE are composed of fibrin along with entangled RBCs, WBCs and platelets. Vegetations in NBTE are sterile, bland and do not cause tissue destruction. The underlying valve shows swollen collagen, fibrinoid change and capillary proliferation but does not show any inflammatory infiltrate.

Embolic phenomenon is seen in many cases of NBTE and results in infarcts in the brain, lungs, spleen and kidneys. The bland vegetations of NBTE on infection may produce bacterial endocarditis.

INFECTIVE (BACTERIAL) ENDOCARDITIS

DEFINITION Infective or bacterial endocarditis (IE or BE) is serious infection of the valvular and mural endocardium caused by different forms of microorganisms and is characterised by typical infected and friable vegetations. A few specific forms of IE are named by the microbial etiologic agent causing them e.g. tubercle bacilli, fungi etc. Depending upon the severity of infection, BE is subdivided into 2 clinical forms:

1. **Acute bacterial endocarditis (ABE)** is fulminant and destructive acute infection of the endocardium by highly virulent bacteria in a previously normal heart and almost invariably runs a rapidly fatal course in a period of 2-6 weeks.

2. **Subacute bacterial endocarditis (SABE) or endocarditis lenta** (*lenta* = slow) is caused by less virulent bacteria in a

Table 14.7 Distinguishing features of acute and subacute bacterial endocarditis.

| FEATURE | ACUTE | SUBACUTE |
|--|--|--|
| 1. <i>Duration</i> | <6 weeks | >6 weeks |
| 2. <i>Most common organisms</i> | <i>Staph. aureus</i> , β-streptococci | <i>Streptococcus viridans</i> |
| 3. <i>Virulence of organisms</i> | Highly virulent | Less virulent |
| 4. <i>Previous condition of valves</i> | Usually previously normal | Usually previously damaged |
| 5. <i>Lesion on valves</i> | Invasive, destructive, suppurative | Usually not invasive or suppurative |
| 6. <i>Clinical features</i> | Features of acute systemic infection | Splenomegaly, clubbing of fingers, petechiae |

previously diseased heart and has a gradual downhill course in a period of 6 weeks to a few months and sometimes years.

Although classification of bacterial endocarditis into acute and subacute forms has been largely discarded because the clinical course is altered by antibiotic treatment, still a few important distinguishing features are worth noting (**Table 14.7**). However, features of the vegetations in the two forms of BE are difficult to distinguish.

INCIDENCE Introduction of antibiotic drugs has helped greatly in lowering the incidence of BE as compared with its incidence in the pre-antibiotic era. Though BE may occur at any age, most cases of ABE as well as SABE occur over 50 years of age. Males are affected more often than females.

ETIOLOGY All cases of BE are caused by *infection with microorganisms* in patients having certain *predisposing factors*.

A. Infective agents About 90% cases of BE are caused by streptococci and staphylococci.

◆ *In ABE*, the most common causative organisms are virulent strains of staphylococci, chiefly *Staphylococcus aureus*. Others are pneumococci, gonococci, β-streptococci and enterococci.

◆ *In SABE*, the commonest causative organisms are the streptococci with low virulence, predominantly *Streptococcus viridans*, which forms part of normal flora of the mouth and pharynx. Other less common etiologic agents include other strains of streptococci and staphylococci (e.g. *Streptococcus bovis* which is the normal inhabitant of gastrointestinal tract, *Streptococcus pneumoniae*, and *Staphylococcus epidermidis* which is a commensal of the skin), gram-negative enteric bacilli (e.g. *E. coli*, *Klebsiella*, *Pseudomonas* and *Salmonella*), pneumococci, gonococci and *Haemophilus influenzae*.

B. Predisposing factors There are 3 main types of factors which predispose to the development of both forms of BE:

◆ Conditions initiating transient bacteraemia, septicaemia and pyaemia.

◆ Underlying heart disease.

◆ Impaired host defenses.

1. *Bacteraemia, septicaemia and pyaemia*: Bacteria gain entry to the blood stream causing transient and clinically silent bacteraemia in a variety of day-to-day procedures as well as from other sources of infection. Some of the common examples are:

- i) Periodontal infections such as trauma from vigorous brushing of teeth, hard chewing, tooth extraction and other dental procedures.
- ii) Infections of the genitourinary tract such as in catheterisation, cystoscopy, obstetrical procedures including normal delivery and abortions.
- iii) Infections of gastrointestinal and biliary tract.
- iv) Surgery of the bowel, biliary tract and genitourinary tracts.
- v) Skin infections such as boils, carbuncles and abscesses.
- vi) Upper and lower respiratory tract infections including bacterial pneumonias.
- vii) Intravenous drug abuse.
- viii) Cardiac catheterisation and cardiac surgery for implantation of prosthetic valves.

2. *Underlying heart disease:* SABE occurs much more frequently in previously diseased heart valves, whereas the ABE is common in previously normal heart. Amongst the commonly associated underlying heart diseases are the following:

- i) Chronic rheumatic valvular disease in about 50% cases.
- ii) Congenital heart diseases in about 20% cases. These include VSD, subaortic stenosis, pulmonary stenosis, bicuspid aortic valve, coarctation of the aorta, and PDA.
- iii) Other causes are syphilitic aortic valve disease, atherosclerotic valvular disease, floppy mitral valve, and prosthetic heart valves.

3. *Impaired host defenses:* All conditions in which there is depression of specific immunity, deficiency of complement and defective phagocytic function, predispose to BE. Following are some of the examples of such conditions:

- i) Impaired specific immunity in lymphomas.

- ii) Leukaemias.

iii) Cytotoxic therapy for various forms of cancers and transplant patients.

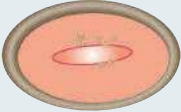

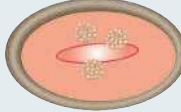

- iv) Deficient functions of neutrophils and macrophages.

PATHOGENESIS Bacteria causing BE on entering the blood stream from any of the above-mentioned routes are implanted on the cardiac valves or mural endocardium because they have surface adhesion molecules which mediate their adherence to injured endocardium. There are several predisposing conditions which explain the development of bacterial implants on the valves:

1. The circulating bacteria are lodged much more frequently on *previously damaged valves* from diseases, chiefly RHD, congenital heart diseases and prosthetic valves, than on healthy valves.
2. Conditions producing *haemodynamic stress* on the valves are liable to cause damage to the endothelium, favouring the formation of platelet-fibrin thrombi which get infected from circulating bacteria.
3. Another alternative hypothesis is the occurrence of *non-bacterial thrombotic endocarditis* from prolonged stress which is followed by bacterial contamination.

MORPHOLOGIC FEATURES The characteristic pathologic feature in both ABE and SABE is the presence of typical vegetations or verrucae on the valve cusps or leaflets, and less often, on mural endocardium, which are quite distinct for other types. A summary of the distinguishing features of the principal types of vegetations is presented in **Table 14.8**.

Table 14.8 Distinguishing features of vegetations in major forms of endocarditis.

| FEATURE | RHEUMATIC | LIBMAN-SACKS | NON-BACTERIAL THROMBOTIC | BACTERIAL (INFECTIVE) |
|---|---|---|---|--|
| 1. <i>Valves commonly affected</i> | Mitral alone; mitral and aortic combined | Mitral, tricuspid | Mainly mitral; less often aortic and tricuspid | Mitral; aortic; combined mitral and aortic |
| 2. <i>Location on valve cusps or leaflets</i> | Occur along the line of closure, atrial surface of atrioventricular valves and ventricular surface of semilunar valves | Occur on both surfaces of valve leaflets or cusps, in the valve pockets | Occur along the line of closure | SABE more often on diseased valves; ABE on previously normal valves; location same as in RHD |
| 3. <i>Macroscopy</i> |  Small, multiple, warty, grey brown, translucent, firmly attached, generally produce permanent valvular deformity |  Medium-sized, multiple, generally do not produce significant valvular deformity |  Small but larger than those of rheumatic, single or multiple, brownish, firm, but more friable than those of rheumatic |  Often large, grey-tawny to greenish, irregular, single or multiple, typically friable |
| 4. <i>Microscopy</i> | Composed of fibrin with superimposed platelet thrombi and no bacteria, Adjacent and underlying endocardium shows oedema, proliferation of capillaries, mononuclear inflammatory infiltrate and occasional Aschoff bodies. | Composed of fibrinoid material with superimposed fibrin and platelet thrombi and no bacteria. The underlying endocardium shows fibrinoid necrosis, proliferation of capillaries and acute and chronic inflammatory infiltrate including the haematoxylin bodies of Gross. | Composed of degenerated valvular tissue, fibrin-platelets thrombi and no bacteria. The underlying valve shows swelling of collagen, fibrinoid change, proliferation of capillaries but no significant inflammatory cell infiltrate. | Composed of outer eosinophilic zone of fibrin and platelets, covering colonies of bacteria and deeper zone of non-specific acute and chronic inflammatory cells. The underlying endocardium may show abscesses in ABE and inflammatory granulation tissue in the SABE. |

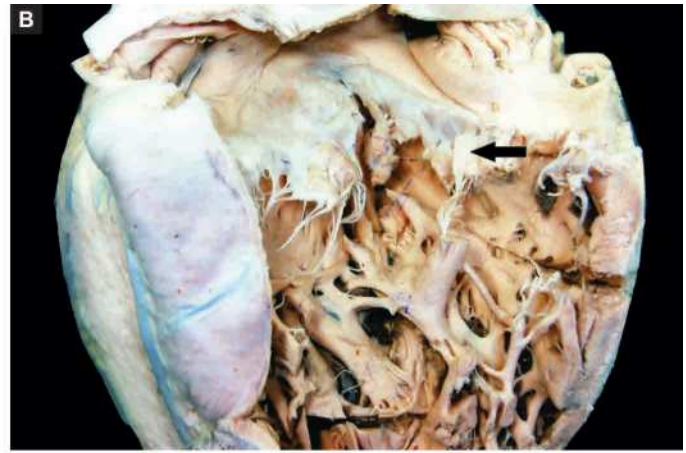

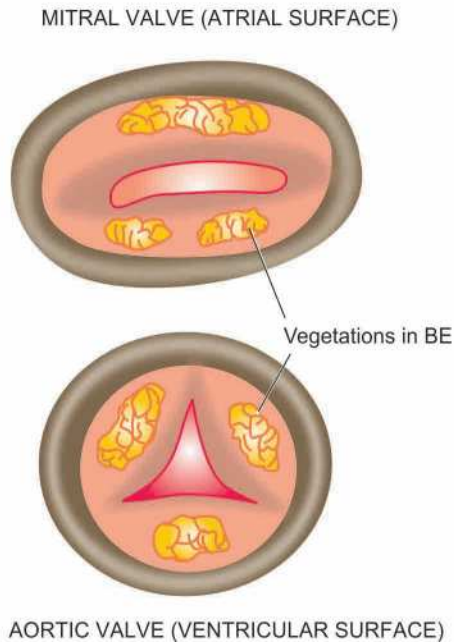

Figure 14.29 Infective endocarditis. A, Location of vegetations on the valves of the left heart. The vegetations are shown on the mitral valve (left upper diagram) as viewed from the left atrium, while those on the aortic valve (left lower diagram) are shown as seen from the left ventricle. B, Vegetations on valves in infective endocarditis. Opened up chambers and valves of the left heart show presence of irregular, soft, elevated grey white friable vegetations on the atrial (superior) surface of the mitral valve (arrow).

Grossly, the lesions are found commonly on the valves of the left heart, most frequently on the mitral, followed in descending frequency, by the aortic, simultaneous involvement of both mitral and aortic valves, and quite rarely on the valves of the right heart. The vegetations in SABE are more often seen on previously diseased valves, whereas the vegetations of ABE are often found on previously normal valves. Like in RHD, the vegetations are often located on the atrial surface of atrioventricular valves and ventricular surface of the semilunar valves. They begin from the contact areas of the valve and may extend along the surface of the valves and on to the adjacent endocardium (**Fig. 14.29**).

The *vegetations* of BE vary in size from a few millimeters to several centimeters, grey-tawny to greenish, irregular, single or multiple, and typically *friable*. They may appear

flat, filiform, fungating or polypoid. The vegetations in ABE tend to be bulkier and globular than those of SABE and are located more often on previously normal valves, may cause ulceration or perforation of the underlying valve leaflet, or may produce myocardial abscesses.

Microscopically, the vegetations of BE consist of 3 zones (**Fig. 14.30**):

- i) The *outer layer or cap* consists of eosinophilic material composed of fibrin and platelets.
- ii) Underneath this layer is the *basophilic zone* containing colonies of bacteria. However, bacterial component of the vegetations may be lacking in treated cases.
- iii) The *deeper zone* consists of non-specific inflammatory reaction in the cusp itself, and in the case of SABE there may be evidence of repair.

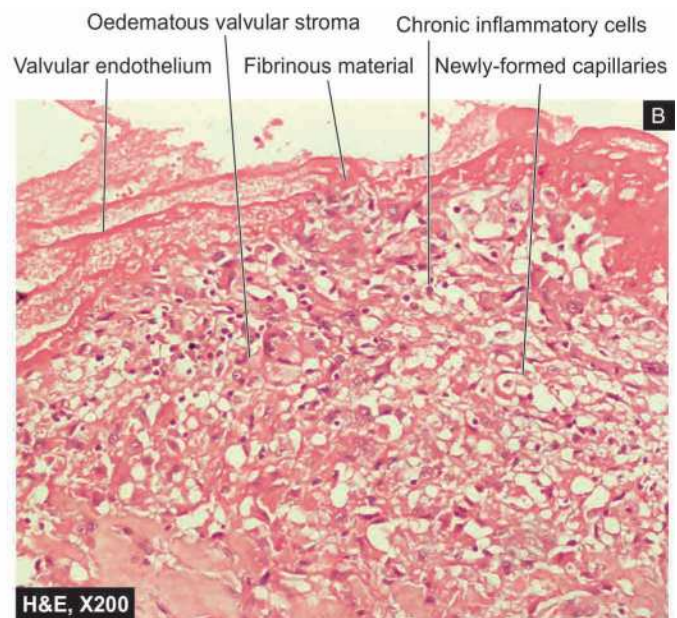

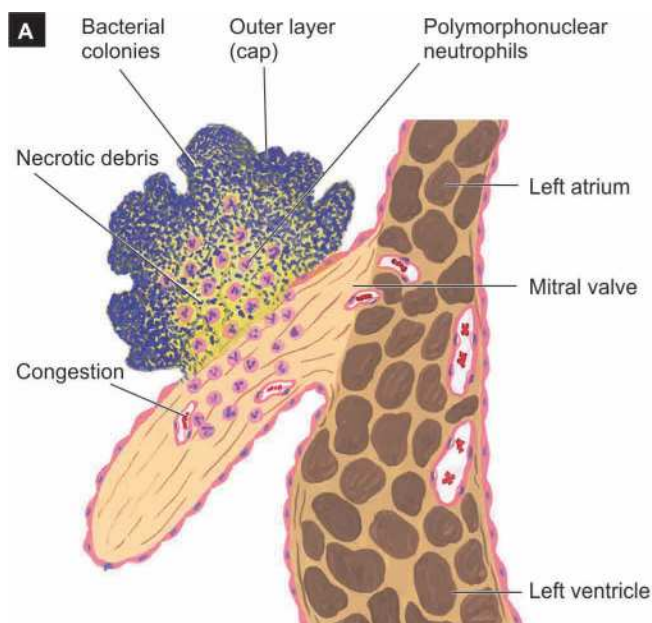

Figure 14.30 Infective endocarditis. A, Microscopic structure of a vegetation of BE on the surface of mitral valve in sagittal section. B, Section of the mitral valve shows fibrin cap on luminal surface, layer of bacteria, and deeper zone of inflammatory cells, with prominence of neutrophils.

In the acute fulminant form of the disease, the inflammatory cell infiltrate chiefly consists of neutrophils and is accompanied with tissue necrosis and abscesses in the valve rings and in the myocardium. In the subacute form, there is healing by granulation tissue, mononuclear inflammatory cell infiltration and fibroblastic proliferation. Histological evidence of pre-existing valvular disease such as RHD may be present in SABE.

COMPLICATIONS AND SEQUELAE Most cases of BE present with fever. The acute form of BE is characterised by high grade fever, chills, weakness and malaise while the subacute form of the disease has non-specific manifestations like slight fever, fatigue, loss of weight and flu-like symptoms. In the early stage, the lesions are confined to the heart, while subsequent progression of the disease leads to involvement of extra-cardiac organs. In general, severe complications develop early in ABE than in SABE. Complications and sequelae of BE are divided into cardiac and extracardiac (**Fig. 14.31**):

A. Cardiac complications These include the following:

- i) Valvular stenosis or insufficiency
- ii) Perforation, rupture, and aneurysm of valve leaflets
- iii) Abscesses in the valve ring
- iv) Myocardial abscesses
- v) Suppurative pericarditis
- vi) Cardiac failure from one or more of the foregoing complications.

B. Extracardiac complications Since the vegetations in BE are typically friable, they tend to get dislodged due to rapid stream of blood and give rise to embolism which is responsible for very common and serious extra-cardiac complications. These are as follows:

- i) Emboli originating from the *left side of the heart* and entering the systemic circulation affect organs like the spleen,

kidneys, and brain causing infarcts, abscesses and mycotic aneurysms.

ii) Emboli arising from *right side of the heart* enter the pulmonary circulation and produce pulmonary abscesses.

iii) *Petechiae* may be seen in the skin and conjunctiva due to either emboli or toxic damage to the capillaries.

iv) In SABE, there are painful, tender nodules on the finger tips of hands and feet called *Osler's nodes*, while in ABE there is appearance of painless, non-tender subcutaneous maculopapular lesions on the pulp of the fingers called *Janeway's spots*. In either case, their origin is due to toxic or allergic inflammation of the vessel wall.

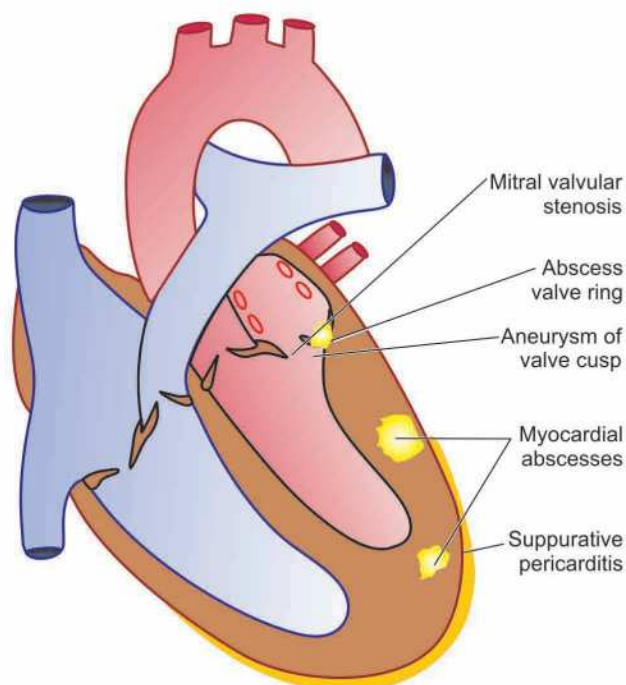

v) *Focal necrotising glomerulonephritis* is seen more commonly in SABE than in ABE. Occasionally diffuse glomerulonephritis may occur. Both these have their pathogenesis in circulating immune complexes (hypersensitivity phenomenon) (page 654).

Treatment of BE with antibiotics in adequate dosage kills the bacteria but complications and sequelae of healed endocardial lesions may occur even after successful therapy. The *causes of death* are cardiac failure, persistent infection, embolism to vital organs, renal failure and rupture of mycotic aneurysm of cerebral arteries.

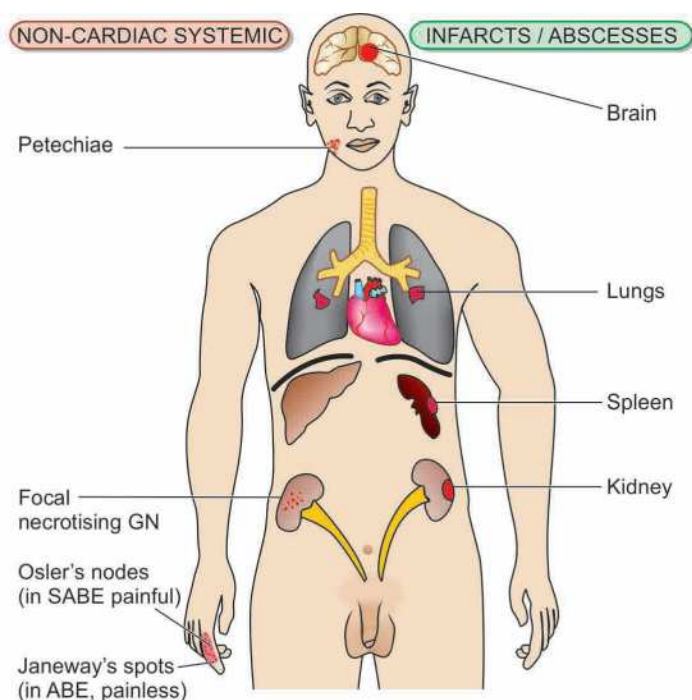

SPECIFIC TYPES OF INFECTIVE ENDOCARDITIS

Besides BE, various other microbes may occasionally produce infective endocarditis which are named according to the etiologic agent causing it. These include the following:

1. Tuberculous endocarditis Though tubercle bacilli are bacteria, tuberculous endocarditis is described separate from the bacterial endocarditis due to specific granulomatous inflammation found in tuberculosis. It is characterised by presence of typical tubercles on the valvular as well as mural endocardium and may form tuberculous thromboemboli.

A, CARDIAC SEQUELAE OF INFECTIVE ENDOCARDITIS

B, EXTRA-CARDIAC COMPLICATIONS

Figure 14.31 Complications and sequelae of infective endocarditis.

2. Syphilitic endocarditis The endocardial lesions in syphilis have already been described in relation to syphilitic aortitis on page 381. The severest manifestation of cardiovascular syphilis is aortic valvular incompetence.

3. Fungal endocarditis Rarely, endocardium may be infected with fungi such as from *Candida albicans*, *Histoplasma capsulatum*, *Aspergillus*, *Mucor*, coccidioidomycosis, cryptococcosis, blastomycosis and actinomycosis. Opportunistic fungal infections like candidiasis and aspergillosis are seen more commonly in patients receiving long-term antibiotic therapy, intravenous drug abusers and after prosthetic valve replacement. Fungal endocarditis produces an appearance similar to that in BE but the vegetations are bulkier in fungal endocarditis.

4. Viral endocarditis There is only experimental evidence of existence of this entity.

5. Rickettsial endocarditis Another rare cause of endocarditis is from infection with rickettsiae in Q fever.

GIST BOX 14.8

Non-rheumatic Endocarditis

- Endocarditis can be *non-infective* and *infective* types; most types are characterised by the presence of 'vegetations' or 'verrucae'.
- Atypical verrucous endocarditis is a manifestation of collagen diseases. Vegetations are small, granular and multiple.
- Non-bacterial thrombotic endocarditis is an involvement of the heart valves by sterile thrombotic vegetations, often preceded by hypercoagulable state.
- Infective or bacterial endocarditis occurs following conditions initiating transient bacteraemia, septicaemia and pyaemia, underlying heart disease and impaired host defenses. It is characterised by typical infected and friable vegetations.
- Since vegetations in BE are typically friable, they tend to get dislodged due to rapid stream of blood and give rise to embolism and cause serious extra-cardiac complications.

3. Non-bacterial thrombotic endocarditis (page 425)
4. Libman-Sacks endocarditis (page 424)
5. Syphilitic valvulitis (page 431)
6. Calcific aortic valve stenosis
7. Calcification of mitral annulus
8. Myxomatous degeneration (floppy valve syndrome)
9. Carcinoid heart disease.

The major forms of vegetative endocarditis involving the valves have already been described. Others along with the consequences of these valvular diseases in the form of stenosis and insufficiency of the heart valves are described below.

MITRAL STENOSIS

Mitral stenosis occurs in approximately 40% of all patients with RHD. About 70% of the patients are women. The latent period between the rheumatic carditis and development of symptomatic mitral stenosis is about two decades.

ETIOLOGY Mitral stenosis is generally rheumatic in origin. Less common causes include bacterial endocarditis, Libman-Sacks endocarditis, endocardial fibroelastosis and congenital parachute mitral valve.

MORPHOLOGIC FEATURES The appearance of the mitral valve in stenosis varies according to the extent of involvement. Generally, the valve leaflets are diffusely thickened by fibrous tissue and/or calcific deposits, especially towards the closing margin. There are fibrous adhesions of mitral commissures and fusion and shortening of chordae tendineae. In less extensive involvement, the bases of the leaflets of mitral valve are mobile while the free margins have puckered and thickened tissue with narrowed orifice; this is called as '*purse-string puckering*'. The more advanced cases have rigid, fixed and immobile diaphragm-like valve leaflets with narrow, slit-like or oval mitral opening, commonly referred to as '*button-hole*' or '*fish-mouth*' mitral orifice (Fig. 14.32,B).

EFFECTS In normal adults, the mitral orifice is about 5 cm². Symptomatic mitral stenosis develops if the valve opening is reduced to 1 cm² resulting in significant elevation of left atrial pressure from the normal of 12 mmHg to about 25 mmHg leading to dilatation of the left atrium. Elevated left atrial pressure, in turn, raises pressure in the pulmonary veins and capillaries, reducing the pulmonary function and causing exertional dyspnoea which is the chief symptom of mitral stenosis. The effects of mitral stenosis can thus be summarised as under:

1. Dilatation and hypertrophy of the left atrium.
2. Normal-sized or atrophic left ventricle due to reduced inflow of blood.
3. Pulmonary hypertension resulting from passive backward transmission of elevated left atrial pressure which causes:
 - i) chronic passive congestion of the lungs;
 - ii) hypertrophy and dilatation of the right ventricle; and
 - iii) dilatation of the right atrium when right heart failure supervenes.

MITRAL INSUFFICIENCY

Mitral insufficiency is caused by RHD in about 50% of patients but in contrast to mitral stenosis, pure mitral insufficiency

VALVULAR DISEASES AND DEFORMITIES

Valvular diseases are various forms of congenital and acquired diseases which cause valvular deformities. Many of them result in cardiac failure. Rheumatic heart disease is the most common form of acquired valvular disease. Valves of the left side of the heart are involved much more frequently than those of the right side of the heart. The mitral valve is affected most often, followed in descending frequency, by the aortic valve, and combined mitral and aortic valves. The valvular deformities may be of 2 types: stenosis and insufficiency:

◆ *Stenosis* is the term used for failure of a valve to open completely during diastole resulting in obstruction to the forward flow of the blood.

◆ *Insufficiency or incompetence or regurgitation* is the failure of a valve to close completely during systole resulting in back flow or regurgitation of the blood.

The congenital valvular diseases have already been described (page 406). Various acquired valvular diseases that may deform the heart valves are listed below:

1. RHD, the commonest cause (page 418)
2. Infective endocarditis (page 425)

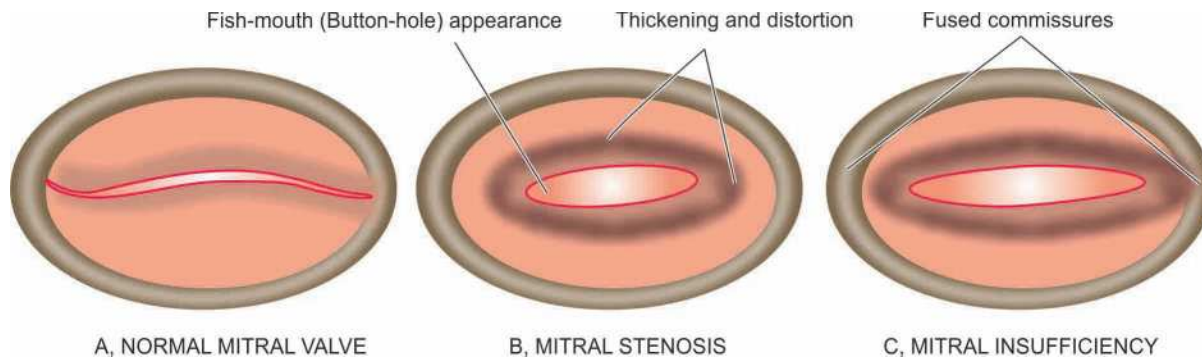

Figure 14.32 Mitral valve disease. Normal mitral valve (A) contrasted with mitral stenosis (B) and mitral insufficiency (C).

occurs more often in men (75%). Subsequently, mitral insufficiency is associated with some degree of mitral stenosis.

ETIOLOGY All the causes of mitral stenosis may produce mitral insufficiency, RHD being the most common cause. In addition, mitral insufficiency may result from non-inflammatory calcification of mitral valve annulus (in the elderly), myxomatous transformation of mitral valve (floppy valve syndrome), rupture of a leaflet or of the chordae tendineae or of a papillary muscle. A few other conditions cause mitral insufficiency by dilatation of the mitral ring such as in myocardial infarction, myocarditis and left ventricular failure in hypertension.

MORPHOLOGIC FEATURES The appearance of the mitral valve in insufficiency varies according to the underlying cause. The rheumatic process produces rigidity, deformity and retraction of the valve leaflets and fusion of commissures as well as shortening and fusion of chordae tendineae (**Fig. 14.32,C**).

◆ In *myxomatous degeneration* of the mitral valve leaflets (floppy valve syndrome) which is described on page 431, there is prolapse of one or both leaflets into the left atrium during systole.

◆ In *non-inflammatory calcification* of mitral annulus seen in the aged, there is irregular, stony-hard, bead-like thickening in the region of mitral annulus without any associated inflammatory changes. It is thought to reflect degenerative changes of ageing.

EFFECTS The regurgitant mitral orifice produces progressive increase in left ventricular end-diastolic volume as well as pressure since the left ventricle cannot empty completely. This results in rise in left atrial pressure and dilatation. As a consequence of left atrial hypertension, pulmonary hypertension occurs resulting in pulmonary oedema and right heart failure. In symptomatic cases of mitral insufficiency, the major symptoms are related to decreased cardiac output (e.g. fatigue and weakness) and due to pulmonary congestion (e.g. exertional dyspnoea and orthopnoea) but the features are less well marked than in mitral stenosis. The effects of mitral insufficiency are summarised as under:

1. Dilatation and hypertrophy of the left ventricle.
2. Marked dilatation of the left atrium.
3. Features of pulmonary hypertension such as:
 - i) chronic passive congestion of the lungs;
 - ii) hypertrophy and dilatation of the right ventricle; and
 - iii) dilatation of the right atrium when right heart failure supervenes.

AORTIC STENOSIS

Aortic stenosis comprises about one-fourth of all patients with chronic valvular heart disease. About 80% patients of symptomatic aortic stenosis are males. It is of 2 main types: non-calcific and calcific type, the latter being more common.

1. Non-calcific aortic stenosis The most common cause of non-calcific aortic stenosis is chronic RHD. Other causes are congenital valvular and subaortic stenosis and congenitally bicuspid aortic valve.

2. Calcific aortic stenosis Calcific aortic stenosis is more common type. Various causes have been assigned to it. These include healing by scarring followed by calcification of aortic valve such as in RHD, bacterial endocarditis, *Brucella* endocarditis, Mönckeberg's calcific aortic stenosis (page 372), healed congenital malformation and familial hypercholesterolaemic xanthomatosis.

MORPHOLOGIC FEATURES The aortic cusps show characteristic fibrous thickening and calcific nodularity of the closing edges. Calcified nodules are often found in the sinuses of Valsalva. In rheumatic aortic stenosis, the commissures are fused and calcified, while in non-rheumatic aortic stenosis there is no commissural fusion (**Fig. 14.33,B**).

EFFECTS Aortic stenosis becomes symptomatic when the valve orifice is reduced to 1 cm² from its normal 3 cm². The symptoms appear many years later when the heart cannot compensate and the stenosis is quite severe. The major effect of aortic stenosis is obstruction to the outflow resulting in concentric hypertrophy of the left ventricle. Later, when cardiac failure supervenes, there is dilatation as well as hypertrophy of the left ventricle (eccentric hypertrophy).

The *three cardinal symptoms* of aortic stenosis are: exertional dyspnoea, angina pectoris and syncope.

- ◆ Exertional dyspnoea results from elevation of pulmonary capillary pressure.
- ◆ Angina pectoris usually results from elevation of pulmonary capillary pressure and usually develops due to increased demand of hypertrophied myocardial mass.
- ◆ Syncope results from accompanying coronary insufficiency. Sudden death may also occur in an occasional case of aortic stenosis.

AORTIC INSUFFICIENCY

About three-fourth of all patients with aortic insufficiency are males with some having family history of Marfan's syndrome.

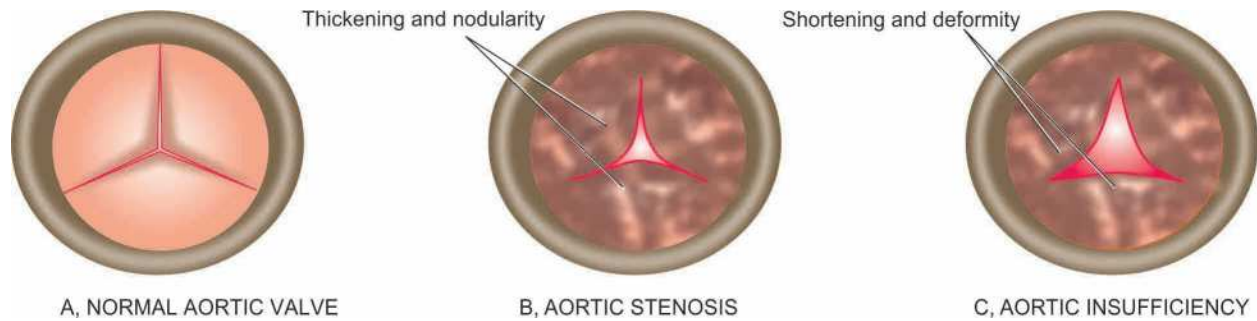

Figure 14.33 Aortic valve diseases. Normal aortic valve (A) contrasted with aortic stenosis (B) and aortic insufficiency (C).

ETIOLOGY In about 75% of patients, the cause is chronic RHD. However, isolated aortic insufficiency is less often due to rheumatic etiology. Other causes include syphilitic valvulitis, infective endocarditis, congenital subaortic stenosis (congenitally bicuspid aortic valve), myxomatous degeneration of aortic valve (floppy valve syndrome), traumatic rupture of the valve cusps, dissecting aneurysm, Marfan's syndrome and ankylosing spondylitis.

MORPHOLOGIC FEATURES The aortic valve cusps are thickened, deformed and shortened and fail to close. There is generally distension and distortion of the ring (Fig. 14.32,C).

EFFECTS As a result of regurgitant aortic orifice, there is increase of the left ventricular end-diastolic volume. This leads to hypertrophy and dilatation of the left ventricle producing massive cardiac enlargement so that the heart may weigh as much as 1000 gm. Failure of the left ventricle increases the pressure in the left atrium and eventually pulmonary hypertension and right heart failure occurs.

The characteristic physical findings in a patient of aortic insufficiency are awareness of the beatings of the heart, poundings in the head with each heartbeat, low diastolic and high pulse pressure, rapidly rising and collapsing water hammer pulse (Corrigan's pulse), booming 'pistol shot' sound over the femoral artery, and systolic and diastolic murmur heard over the femoral artery when it is lightly compressed (Durozier's sign). Sometimes, angina pectoris occurs due to increased myocardial demand or due to coronary insufficiency.

CARCINOID HEART DISEASE

ETIOLOGY Carcinoid syndrome developing in patients with extensive hepatic metastases from a carcinoid tumour is characterised by cardiac manifestations in about half the cases (page 559). The lesions are characteristically located in the valves and endocardium of the right side of the heart. The pathogenesis of the cardiac lesions is not certain. But in carcinoid tumour with hepatic metastasis, there is increased blood level of serotonin secreted by the tumour. The increased concentration of serotonin reaches the right side of the heart and causes the lesions but serotonin is inactivated on passage of the blood through the lungs and hence the left heart is relatively spared. In addition, high levels of bradykinin may play contributory role in carcinoid heart disease. However, chronic infusion of serotonin or bradykinin in experimental animals has not succeeded in producing cardiac lesions; hence

the exact pathogenesis of carcinoid heart disease remains obscure.

MORPHOLOGIC FEATURES In majority of cases, the lesions are limited to the right side of the heart. Both pulmonary and tricuspid valves as well as the endocardium of the right chambers show characteristic cartilage-like fibrous plaques. Similar plaques may occur on the intima of the great veins, the coronary sinus and the great arteries. Occasionally, the lesions may be found on the left side of the heart.

EFFECTS The thickening and contraction of the cusps and leaflets of the valves of the outflow tracts of the right heart result mainly in pulmonary stenosis and tricuspid regurgitation, and to a lesser extent, pulmonary regurgitation and tricuspid stenosis.

MYXOMATOUS DEGENERATION OF MITRAL VALVE (MITRAL VALVE PROLAPSE)

Myxomatous or mucoid degeneration of the valves of the heart is a peculiar condition occurring in young patients between the age of 20 and 40 years and is more common in women. The condition is common and seen in 5% of general adult population. The condition is also known by other synonyms like 'floppy valve syndrome' or 'mitral valve prolapse'.

ETIOLOGY The cause of the condition is not known but in some cases it may be genetically determined collagen disorder. Association with Marfan's syndrome has been observed in 90% of patients. Others have noted myxomatous degeneration in cases of Ehlers-Danlos syndrome and in myotonic dystrophy. However, the myxomatous valvular changes seen in the aged patients are not related to this entity.

MORPHOLOGIC FEATURES Any cardiac valve may be involved but mitral valve is affected most frequently. The disease is usually most severe and most common in the posterior leaflet of the mitral valve. The affected leaflet shows either excessive or redundant leaflet tissue, which is opaque white, soft and floppy. Cut section of the valve reveals mucoid or myxoid appearance. A significant feature is the ballooning or aneurysmal protrusion of the affected leaflet and hence the name 'mitral valve prolapse' and 'floppy valve syndrome'.

Microscopically, the enlarged cusp shows loose connective tissue with abundant mucoid or myxoid material due to abundance of mucopolysaccharide.

EFFECTS Usually the condition does not produce any symptoms or significant valvular dysfunction. The condition is recognised during life by the characteristic mid-systolic click followed by a systolic murmur due to mildly incompetent mitral valve caused by the mitral valve prolapse. Occasionally, complications may develop such as superimposed infective endocarditis, mitral insufficiency and arrhythmias. Rarely, sudden death from serious ventricular arrhythmias may occur.

GIST BOX 14.9 Valvular Diseases and Deformities.

- ▣ Valvular diseases may be congenital or acquired and cause valvular deformities.
- ▣ RHD is the most common form of acquired valvular disease.
- ▣ Valves of the left side of the heart, particularly mitral valve, are involved much more often.
- ▣ Mitral stenosis, often from RHD, is accompanied with dilatation and hypertrophy of the left atrium.
- ▣ Mitral insufficiency causes dilatation and hypertrophy of the left ventricle.
- ▣ In aortic stenosis, aortic cusps show fibrous thickening and calcific nodularity of the closing edges, while in aortic insufficiency aortic valve cusps are thickened, deformed and shortened and fail to close.
- ▣ In carcinoid heart disease, the lesions are limited to the right side of the heart, i.e. both pulmonary and tricuspid valves.
- ▣ Myxomatous degeneration of mitral valve is associated with Marfan's syndrome and causes mitral valve prolapse.

MYOCARDIAL DISEASES

Involvement of the myocardium occurs in three major forms of diseases already discussed—*ischaemic heart disease*, *hypertensive heart disease* and *rheumatic heart disease*. In addition, there are two other broad groups of isolated myocardial diseases:

- I. *Myocarditis* i.e. inflammatory involvement of the myocardium
- II. *Cardiomyopathy* i.e. a non-inflammatory myocardial involvement.

MYOCARDITIS

Inflammation of the heart muscle is called myocarditis. It is a rather common form of heart disease that can occur at any age. Its exact incidence is difficult to ascertain as the histological examination has been largely confined to autopsy material. Reports from different studies have estimated the incidence of myocarditis in 1 to 4% of all autopsies.

A number of classifications of myocarditis have been proposed in the past as follows:

- ◆ *Interstitial and parenchymatous type*, depending upon whether the inflammation is confined to interstitial tissue or the parenchyma.
- ◆ *Specific and non-specific type*, depending upon whether the inflammation is granulomatous or non-specific type.
- ◆ *Acute, subacute and chronic type*, depending upon the duration of inflammatory response.

Table 14.9 Etiologic classification of myocarditis.

- I. INFECTIVE MYOCARDITIS
 1. Viral myocarditis
 2. Suppurative myocarditis
 3. Toxic myocarditis
 4. Infective granulomatous myocarditis
 5. Syphilitic myocarditis
 6. Rickettsial myocarditis
 7. Protozoal myocarditis
 8. Helminthic myocarditis
 9. Fungal myocarditis
- II. IDIOPATHIC (FIEDLER'S) MYOCARDITIS
 1. Diffuse type
 2. Giant cell (idiopathic granulomatous) type
- III. MYOCARDITIS IN CONNECTIVE TISSUE DISEASES
 1. Rheumatoid arthritis
 2. Lupus erythematosus
 3. Polyarteritis nodosa
 4. Dermatomyositis
 5. Scleroderma
- IV. MISCELLANEOUS TYPES OF MYOCARDITIS
 1. Physical agents
 2. Chemical agents
 3. Drugs
 4. Immunologic agents
 5. Metabolic derangements

However, currently most commonly used is *etiologic classification* given in **Table 14.9**.

According to this classification, myocarditis is divided into 4 main etiologic types described below.

I. INFECTIVE MYOCARDITIS

A number of infectious agents such as bacteria, viruses, protozoa, parasites, fungi, rickettsiae and spirochaetes may cause myocarditis by direct invasion or by their toxins. Some of the common forms are described below.

1. VIRAL MYOCARDITIS A number of viral infections are associated with myocarditis. Some of the common examples are influenza, poliomyelitis, infectious mononucleosis, hepatitis, smallpox, chickenpox, measles, mumps, rubella, viral pneumonias, coxsackievirus and HIV infections. Cardiac involvement occurs in about 5% of viral infections. Viral myocarditis usually appears after a few days to a few weeks of viral infections elsewhere in the body. The damage to the myocardium is caused either by direct viral cytotoxicity or by cell-mediated immune reaction. Regardless of the type of virus, the pathologic changes are similar.

Grossly, the myocardium is pale and flabby with dilatation of the chambers. There may be focal or patchy areas of necrosis.

Histologically, there are changes of acute myocarditis. Initially, there is oedema and infiltration of the interstitial tissue by neutrophils and lymphocytes. Later, there is necrosis of individual myocardial fibres and the infiltrate consists of lymphocytes and macrophages (**Fig. 14.34**).

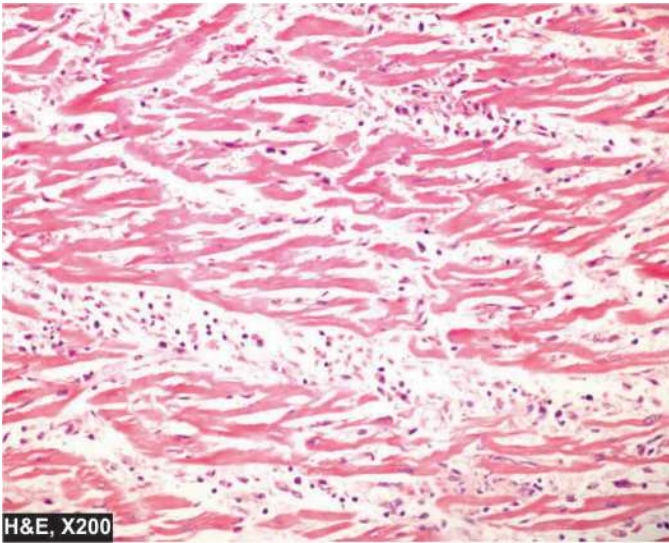

Figure 14.34 Lymphocytic myocarditis showing focal inflammatory destruction of myocardial fibres and lymphocytic infiltrate in the interstitial tissue.

2. SUPPURATIVE MYOCARDITIS Pyogenic bacteria, chiefly *Staphylococcus aureus* or *Streptococcus pyogenes*, which cause septicaemia and pyaemia may produce suppurative myocarditis. As already pointed out, acute bacterial endocarditis may sometimes cause bacterial myocarditis (page 425).

Grossly, There are either abscesses in the myocardium or there is diffuse myocardial involvement.

Microscopically, the exudate chiefly consists of neutrophils, admixed with lymphocytes, plasma cells and macrophages. There may be foci of myocardial degeneration and necrosis with areas of healing by fibrosis.

3. TOXIC MYOCARDITIS A number of acute bacterial infections produce myocarditis by toxins e.g. in diphtheria, typhoid fever and pneumococcal pneumonia.

Grossly, the appearance is similar to that seen in viral myocarditis.

Histologically, there are small foci of coagulative necrosis in the muscle which are surrounded by nonspecific acute and chronic inflammatory infiltrate.

Toxic myocarditis manifests clinically by cardiac arrhythmias or acute cardiac failure due to involvement of the conduction system. It may cause sudden death.

4. GRANULOMATOUS MYOCARDITIS Tuberculosis, brucellosis and tularaemia are some examples of bacterial infections characterised by granulomatous inflammation in the myocardium. Sarcoidosis, though not a bacterial infection, has histological resemblance to other granulomatous myocarditis. Tuberculous myocarditis is rare and occurs either by haematogenous spread or by extension from tuberculous pericarditis. The condition must be distinguished from idiopathic granulomatous (giant cell) myocarditis (described later).

5. SYPHILITIC MYOCARDITIS Syphilitic involvement of the myocardium may occur in 2 forms—a *gummatous lesion* consisting of granulomatous inflammation which is more

common, and a *primary non-specific myocarditis* which is rare. The syphilitic gummas in the myocardium may be single or multiple and may be grossly discernible. The gummas may affect the conduction system of the heart.

6. RICKETTSIAL MYOCARDITIS Myocarditis occurs quite frequently in scrub typhus (*R. tsutsugamushi*) and Rocky Mountain typhus fever caused by spotted *rickettsii*.

Microscopically, there is interstitial oedema and focal or patchy infiltration by inflammatory cells which include lymphocytes, plasma cells, macrophages, mast cells and eosinophils but necrosis and degeneration are generally not present.

7. PROTOZOAL MYOCARDITIS Chagas' disease and toxoplasmosis are the two protozoal diseases causing myocarditis. Chagas' disease caused by *Trypanosoma cruzi* frequently attacks myocardium besides involving the skeletal muscle and the central nervous system. Toxoplasmosis caused by intracellular protozoan, *Toxoplasma gondii*, sometimes causes myocarditis in children and adults.

Microscopically, both these conditions show focal degeneration and necrosis of the myocardium, oedema and cellular infiltrate consisting of histiocytes, plasma cells, lymphocytes and a few polymorphs. The organisms are found in the muscle fibres.

8. HELMINTHIC MYOCARDITIS *Echinococcus granulosus* and *Trichinella spiralis* are the two intestinal helminths which may cause myocarditis. *Echinococcus* rarely produces hydatid cyst in the myocardium while the larvae of *Trichinella* in trichinosis cause heavy inflammation in the myocardium as well as in the interstitial tissue.

9. FUNGAL MYOCARDITIS Patients with immunodeficiency, cancer and other chronic debilitating diseases are more prone to develop fungal myocarditis. These include: candidiasis, aspergillosis, blastomycosis, actinomycosis, cryptococcosis, coccidioidomycosis and histoplasmosis.

II. IDIOPATHIC (FIEDLER'S) MYOCARDITIS

Idiopathic or Fiedler's myocarditis is an isolated myocarditis unaccompanied by inflammatory changes in the endocardium or pericardium and occurs without the usual apparent causes. The condition is rapidly progressive and causes sudden severe cardiac failure or sudden death.

Grossly, the heart is soft and flabby. The cardiac chambers are generally dilated and sometimes show hypertrophy. There are yellow-grey focal lesions throughout the myocardium. Mural thrombi are commonly present.

Histologically, two forms of idiopathic myocarditis are described: diffuse type and giant cell (idiopathic granulomatous) type.

i) Diffuse type is more common of the two. It is characterised by diffuse non-specific inflammatory infiltrate consisting of lymphocytes, plasma cells, macrophages, eosinophils and a few polymorphs in the interstitial tissue without formation of granulomas. Late stage shows healing by fibrosis.

ii) **Giant cell type or idiopathic granulomatous type** is characterised by formation of non-caseating granulomas consisting of macrophages, lymphocytes, plasma cells and multinucleate giant cells. The giant cells are of foreign body or Langhans' type or of myogenic origin. The granulomas do not show presence of acid-fast bacilli or spirochaetes. Some have suggested relationship of this condition with sarcoidosis but sarcoid granulomas are known to occur in the myocardium secondary to generalised sarcoidosis.

III. MYOCARDITIS IN CONNECTIVE TISSUE DISEASES

Inflammatory involvement of the myocardium occurs in a number of connective tissue diseases such as rheumatoid arthritis, lupus erythematosus, polyarteritis nodosa, dermatomyositis and scleroderma. The pathologic changes in the heart muscle are similar to the changes seen in other organs in these conditions as described elsewhere in relevant chapters.

IV. MISCELLANEOUS TYPES OF MYOCARDITIS

Apart from the above forms of myocarditis, miscellaneous group consists of myocarditis caused by a variety of agents—physical and chemical agents, drugs and metabolic derangements.

1. Physical agents Physical agents like contusion of the myocardium, heat stroke, cardiac surgery and irradiation can initiate non-specific myocarditis. The features consist of an infiltrate of neutrophils, eosinophils and mononuclear cells and shows contraction-band necrosis of the myocardial fibres.

2. Chemical agents Toxic chemicals such as arsenic, phosphorus and carbon monoxide cause focal areas of degeneration and necrosis of myocardial fibres and non-specific inflammatory reaction, chiefly consisting of lymphocytes and macrophages.

3. Drugs Changes similar to those induced by chemical poisons are produced by certain drugs such as phenothiazine compounds, sulfonamides, catecholamines and cytotoxic compounds.

4. Immunologic agents Myasthenia gravis, Friedreich's ataxia, and progressive muscular dystrophies initiate a state of autoimmunisation against the myocardium resulting in focal myocardial degeneration and necrosis with secondary inflammatory reaction. Later, there may be myocardial fibrosis.

5. Metabolic derangements Uraemia, hypokalaemia and shock are associated with degeneration and necrosis of the myocardial fibres, oedema of the interstitial tissue and non-specific inflammatory reaction.

CARDIOMYOPATHY

Cardiomyopathy literally means disease of the heart muscle but the term was originally coined to restrict its usage to *myocardial disease of unknown cause*. The WHO definition of cardiomyopathy also excludes heart muscle diseases of known etiologies. However, the term cardiomyopathy has been loosely used by various workers for myocardial diseases of known etiology as well e.g. alcoholic cardiomyopathy, amyloid cardiomyopathy, ischaemic cardiomyopathy etc. This controversy is resolved by classifying all cardiomyopathies into two broad groups:

Table 14.10 Classification of primary cardiomyopathies.

| | |
|----|---|
| 1. | IDIOPATHIC DILATED (OR CONGESTIVE) CARDIOMYOPATHY |
| 2. | IDIOPATHIC HYPERTROPHIC CARDIOMYOPATHY |
| | i) Obstructive type |
| | ii) Non-obstructive type |
| 3. | IDIOPATHIC RESTRICTIVE (OR OBLITERATIVE OR INFILTRATIVE) CARDIOMYOPATHY |
| | i) Cardiac amyloidosis |
| | ii) Endocardial fibroelastosis |
| | iii) Endomyocardial fibrosis |
| | iv) Löeffler's endocarditis (fibroplastic parietal endocarditis with peripheral blood eosinophilia) |
| | v) Other forms |

A) *Primary cardiomyopathy* i.e. heart muscle disease with unknown underlying cause.

B) *Secondary cardiomyopathy* i.e. myocardial disease with known underlying cause.

Based on these principles, a classification of primary cardiomyopathy and its subtypes is presented in **Table 14.10**.

A. PRIMARY CARDIOMYOPATHY

This is a group of myocardial diseases of unknown cause. It is subdivided into the following 3 pathophysiologic categories (**Fig. 14.35**):

1. Idiopathic dilated (congestive) cardiomyopathy.
2. Idiopathic hypertrophic cardiomyopathy.
3. Idiopathic restrictive or obliterative or infiltrative cardiomyopathy.

Idiopathic Dilated (Congestive) Cardiomyopathy

This type of cardiomyopathy is characterised by gradually progressive cardiac failure along with dilatation of all the four chambers of the heart. The condition occurs more often in adults and the average survival from onset to death is less than 5 years.

ETIOLOGY Though the etiology is unknown, a few hypotheses based on associations with the following conditions have been proposed:

i) Possible association of *viral myocarditis* (especially coxsackievirus B) with dilated cardiomyopathy, due to presence of viral nucleic acids in the myocardium, has been noted.

ii) Association with *toxic damage* from cobalt and chemotherapy with doxorubicin and other anthracyclines is implicated in some cases.

iii) *Inherited mutations* have been implicated due to occurrence of disease in families. Mutations in certain sarcomere proteins such as cardiac troponin-T and I, β - and α -myosin, and α -cardiac actin have been observed. Abnormality in protein due to mutations causes contractile dysfunction. Another mutation in cytoskeletal protein dystrophin gene on X-chromosome has been held responsible for muscular dystrophy as well as dilated cardiomyopathy.

iv) *Chronic alcoholism* has been found associated with dilated cardiomyopathy. It may be due to thiamine deficiency induced by alcohol and resulting in beri-beri heart disease (page 247).

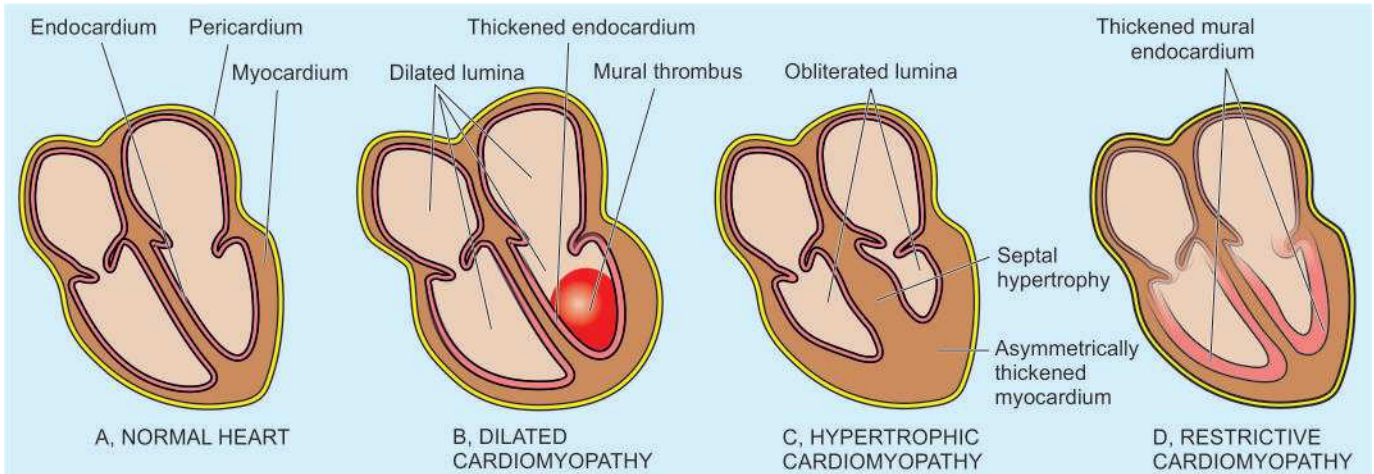

Figure 14.35 The major pathophysiologic forms of idiopathic cardiomyopathies.
